- The Stroop Color Test and the 2&7 Processing Speed Test (to detect problems with mental processing including speed).
- Rivermead Post-Concussion Symptoms Questionnaire, which measures the severity of post-concussion symptoms.
- The Hopkins Verbal Learning A (HVLA) test and the Digit Span Forward examination, which test verbal learning and recall including digit sequence recall.

A post-concussion migraine headache has been reported especially with soccer and English football.<sup>67</sup> This type of migraine resembles the classic migraine (migraine with aura) and usually resolves within 48 hours. A strikingly different type of headache is one in which there are associated signs of pupillary dilation and sweating. In between attacks there may be a partial Horner's syndrome. This type of headache is sometimes called traumatic dysautonomic cephalgia. It is thought to be caused by sympathetic fiber injury in the neck; it has been treated medically with  $\beta$ -blockers.

Finally, an insidious and potentially life-threatening condition associated with head trauma and headache is second-impact syndrome.<sup>68</sup> An athlete who suffers what appears to be minor head trauma develops cerebral edema that is not resolved at the time of a second head injury. Rapid swelling and subsequent death may occur. The recognition of this condition has led to recommendations that are far more conservative than in the past. Close observation of the athlete following head trauma and restriction from participation when there is LOC or persistent amnesia are common guideline recommendations.

# Other Headaches

Patients with coexisting metabolic disease may experience headaches related to the disorder. See [Table 17-1](#) for a list of these disorders.

Patients may report severe headache related to intercourse. This headache, called orgasmic or coital, is uncommon; however, when it occurs it is described as similar to migraine and can occur with sexual arousal or orgasm. Although almost always benign, given the exertional aspect of the occurrence, investigation for intracranial pathology, including neoplasm and aneurysm, should be pursued.

Paroxysmal headache refers to sudden jolts of head pain that occur for no apparent reason. These typically last for a few minutes to as much as an hour. Mostly benign, there is a possibility of involvement of the intracranial ventricular system, especially when associated with “drop attacks,” vomiting, or loss of consciousness. Specifically, cystic masses of the third ventricle are possible and warrant special imaging investigation.

The insidious onset of short, stabbing headache pain has been divided into a group of disorders that includes cluster headache and a benign form that has no associated structural lesion. Chronic paroxysmal hemicrania (formerly called Sjaastad syndrome) is similar to cluster headache but the attacks are less severe. This type of headache is found primarily in women and seems responsive to indomethacin but not other NSAIDs. (Cluster headaches are not responsive to indomethacin and are found primarily in males.)

# The New Headache

Most primary headaches have their initial onset at an early age and are recurrent. Therefore, a middle-aged or older individual complaining of a headache that feels “different” should warrant concern. A common scenario would be an older patient complaining of a temporal headache. If there are associated complaints of either an aching upper trunk area or vision difficulties, consider temporal arteritis. This systemic process becomes evident as a pulsating, hard, nodular temporal area associated with headache. Unfortunately, this process occludes other arteries and often leads to blindness. Biopsy and medical treatment (corticosteroids) are necessary to identify temporal arteritis and prevent blindness, respectively.

Headaches that are constant and/or severe without reprieve are likely to indicate an intracranial process and should necessitate a referral for further evaluation prior to an attempt at chiropractic treatment. Approximately 9% of cerebrovascular events are missed on the patient’s first visit to the emergency department, with patients with a subarachnoid hemorrhage (SAH) missed about 20% of the time.<sup>69</sup> SAH is due to a ruptured berry-aneurysm 75% of the time, and 10% of the time is due to an arteriovenous malformation (AVM). The standard with unexplained severe headache in the emergency department is the “CT-LP” rule, which begins with a cranial CT and with negative findings moves to a lumbar puncture. Researchers were interested in seeing if there was a historical cluster that might identify the patient who is likely to have an SAH so that CT could be bypassed and move to the lumbar puncture, saving time, expense, and perhaps the patient’s life. In a 2013 publication,<sup>70</sup> researchers presented a study that defined the Ottawa SAH Rule. In this cross-sectional study any one of six findings led to a sensitivity of 100% for SAH in patients with acute-onset headache (i.e., peaking within an hour). These include age  $\geq$  40 years, neck pain or stiffness, witnessed loss of consciousness, onset during exertion,

thunder-clap headache (instantly peaking pain), and limited neck flexion on examination. The specificity, though, is quite low, at only around 15%. So although able to effectively rule out SAH, it may not be of much value in differentially diagnosing other causes of similar presentations.

## Primary Headaches

Question the patient regarding the three primary headaches: migraine (with and without aura), tension-like, and cluster. There are often key clues to one of these differentials.

Using IHS criteria:<sup>71</sup>

## Migraine with Aura

Patient must have at least two attacks with three of the following characteristics:

1. There are one or more resolved aura symptoms.
2. At least one aura symptom that develops gradually over 5 to 20 minutes and lasts for less than 60 minutes, or two or more aura symptoms occur in sequence.
3. Aura does not last more than one hour (if more than one aura symptom, proportionally rated).
4. The headache follows the aura (headache-free interval less than one hour) or headache begins before or simultaneously with aura.

Also, history, including both a physical and neurological examination, does not suggest another cause. The aura includes reversible disturbances, usually either visual (e.g., zig-zag lines, flickering lights, or vision loss), sensory (e.g.,

pins-and-needles sensation or numbness), or dysphasic speech disturbances.

## **Migraine without Aura**

Patient must have had at least five attacks lasting 4 to 72 hours (untreated or unsuccessfully treated) (in children, 2 to 48 hours) with at least two of the following:

- 1.** Unilateral location (59% of patients)
- 2.** Pulsating quality (85% of patients)
- 3.** Moderate to severe intensity that inhibits or prohibits daily activities
- 4.** Aggravated by or causing avoidance of routine physical activities such as climbing stairs or comparable activity

Patient must also have with at least one of the following:

- 1.** Associated nausea (73% of patients) and vomiting
- 2.** Photophobia (80% of patients) and phonophobia (76% of patients)

Also, history—physical and neurological examination—does not suggest another cause. Premonitory symptoms for both types of migraine headaches occur hours to a day or two prior to the headache and include symptoms such as fatigue, neck stiffness, difficulty concentrating, sensitivity to light or sound, nausea, blurred vision, yawning, and pallor. These are not to be confused with the aura, which has a distinct preheadache occurrence.

It is important to note the following history findings from the research literature for migraineurs:

- 70% of migraine sufferers have a family history (1.9-fold increased risk of migraine without aura if found in first-degree relatives)<sup>72</sup>
- 75% report associated neck pain<sup>73</sup>
- 46% report tearing or nasal congestion<sup>74</sup>
- 50% report the following triggers:<sup>75,76</sup>
  - change of weather
  - stress
  - lack of sleep or fatigue
  - alcohol
  - food triggers (including but not limited to chocolate, fried foods, dairy products, and nitrates including those in cured meats and fish)
- Comorbid conditions include<sup>77-79</sup> psychiatric disorders (including major depression and bipolar disease),<sup>80</sup> generalized anxiety disorders and associated panic and phobia disorders, vestibular disorders such as Ménière's,<sup>81</sup> Raynaud's syndrome, multiple sclerosis, mitral valve prolapse syndrome, patent foramen ovale,<sup>74</sup> and malignant hypertension.

Women with migraine are at higher risk for ischemic stroke especially if they:

- use combined oral contraceptives (COCs) and hormone replacement therapy
- smoke This risk is significant only for women who suffer from migraine with aura. Female patients having migraine with aura headaches who do take COCs or hormonal replacement therapy should be referred back to the prescribing doctor. Female patients with migraine who smoke should be counseled to the increased risk for stroke and placed in a smoking cessation program. Chronic migraine is a category reserved for those suffering 15 or more headaches per

month for at least three months in the absence of medication overuse.

## Cervicogenic

Cervicogenic headache is distinct in that it is caused by an abnormality of structures in the neck. The older HIS criteria were relatively specific and included the following.

Headache is usually on one side of the head only. It tends to last between three hours to a week, recurring at intervals varying between as little as two days to as long as three months. Patients may have migraine-like associated symptoms of nausea, vomiting, and sensitivity to light.

- Pain is localized to the neck or suboccipital region and may project to other areas around the head, including the orbital area.
- Pain is provoked or aggravated by specific neck movements (such as flexing the neck or bending forward) or maintained neck positions.
- At least one of the following is found:
  - 1.** restricted neck movements
  - 2.** change in neck muscle contour, texture, tone, or response to active or passive stretching or contraction
  - 3.** abnormal tenderness of neck muscles
- Radiological evaluation reveals at least one of the following:
  - 1.** movement abnormalities in flexion/extension
  - 2.** abnormal posture
  - 3.** fracture, congenital abnormalities, bone tumors, rheumatoid arthritis, or other pathology (not to include spondylosis or osteochondrosis)

The most recent classification by the HIS has eliminated the specificity of duration and of location. There is a criterion stating that headache resolves within three months due to successful treatment of the underlying cause. The newer classification also lists cervicogenic as either a primary or secondary headache diagnosis, primarily based on which headache appears first. A separate classification is given for headaches secondary to neck or head trauma (e.g., headache associated with whiplash).

## Cluster

Cluster headaches are part of a large group of disorders now referred to as trigeminal autonomic cephalalgias (TAC) based on new understanding regarding their cause. They share the clinical features of headache with associated cranial parasympathetic autonomic features. This is believed to be due to activation of a trigeminal parasympathetic reflex with secondary clinical features that are sympathetic. For cluster headaches, patients must have experienced at least five episodes of headaches to qualify. There is severe unilateral, orbital, supraorbital, or temporal pain that peaks in 10 to 15 minutes, lasting 15 to 180 minutes with pain resolving rapidly. In addition, cluster headaches exhibit the following features:

- Cluster headaches tend to occur at night more than other headaches. Cycles are over a few weeks or months, with some lasting years, and the frequency of attacks is from one to eight per day. Headache macro cycles are usually months or years apart.
- Headaches are associated with at least one of the following: conjunctival injection, rhinorrhea, lacrimation, miosis, nasal congestion, ptosis, forehead and facial sweating, or eyelid edema.

A chronic version lasts for more than a year, and remission lasts less than one month. Also, 5% of patients have a partial Horner's syndrome. It is important to note that a similar, less severe presentation is called chronic paroxysmal hemicrania. This type of headache is more common in females and seems to be responsive to indomethacin but not other NSAIDs. Another TAC disorder is short-lasting, unilateral, neuralgiform headache attacks with conjunctival injection (SUNCT). These are distinct attacks that last for brief periods and are clinically dominated primarily with lacrimation and unilateral redness of the ipsilateral eye.

---

## **Episodic Tension-Type**

Patient must have at least 10 previous headaches with a total of less than 180 days of headache in a given year, with each headache lasting 30 minutes to 7 days. There will be at least two of the following:

- 1.** Pressing or tightening description (nonpulsatile)
- 2.** Mild to moderate in intensity
- 3.** Bilateral
- 4.** Not aggravated by climbing stairs or similar activity

Also, there is no nausea or vomiting, and photophobia and phonophobia are absent (may have one or the other alone). Episodic, tension-type headaches are further classified as infrequent, frequent, and chronic.

It is important to determine past therapies and their effects on the patient's headaches. Most important is the determination of medication. When a patient with migraine takes either ergotamine or nonsteroid anti-inflammatory drugs (NSAIDs) continuously for more than three days or stops taking the drug suddenly, a rebound effect occurs in many patients, creating a headache often worse than the

original—a common cause of emergency department visits. Ibuprofen and naproxen do not appear to be common culprits. The most commonly used medications that appear associated with rebound include but are not limited to:

- Ergotamines including Migranal
- The triptans including sumatriptan (Imitrex; others include Zomig and Amerge)
- Caffeine-containing OTC analgesics such as Excedrin
- Decongestants
- Butalbital medications including Fiorinal and phrenilin
- General vasoconstrictors such as Midrin
- Narcotics including Percocet or Tylenol #3

## **Examination**

- Rule out secondary causes of headaches, searching for signs indicating tumor, infection, intracranial hemorrhage, glaucoma, etc.
- Determine whether any musculoskeletal abnormalities appear to be contributing or causing (cervicogenic) a patient's headaches.
- Determine the need for radiography or special imaging.

The primary role of the standard physical examination is to rule out secondary causes of headache such as tumor, infection, intracranial hemorrhage, and glaucoma. In patients with either a history of head trauma or associated neurologic signs or symptoms, a thorough neurologic examination must be performed. Emphasis on cranial nerve, vestibular, and pathologic reflex testing is necessary to rule out referable disorders. If the neurologic symptoms are transient, and therefore objective evidence on neurologic examination is lacking, refer for further evaluation (unless classic for the prodrome of migraine with aura). Although

rarely confused with a “headache,” glaucoma should be considered in patients complaining primarily of an orbital location to their pain. A quick evaluation is performed by shining a light tangentially across the eye, looking for a crescent-shaped shadow covering more than half the nasal side of the iris. This indicates a closed angle. In screening for intracranial pressure, ophthalmoscopic examination of the fundus for papilledema is necessary.

The examination process specific to those using manual therapy may provide the only clues to primary headache. The literature to date suggests that several musculoskeletal abnormalities are more prevalent in primary headache sufferers, including the following:

- Intersegmental hypomobility (primarily in the upper cervical area)<sup>82-86</sup>
- Specific tender points<sup>87,88</sup>
- Dysfunctional motion of the cervical spine<sup>89-91</sup>
- Postural imbalance (forward head position and round-shoulder appearance)<sup>92,93</sup>

---

## **Radiologic and Special Imaging for Headaches**

Radiologic or advanced imaging for headaches is still controversial. Although research indicates possible radiographic findings such as hypomobility or a lordotic/hypolordotic cervical curve, the addition of this information clinically may be irrelevant to the diagnosis. For patient management, it may be arguable that this information allows one to pursue correction of these apparent biomechanical associations.

The literature suggests that the use of special imaging is rarely justified with headache sufferers. This is based on the following:

- Of all the patients with tumor or other conditions requiring cranial surgery only 5% had headache as a primary complaint (other neurologic findings were suggestive).<sup>94</sup>
- The yield for a positive scan was as low as 1/11,200 patients with headaches.

Similar findings have been demonstrated in the pediatric population.<sup>95</sup> However, common sense dictates that if the headache is severe, especially in a child, or unrelenting and not responsive to medication, imaging is an important tool for ruling out serious disorders.

## Management

- Modify lifestyle factors that may be contributors.
- Treat with chiropractic manipulative therapy and adjunctive therapies.
- Refer for other nonpharmacologic treatment if chiropractic manipulative therapy (CMT) is ineffective.
- Refer for medical management if other nonpharmacologic treatment is ineffective.

Although it is important to narrow down the diagnostic impression for purposes of referral or correction of minor triggers, it must be remembered that many primary sufferers—in particular, patients with migraine and tension-like headache—may have other secondary contributing factors. In addition, the chiropractic manipulative treatment of these patients has not been demonstrated to be specific to headache type. It is therefore important to tailor the treatment to the patient with a focused approach to the primary headache and a holistic approach to contributing factors, including musculoskeletal, environmental, and psychologic. Management decisions and interpretations

must also take into account the fact that the placebo effect in most studies of headache suggests an average positive response in the 30% range.<sup>96</sup>

## General Approach

The literature for primary headache treatment is, like many conditions, muddled by lack of definition. There are also problems with well-controlled trials. However, taken as a whole, the literature reveals a relationship between cervical dysfunction and headaches.<sup>97-105</sup> More specifically, and most recently, randomized studies indicate improvement with manipulation and possibly advantages with the use of manipulation over the use of antidepressant medication in the treatment of chronic tension-like and migraine headaches.<sup>106-108</sup> Two recent reviews of the literature tend to support the role of manipulation in the management of tension-like and cervicogenic headache.<sup>109,110</sup> One is a Duke University study that completed a process begun by the Agency for Healthcare Research and Quality entitled *Evidence Report: Behavioral and Physical Treatments for Tension-type and Cervicogenic Headache*. Although the analysis of the literature supports chiropractic manipulation in the management of cervicogenic headaches, there was no evidence to support manipulation over various soft tissue procedures for episodic tension-type headache.

Consideration for other adjunctive or alternative therapies is based on suggestions listed below:

- Biofeedback. Biofeedback is a form of operant conditioning in which the patient uses electromyographic (EMG) or thermal cues to attempt control of either skeletal muscle (with EMG cues) or smooth/vascular muscle (with thermal cues). EMG uses surface electrodes with a video display for patient

monitoring. Thermal biofeedback records peripheral temperature through the use of an index finger sensor with measurements displayed on a screen. Although the mechanism is not clear, it appears that biofeedback can be a useful tool in the treatment of headaches. One study<sup>111</sup> indicated good long-term success. Specifically, one study<sup>112</sup> indicated a better result with trapezius biofeedback than with frontal biofeedback or relaxation therapy. Biofeedback may also be helpful in decreasing chronic headache sufferers' dependency on medication.<sup>113</sup>

- Exercise. Although not used specifically for headache, it is anecdotally reported and supported in one study<sup>114</sup> that aerobic exercise may be of some benefit to patients with headache. Perhaps the mechanism is due more to psychologic well-being aspects than to direct measurable factors.
- Physiotherapy. When spinal pain or muscle tender ness is associated with a headache, physical therapy may be added to augment the effect of manipulation.
- Acupuncture. Although many anecdotal reports claim success with acupuncture, when compared with physiotherapy, acupuncture consistently is less effective, although it does appear to help.<sup>115-118</sup> One small controlled study<sup>119</sup> indicated no significant difference over time between acupuncture and a placebo treatment.

## **Specific Recommendations for Specific Headaches**

Some specific recommendations are made for specific headache types with the caution that there is often overlap

among these headaches, and therapy that works for one may be beneficial with another.

## Migraine

Patients with an aura to their headache can and should be managed with a treatment trial of manipulation (provided that high-risk indicators are absent). Specific recommendations would include the following:

- Keep sleep schedule as regular as possible, avoiding under- or oversleeping.
- Avoid skipping meals.
- Avoid food triggers.
- Manage stress through training and time management techniques.

Nutritional support may be helpful (see [Table 17-4](#)).

Women suffering from migraine with aura who are taking contraceptives or hormonal replacement therapy (HRT) should be referred to the prescribing medical doctor due to a small increase in risk for stroke. Those on contraceptives or HRT who smoke should be counseled on the need to stop smoking due to a significant increased risk of stroke when combined with having migraine headaches.

---

### **Tension-type and Cervicogenic**

Management is often more difficult given that some of the factors may be external and more under patient control and choice. Following are some recommendations:

- Correct any postural imbalances, in particular in the cervicothoracic regions.
- Pay particular attention to instruction of proper ergonomics in workstation environments.

- Consider the addition of myofascial and trigger point therapy.
- Educate the patient in self-stretching and exercise techniques.

**Table 17-4** Nutritional Support for Migraine Headaches

Substance	How Might It Work?	Dosage	Special Instructions	Contraindications and Possible Side Effects
Feverfew (tanacetum parthenium)	May prevent constriction of blood vessels through inhibition of platelet serotonin release and maintain central levels of serotonin.	100-mg capsule (0.6% parthenolide) one time daily (up to 500 mg of parthenolide in one study).	Take with meals on a consistent basis. May take 4–6 weeks to work.	Contraindicated in pregnancy, when lactating, in children under 2 years of age. Side effects may include gastrointestinal upset or rash. Withdrawal symptoms include nervousness, tension, insomnia, and joint stiffness.
5-HTP (5-Hydroxytryptophan)	Increases serotonin levels, which may decrease symptoms of pain, insomnia, depression, headache, etc.	50–100 mg three times daily.	Best taken with meals. Should be taken with pyridoxal 5 phosphate (included in recommended supplement).	Do not combine with Imitrex or other SSRI or MAOI antidepressants. Taking more than recommended dose may lead to serotonin syndrome. Safety unknown for pregnant or lactating women.
Omega-3 (EPA & DHA)	Source of omega-3 fatty acids increases anti-inflammatory prostaglandins.	1,000 mg of EPA and 700 mg of DHA daily for at least 2 months.	None.	Long-term use of fish oils at more than 3–4 g/day may cause problems due to elevated blood sugar, cholesterol, or glucose levels. Side effects may include nose bleeds or gastrointestinal upset.
Calcium and vitamin D	May have effect on arterial smooth muscle tone.	800 mg of calcium per day and 400 IU of vitamin D per day.	None.	Individuals with chronic kidney disease, sarcoidosis, kidney stones, or hyperparathyroidism should not take extra calcium.
Riboflavin	May correct a mitochondrial energy metabolism dysfunction.	400 mg/day.	None.	May cause mild diarrhea or polyuria. Fluorescent yellow urine.
Multivitamin/mineral (containing magnesium, vitamins B2, B6)	B6 helps break down histamine. Magnesium helps maintain vessel tone and prevents neuronal overexcitability.	Should include 360 mg of magnesium per day.	None.	More than 350–500 mg of magnesium per day may cause diarrhea in some individuals.

Key: SSRI, selective serotonin reuptake inhibitor; MAOI, monoamine oxidase inhibitor; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid.

*Note:* The above have not been approved by the Food and Drug Administration for the treatment of this disorder.

# Cluster

- Avoid alcohol and smoking.
- Use 100% oxygen (7–10 L/min for 10–12 minutes).

# Sinus

- One chiropractic study<sup>120</sup> suggests a nasal-specific technique that is popular among a small group of chiropractors.
- The application of warm compresses or butterfly diathermy may be helpful.
- OTC decongestants may help temporarily.
- If specific to airplane travel, the use of a decongestant nasal spray may help.

When a conservative approach is taken, it is important to understand the difficulties associated with treatment of asymptomatic patients. In other words, although a patient may have a history of migraines, it is often the case that he or she does not have the headache at the time of the examination and initial care. How does one determine outcome without an outcome measure? Traditionally it has been an acceptable course to attempt reduction of the associated findings of muscle hypertonicity or spinal segmental fixation (which in themselves can be considered outcome measures) and suggest appropriate lifestyle changes. The course of care often extends for two to three weeks. If the patient has infrequent headaches, it is likely that this period will not extend into the next predicted headache occurrence. If the patient has not had a headache, it would seem appropriate to discontinue constant care until the patient is symptomatic, at which time an aggressive, high-frequency approach for two to

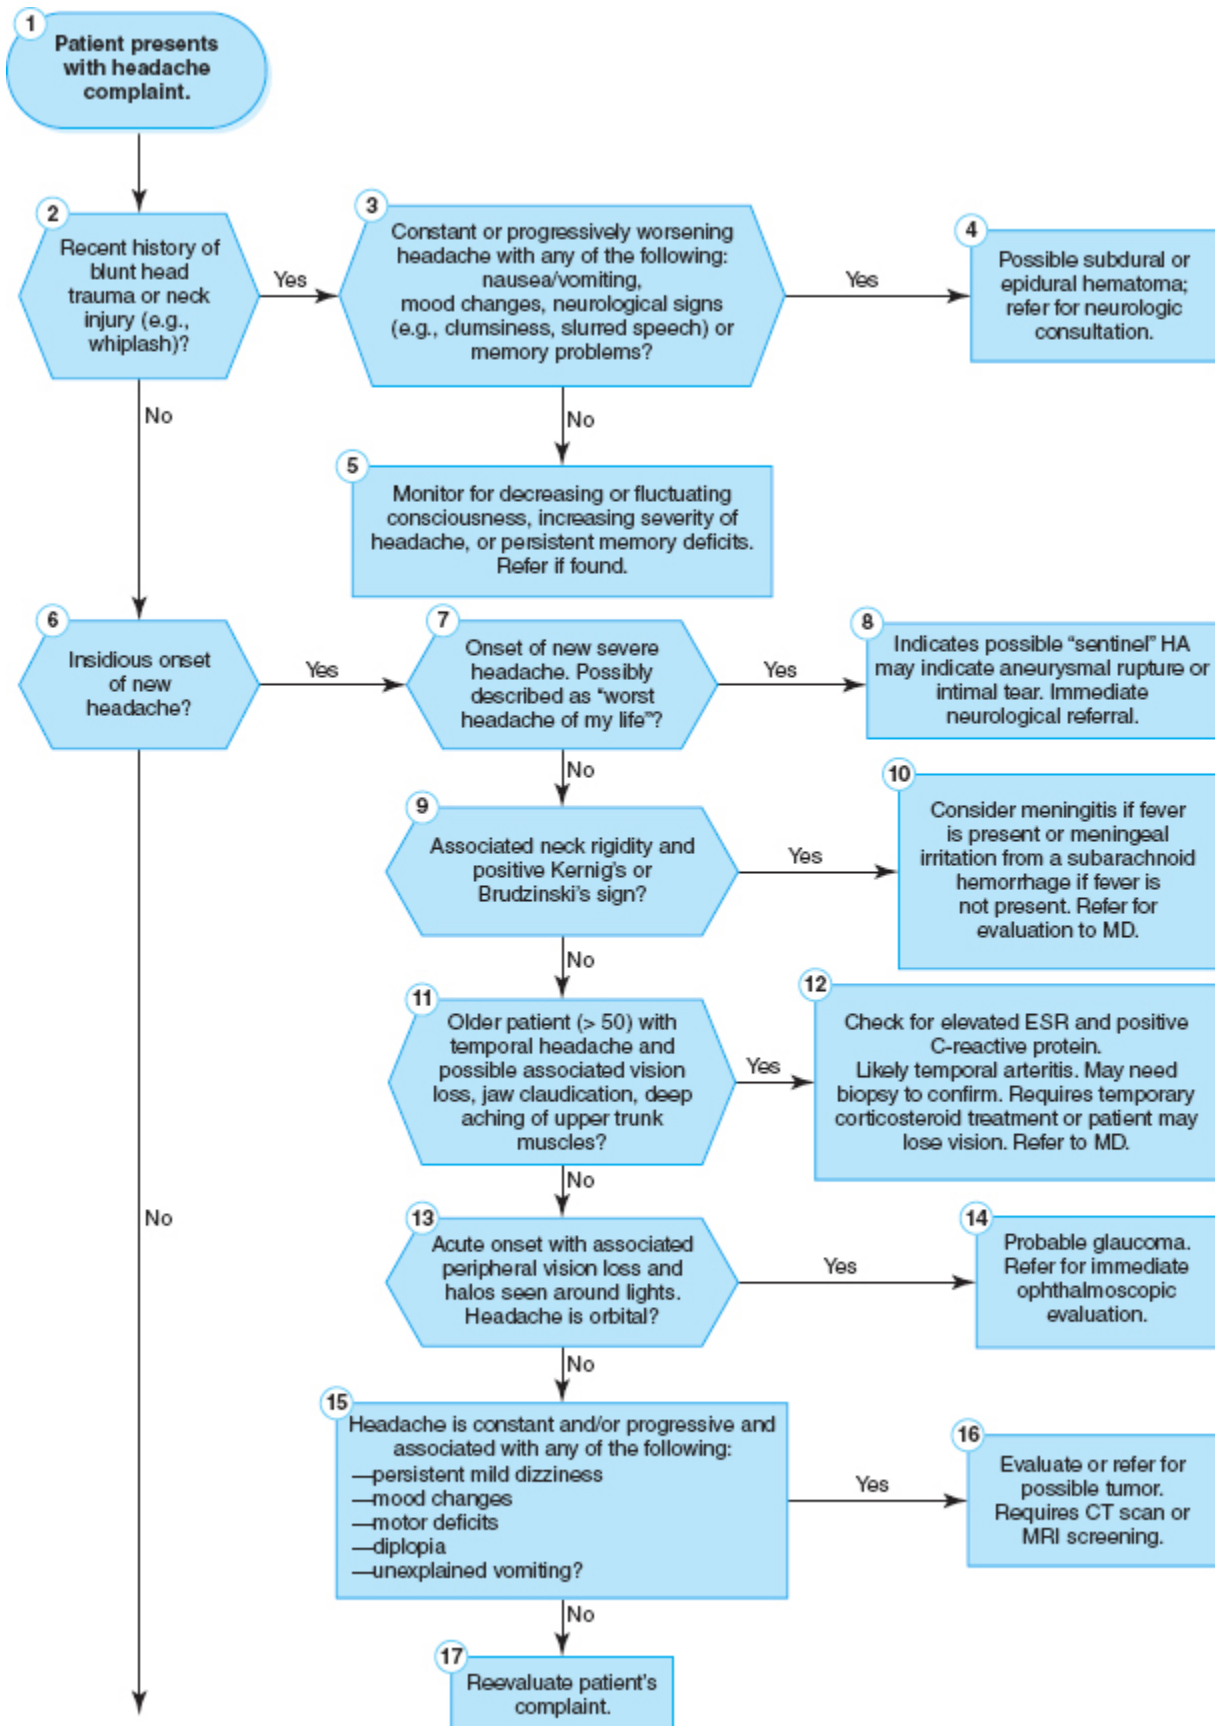

three weeks followed by a return to more of a maintenance status is appropriate. To be considered effective, treatment should have aborted the attack, decreased the intensity, or reduced the duration of an attack. If not, perhaps one more trial during a symptomatic period is reasonable. If two or three predicted headache occurrences do not occur or are reduced in intensity, treatment may have been effective. It would not seem appropriate to continue this treatment course, however, without these positive indicators. Referral for other conservative approaches or medical treatment seems appropriate when a conservative trial is ineffective.

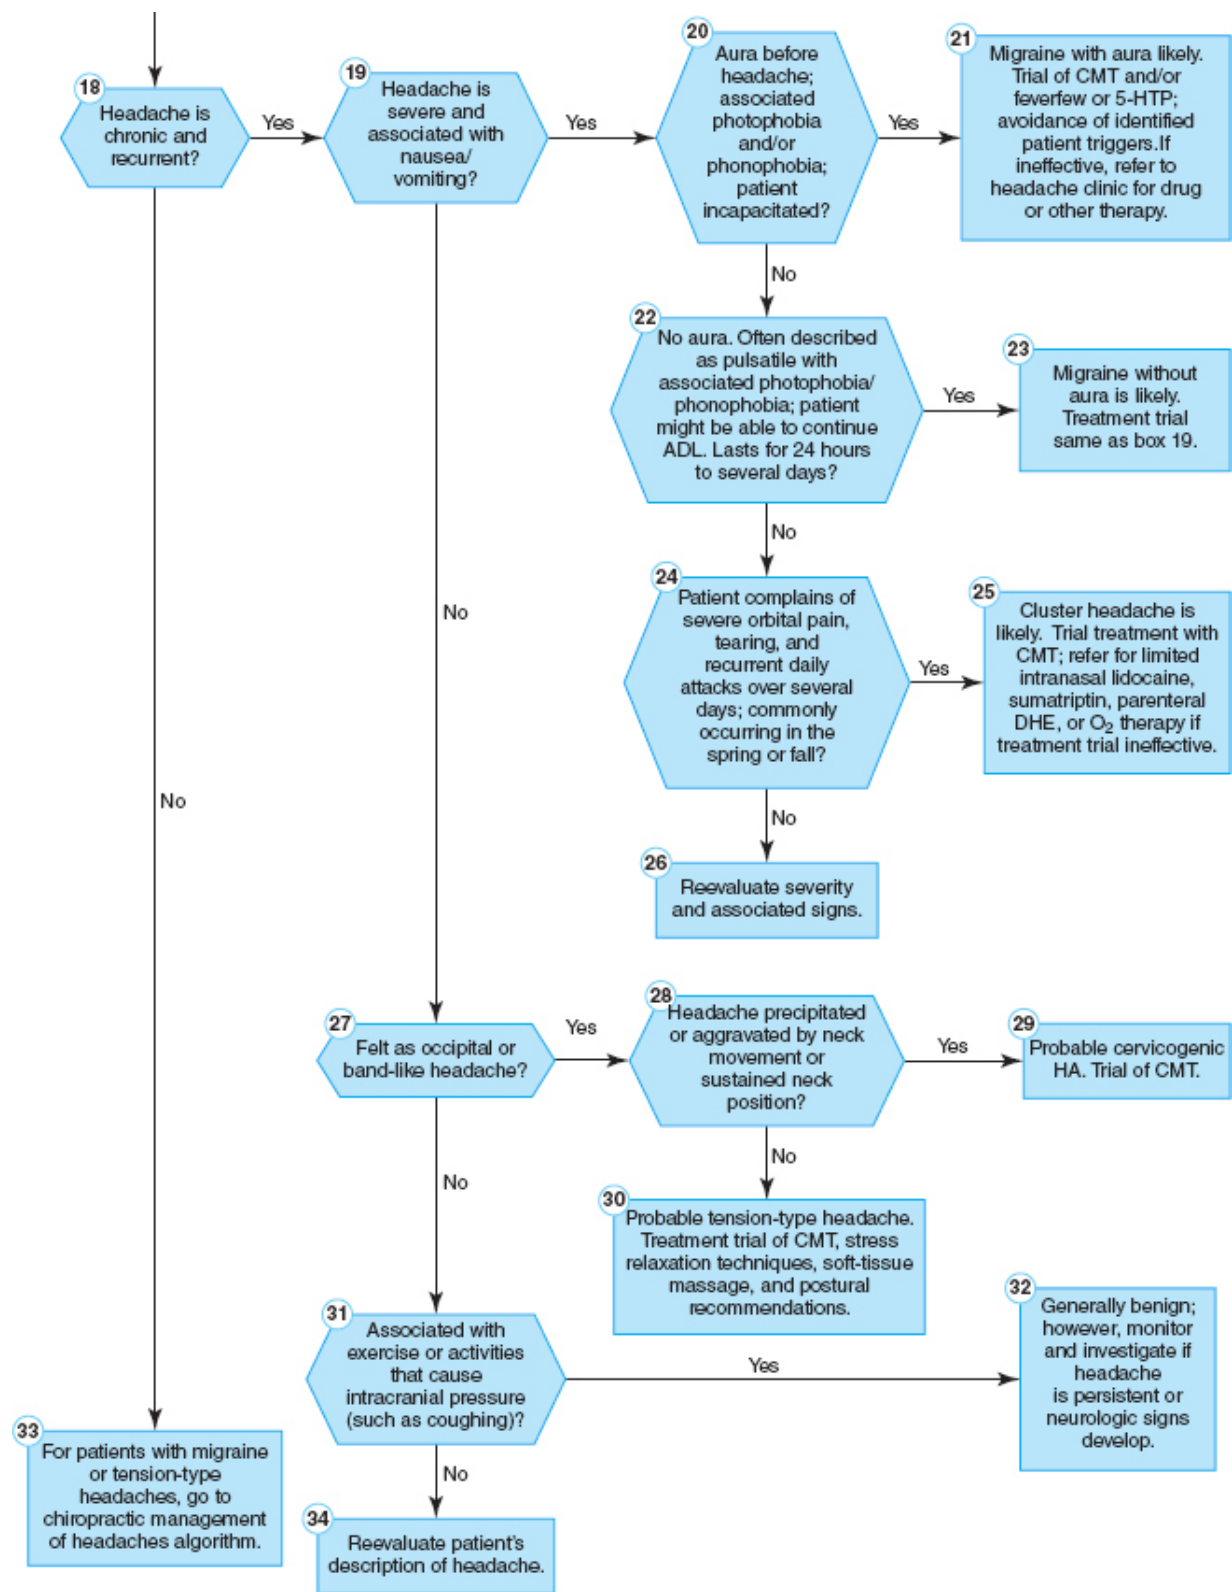

The medical treatment of migraine headaches is primarily abortive or prophylactic. Abortive medications include mainly ergot derivatives and sumatriptan succinate (serotonin receptor agonist). Prophylactic medications include those used for other conditions such as antihypertensives, antidepressants, and antiseizure drugs. If the patient suddenly withdraws any of these prescribed medications, he or she runs the risk of a rebound effect. This is particularly true with ergotamine and NSAIDs. Also, ergotamine, aspirin, or NSAIDs should not be taken more than a few days consecutively because of the same risk of rebound migraine.

Medical treatment for cluster headaches includes many of the same medications used for abortive treatment of migraine including sumatriptan and ergots. In addition, intranasal lidocaine and prescribed oxygen may be helpful in aborting an attack.

## Algorithms

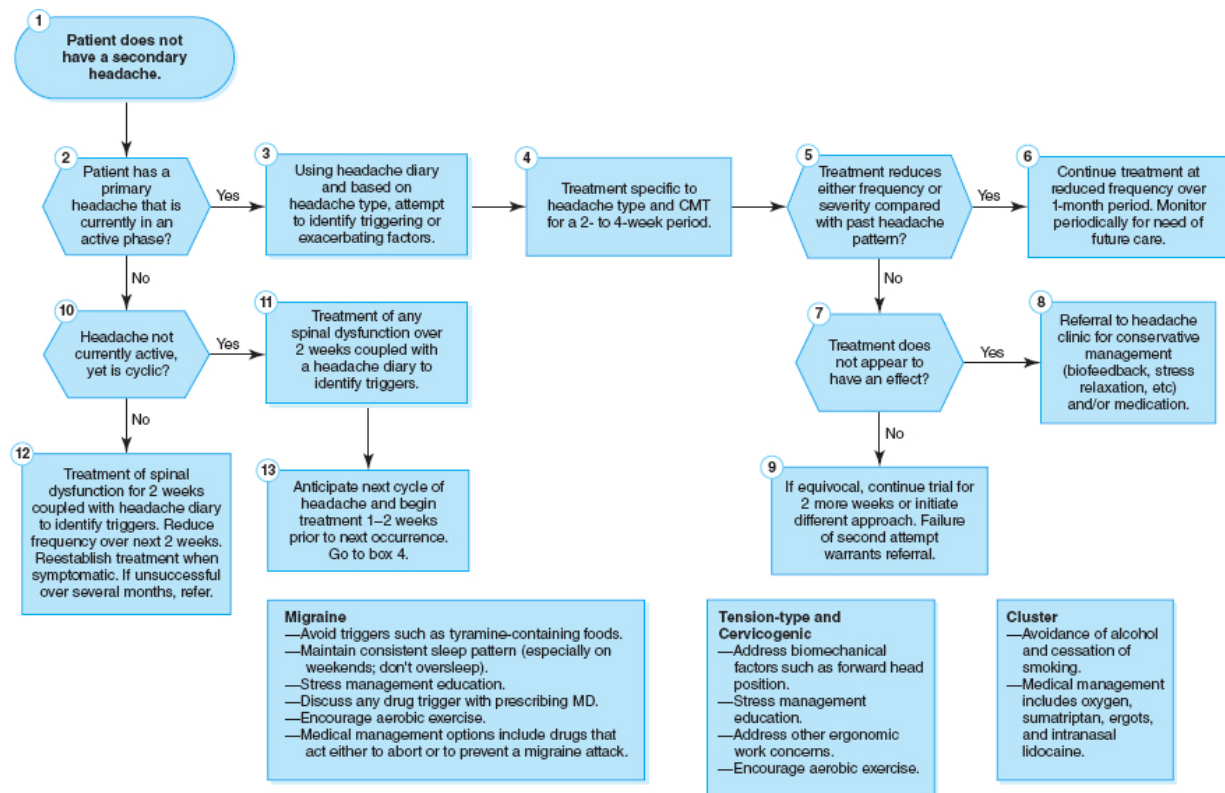

Algorithms for evaluation and management of headache and chiropractic management of primary headaches are presented in **Figures 17-2** and **17-3**.

**Figure 17-2** Headache—Algorithm

**Figure 17-3** Chiropractic Management of Primary Headaches—Algorithm

# Selected Headache Disorders

## Migraine with Aura (Classic Migraine)

### Classic Presentation

The patient is often female and presents with a complaint of unilateral throbbing headaches that are preceded by an aura. The prodrome consists of a progressively increasing (fortification) scotoma (blind spot) surrounded by flashing lights (scintillation). This lasts for about 30 minutes and is replaced by a disabling headache that lasts for several hours to as long as one to three days, causing the patient to seek a dark, quiet environment. There is often associated nausea and vomiting. There is a family history of similar headaches.

### Cause

Once believed to be purely vascular, migraine headaches are believed to be neurogenic. Migraine with aura accounts for only 10% to 15% of all migraines. Current research findings<sup>121</sup> suggest one or a combination of the following:

- Trigeminal axons are prompted to release vasoactive peptides that cause vascular inflammation; this inflammation irritates meningeal nerve fibers.
- There is a dysfunction of the serotonergic-based, central inhibitory pain system allowing a lowering of the pain threshold so that even normal stimuli may cause pain.
- There is an inherited problem with dopamine metabolism.
- A spreading wave of cortical depression occurs (changes proceeding from a wave of hyperpolarization followed by depolarization). This correlates with a spreading wave of decreased cerebral blood flow that lasts for one to several hours and then transitions into a phase of hyperemia. This reactive hyperemia does not necessarily correlate with the headache. Many times the headache occurs during the period of decreased cerebral blood flow. The aura is due to hyperexcitability of the occipital cortex in many patients with visual symptoms.<sup>122</sup>
- The trigeminal afferent input and the upper spinal nerve (C1-C3) input converge in the trigeminocervical nucleus in the spinal cord; because of this convergence, misinterpretation of the pain origin may lead to a referred headache phenomenon.

- Based on recent observations, it appears that branches of the trigeminal nerve may be entrapped in craniocervical musculature triggering chronic migraine attacks. Botox injection or cosmetic surgical release has resulted in migraine relief in some patients.

There appear to be a wide variety of triggers for migraine, including variation in sleeping or eating habits, environmental pollutants, certain medications (including vasodilators), and food. With food, the primary triggers include chocolate, caffeine, nitrates, cheese, nuts, wine, and a host of other individualized triggers. There is also a hormonal relationship, as is seen in women. Although in adults there is a clear female predominance, there is some evidence that under the age of 12 years, migraine is more common in boys.<sup>123</sup> There is a gradual shift to female predominance such that at age 20 years the female-to-male ratio is 2:1 and between 42 and 44 years it is about 3:1. The one-year prevalence for migraine was 11.7%: 5.6% in men and 17.1% in women.<sup>124</sup> Thirty-one percent of migraineurs have a headache attack occurrence of three or more times per month with 3.7% reporting severe impairment. At least 25.7% meet the criteria for preventive treatment.

When the aura is the prominent feature or if it outlasts the headache, it is referred to as a complicated migraine.<sup>125</sup> When the prodromal signs or symptoms predominate they are often referred to as migraine equivalents. There are three types of complicated migraines: ophthalmoplegic, where the third, fourth, and sixth cranial nerves are involved, often causing diplopia and eye pain; hemiplegic, where there is paresis on one half of the body, often lasting days; and basilar, where the vertebrobasilar system is involved, leading to accompanying vertigo, diplopia, tinnitus, and ataxia.

There are many subtypes of migraine. A particular concern is a basilar migraine where symptoms and signs of brainstem dysfunction predominate. In such cases, vertigo, dysarthria, tinnitus, hypoacusia, diplopia, visual symptoms in both temporal and nasal fields in both eyes, ataxia, decreased level of consciousness, and bilateral paresthesias may occur. It appears that in addition to the pons, the cerebellum may be involved due to dysfunctional calcium channels. These patients may respond better to the antiepileptic preventive medications available.<sup>126</sup>

The risk of stroke is higher in all patients with migraine, although the higher risk associated with contraceptives places more danger on women taking combined oral contraceptives (COCs).<sup>127</sup> Two studies by Kurth et al.<sup>128,129</sup> examined the cardiovascular risk for individuals with migraine. One study focused on men and found that they had a higher risk for myocardial infarction. The distinction between migraine with or without aura was not available. For females, there was no increased risk for migraine without aura.

However, for migraine with aura, cardiovascular disease, myocardial infarction, ischemic stroke, coronary revascularization, and angina were found to be higher in active migraine sufferers. This was supported by another study by Diener et al.<sup>130</sup>

# Evaluation

The physical examination is rarely revealing and is usually used to rule out secondary causes that may resemble migraine with aura, such as a TIA or glaucoma. The aura is generally visual, with the most common descriptions as blind spots, flashing lights, and zig-zag lines. Occasionally it is described as having a “bubbling” appearance, movement like “an old-time movie” (strobe-like), and “morphing” of images (often circular into angular), among others. Aura may also be as simple as blurriness of vision. Any neurological manifestation is possible, including olfactory, paresthesias (common is digitolingual [tongue and down the arm to fingers]), temporary weakness of facial muscles or limbs, and other neurological manifestations. The combination of an aura that is often visual that occurs prior to a severe headache and an early age onset—often in early adulthood—is highly suggestive. Migraine with aura occurs less frequently than other headaches, often only once or twice a month or less. In making clinical decisions regarding imaging, a 2006 review by Detsky et al.<sup>131</sup> revealed that the best predictors of migraine could be applied using a mnemonic: POUNDing (Pulsating, duration of 4–72 hOurs, Unilateral, Nausea, Disabling). If four of the criteria are met, the accuracy for diagnosing migraine is high, and it decreases with fewer criteria being met. Additionally, they found that on pooled analysis the prediction for serious intracranial problems was increased for cluster headache, abnormal findings on neurologic exam, undefined headache (i.e., unable to categorize into one of the primary types), aggravated by exertion or a Valsalva-type maneuver, and headache with vomiting. When these features are present, patients should be referred for neuroimaging.

Migraine headache in children may be dissimilar to that seen in adults. For example, migraine with or without aura has its peak at an earlier age in males. For migraine with aura, it is age 5 years; migraine without aura, ages 10–11 years.<sup>132</sup> Another distinction is that headaches are more often bilateral in children, often frontotemporal. Occipital headache in children, whether unilateral or bilateral, should be further investigated due to the possibility of a structural lesion. Family history is important. If both parents have migraines, the risk is about 70% for the children, whereas if one parent has migraine, the risk is about 45%. About 20% of children with migraines report visual aura. The distinction may be that spots, colors, dots, or lights are often reported. The aura is generally short-lived, being 30 minutes or less. The description of pounding or pulsating is less common, as are reports of phonophobia and photophobia. Finally, headaches are generally shorter, lasting on average less than two hours. They may be more frequent in children.

# Management

Migraine may respond to chiropractic manipulation.<sup>107,108,133</sup> A treatment trial is worth pursuing. Other conservative options include biofeedback and acupuncture. Linde et al.<sup>134</sup> evaluated, in a randomized controlled trial, the effects of acupuncture on migraine. Interestingly, the results indicated that 51% randomized to an acupuncture group and 53% randomized to a sham acupuncture group improved (i.e., reduction in headache days by at least 50%). Recommendations for nutritional and herbal support include the use of feverfew, 5-HTP (5-hydroxytryptophan), omega-3 fatty acids, magnesium, calcium and vitamin D, and riboflavin.<sup>135-147</sup> (See **Table 17-5**.) Supplementation with magnesium before menses may prevent some women's menstrual migraines.<sup>148</sup>

Medication options are primarily abortive and prophylactic.<sup>149</sup> The primary abortive drugs are ergotamine derivatives and sumatriptan, a serotonin receptor agonist (avoid both during pregnancy). Patients taking ergots, aspirin, or NSAIDs for longer than three days should be warned of a rebound migraine that can occur. This may also occur with sudden withdrawal from other medication. From a medical approach, first-line therapy is over-the-counter medications. One study showed that two tablets of a combination of acetaminophen, aspirin, and caffeine (Excedrin Extra-Strength) was effective for most cases of migraine.<sup>150</sup> This approach is recommended prior to the administration of prescription drugs. A 2013 Cochrane review supports the use of 1,000 mg of aspirin for abortive management of migraine.<sup>151</sup> The concern, of course, is that this level of medication carries with it gastrointestinal risk; primarily gastric ulcers and bleeding. Newer drugs include angiotensin II receptor blockers and topiramate for prophylaxis. Evidence-based guidelines for the protocol of prescription drug management have been published by the U.S. Headache Consortium (a collaborative of seven professional organizations).<sup>152</sup> Also, a review of effectiveness for the various triptans is available in a study by Goadsby et al.<sup>153</sup> With triptans there are concerns related to cardiovascular conditions and pregnancy. The effectiveness of triptans is approximately only 60%.

A series of Cochrane reviews<sup>154-156</sup> in 2012 evaluated the effectiveness of triptans based on the route of delivery. All three routes of intranasal, oral, or rectal demonstrated effectiveness but with a concern of increased adverse events compared with placebo.

Prophylactic treatments include antidepressants and antihypertensives. Additional therapies that have some literature support include subcutaneous histamine (prophylactic),<sup>157</sup> intranasal lidocaine (abortive),<sup>158</sup> and pulsed electromagnetic field therapy.<sup>159,160</sup>

For those patients refractory to conservative management, a medical alternative uses a sequenced approach. This begins with injection of either Botox or anesthetic such as lidocaine.<sup>161</sup> If this relief is sustained, than repeated injection may be necessary. If initially effective in the short term but not the long term, cosmetic surgery to decompress a branch of the trigeminal nerves in entrapped fascial or occipital musculature is now being performed. Long-term studies are still needed.

## **Migraine without Aura (Common Migraine)**

### **Classic Presentation**

The patient is often female complaining of a unilateral, pulsatile headache that is recurrent, which began to occur when she was a young adult. There are no associated visual or other neurologic signs or symptoms. The headache is severe; however, the patient is usually able to continue daily activities. Associated nausea and vomiting occur, with vomiting sometimes providing relief of the headache.

### **Cause**

See migraine with aura above. Migraine without aura accounts for the vast majority of migraine headaches (80% to 85%). It appears that cerebral blood flow and cerebral blood volume may be reduced during the headache phase in patients with migraine without aura.<sup>162</sup> Interestingly, oxygen metabolism and extraction seem unaffected.

### **Evaluation**

The physical examination is used primarily to screen for other secondary causes. The presentation is the primary diagnostic indicator. The main difference between migraine with aura and migraine without aura is the aura. Migraine without aura is usually somewhat less severe; however, it may last longer.

### **Management**

The same principles are applied as outlined above for migraine with aura.

#### **Tension-Type**

### **Classic Presentation**

The patient describes a headache with frequent occurrence that is often worse in the afternoon or early evening. The pain is usually bilateral, often suboccipital or supraorbital. The headaches last for days or weeks. Aspirin or over-the-counter NSAIDs seem to provide relief.

# Cause

Although it was once believed that tension-type headaches were due to muscle tension, it is now recognized that although there are often tender trigger points in the neck and suboccipital area, there is no higher incidence of muscle hypertonicity when compared with other headache types. There is a growing group of researchers who believe that chronic tension-like headaches may represent part of a headache continuum.<sup>163</sup> These patients often begin with migraine attacks that gradually transform (transformed migraine) into more frequent, less severe, tension-type headaches. This may be related to chronic abuse of medication.

# Evaluation

There are no diagnostic findings specific to tension-type headaches. It is not unusual to find tender trigger points and tight muscles in the neck, although these are not exclusive to tension-type headache sufferers. A history of frequent, often bilateral, attacks that are relieved by pain medication is a strong basis for a tension-type headache diagnosis.

# Management

Studies are mixed regarding whether chiropractic manipulation is beneficial for tension-type headache sufferers.<sup>106,164</sup> A recent study that indicated no advantage with chiropractic manipulation utilized a small group of patients, which may reduce the strength of the findings. It is important for patients to avoid continual use of pain medications because of the gastrointestinal consequences.

## Cervicogenic

# Classic Presentation

The presentation is dependent on the criteria and definition of the term *cervicogenic*. The belief that other headaches have a cervicogenic component causes some overlap. Those with a pure cervicogenic headache without overlap may present with a complaint of daily headaches with no associated neurologic signs. There is often reduced movement in neck motion associated with neck pain.

# Cause

Cervicogenic headache is due to referral from soft tissue and articular structures in the neck. Similar to the concept introduced above with migraine headaches, convergence in the trigeminocervical nucleus allows referral of pain from neck origins to the head.

Vernon<sup>165</sup> refers to several causes, including extrasegmental (myofascial structures), intersegmental (deep muscles and ligaments), infrasegmental (nerve roots and dorsal ganglions), and intrasegmental (referral via trigeminocervical nucleus).

# Evaluation

It appears that patients with cervicogenic headache may have indications of restricted movement, in particular at the upper cervical/occiput region.<sup>133</sup> The headache may be made worse in some patients with head movement. Radiographically, there may be indications of arthrosis, but this is not specific for cervicogenic headaches.

# Management

Manipulation is recommended as the primary treatment approach. One study<sup>166</sup> specifically focused on the outcome of patients who met the IHS criteria for cervicogenic headache and found a possible positive effect.

# Cluster

# Classic Presentation

The patient is often a middle-aged male complaining of incredibly painful headaches that are orbital in location. The headaches cluster over days or weeks and then end, to appear again several weeks or months later. The headaches last an average of 30 minutes and are the most painful feeling the patient has felt. The patient has a history of smoking and possibly alcohol abuse.<sup>167</sup>

## Cause/Occurrence

Cluster headaches are believed to be primarily neurovascular and part of a group of trigeminal-autonomic cephalalgias that includes paroxysmal hemicrania and syndrome of short-lasting unilateral neuralgiform headaches

with conjunctival (SUNCT syndrome).<sup>168</sup> Specifically, cluster headaches are characterized by cranial parasympathetic activation and sympathetic impairment.<sup>169</sup> Researchers now believe that cluster headache is due to activation of the ipsilateral inferior hypothalamic gray matter, the ventroposterior thalamus, the anterior cingulate cortex, and bilaterally in the insular based on position emission tomography (PET).<sup>170,171</sup> Triggers during the cluster period include alcohol and some foods.

The frequency of attacks is on average several times per day, often at night, lasting for one to several weeks. Recurrence may not occur for months or even years later. The natural history is for headaches to decrease in frequency and intensity as the patient ages. There are always exceptions to this statistical average.

## Evaluation

The physical examination is unrevealing unless the patient is seen during an attack. During an attack there is often lacrimation associated with a runny nose on the same side as the headache. In a minority of cluster patients, there may be a Horner's syndrome (ptosis, miosis, anhidrosis). Unlike the patient with migraine, the patient with cluster headaches is often agitated and animated during attacks, sometimes beating the head against a wall in an attempt for relief. Some patients commit or attempt suicide because of the severity and recurrence of the headaches.

## Management

The average clinic course is that headaches will gradually diminish over years. It is important to understand the natural history and convey this to the patient given that there is a high suicide rate among patients with cluster headache due to the psychological struggle of believing this is a lifelong sentence.

A new experimental approach for intractable cluster headaches has been electrical stimulation of the hypothalamus. A recent review suggests cautious optimism with this approach.<sup>172</sup>

Unlike migraine and tension-type headaches, there is no clear literature indication of chiropractic manipulation success with cluster headaches. However, given that it appears there may be a similar underlying mechanism, a trial of treatment during a cluster period seems warranted if the patient is amenable. Medical treatment is quite similar to that for migraine including the triptans. A 2010 Cochrane review<sup>173</sup> concluded that triptans were an effective management approach to cluster headache management. It appears that nonoral administration is likely more effective than oral. Additional treatments include 100% oxygen<sup>174</sup> (7 L/min for 15 minutes) and intranasal (5%–10% solution) lidocaine<sup>175</sup> (4% solution). Oxygen therapy is less effective

in older patients and those with chronic cluster attacks. Lidocaine is thought to have an anesthetic effect on the sphenopalatine ganglion. Intravenous magnesium may also be a treatment strategy in some clinics.<sup>176</sup> In a small study<sup>177</sup> patients with medically intractable cluster headache had electrodes implanted in the suboccipital region for the purpose of occipital nerve stimulation. The device seemed to provide relief for the majority of patients.

For refractory cluster headache, gamma knife radiosurgery of the trigeminal nerve root entry zone has been advocated, as have radiofrequency lesions of the sphenopalatine ganglion.<sup>178,179</sup>

## **Temporal Arteritis**

### **Classic Presentation**

The patient is older (> 50 years) complaining of a unilateral headache in the temporal region. The headache is associated with a tender nodule at the superficial temporal artery at the side of the forehead. The patient may also complain of generalized aching and muscular fatigue in the upper trunk area. There may also be complaints of visual dysfunction or blindness of sudden onset.

### **Cause**

Temporal arteritis (giant cell arteritis) is a generalized vasculitis affecting small- and medium-sized arteries. This inflammatory process affects more than just the temporal artery; however, it is largely asymptomatic with other areas of involvement. When the ophthalmic artery is involved, an ischemic optic neuropathy with blindness occurs. One study<sup>180</sup> suggests the possibility of an infectious cause due to cyclic incidence rates over time in a population-based investigation.

### **Evaluation**

The onset of a new headache in an older patient brings temporal arteritis to the list of possibilities. Although it is called “temporal,” only about half of patients feel it in the temples. However, 50% to 70% have scalp tenderness near the area of involvement.<sup>181</sup> Other indicators are jaw claudication, C-reactive protein above 2.45 mg/dL, neck pain, and an erythrocyte sedimentation rate (ESR) above 47 mm/hour. C-reactive protein is more sensitive (100%) than ESR (92%).<sup>182</sup> The combination of elevations gives the best specificity (97%). Visual changes may present as sudden loss of vision due to blockage of the retinal artery.<sup>183</sup> Some patients complain of diplopia.

Dull, aching pain (polymyalgia rheumatica) in the upper trunk area is reported in about 40% of patients with temporal arteritis. Medical biopsy of the temporal artery will confirm the presence of multinucleated giant cells.

## Management

The patient with temporal arteritis must be referred because of the high likelihood of blindness if left untreated. Temporal arteritis is treated with corticosteroids. The length of time varies based on the severity of the disease. Some authors recommend the use of color Doppler sonography to monitor progression.<sup>184</sup>

## **APPENDIX 17-3**

# Headache Diagnosis Matrix

Headache Diagnosis Matrix					
Diagnosis	Comments	History Findings	Positive Examination Findings	Radiography/Special Studies	Treatment Options
Tension-Type Headache	<ul style="list-style-type: none"> <li>Tension headache is the Dx used when there are no indications of neurologic involvement, symptoms are generally mild and responsive to OTCs.</li> <li>Note that if it is suspected that headache is specifically due to subluxations of the cervical spine, should be called (cervicogenic headache).</li> </ul>	<p><i>Age of Onset</i>—Any age</p> <p><i>Onset Characteristics</i>—Generally insidious with onset often occurring in afternoon</p> <p><i>Location</i>—Sub-occipital and band-like in temporal area most common</p> <p><i>Severity</i>—Generally mild, however, wide variation</p> <p><i>Duration</i>—Lasts for hours to days</p> <p><i>Associated S &amp; S</i>—Generally not associated with nausea or vomiting. Generally responsive to over-the-counter pain medication to some degree</p>	<p><i>Nonspecific</i>—Localized tenderness in area of pain and/or in cervical region</p>	<ul style="list-style-type: none"> <li>Radiography not recommended or required.</li> </ul>	<ul style="list-style-type: none"> <li>Chiropractic adjustive technique (CAT).</li> <li>Avoid repetitive use of OTCs.</li> <li>Attempt to change occupational biomechanics if appropriate.</li> <li>Suggest methods to reduce stress.</li> </ul>
Migraine with Aura (Classic Migraine)	<ul style="list-style-type: none"> <li>The aura is a neurologic event lasting from one-half hour to a couple of hours, classically manifested as visual dysfunction such as flashing lights and scotomas.</li> <li>In complex migraines, the aura is the predominant event and may be as severe as temporary hemiparesis.</li> </ul>	<p><i>Age of Onset</i>—Any age is possible; most common onset is late teens/early twenties and then again postmenopausal; predominantly female</p> <p><i>Onset Characteristics</i>—Preceded by aura by one-half hour or so</p> <p><i>Location</i>—Unilateral, pulsatile, often temporal or orbital</p> <p><i>Severity</i>—Quite severe</p> <p><i>Duration</i>—Lasts for hours (occasionally days)</p> <p><i>Associated S &amp; S</i>—Generally associated with nausea or vomiting, photophobia</p>	<p><i>Neurological findings</i>—Indications of temporary sensory or motor deficits may be found during aura, especially with cranial nerves</p> <p><i>Nonspecific</i>—Localized tenderness in area of pain and/or in cervical region</p>	<ul style="list-style-type: none"> <li>In cases where neurologic signs or symptoms are predominant, CAT scan or MRI may be needed to rule out other causes.</li> </ul>	<ul style="list-style-type: none"> <li>Trial of CAT.</li> <li>Feverfew or other supplementation.</li> <li>Maintain regular sleeping and eating patterns.</li> <li>Avoid known triggers.</li> <li>Referral for biofeedback or acupuncture if ineffective.</li> <li>Referral for medical management with sumatriptan.</li> <li>Note that rebound migraine occurs when medication is stopped suddenly or taken for longer than 3 days.</li> </ul>

<b>Migraine without Aura (Common Migraine)</b>	<ul style="list-style-type: none"> <li>Difficulty may exist in differentiating severe tension headaches from migraine without aura.</li> <li>Temporal or orbital location with pulsatile characteristics and poor response to OTCs characterizes migraine without aura.</li> </ul>	<p><i>Age of Onset</i>—Any age is possible; most common onset is late teens/early twenties and then again postmenopausal; predominantly female</p> <p><i>Onset Characteristics</i>—No aura; insidious onset</p> <p><i>Location</i>—Unilateral, pulsatile, often temporal or orbital</p> <p><i>Severity</i>—Quite severe</p> <p><i>Duration</i>—Generally last for days</p> <p><i>Associated S &amp; S</i>—Generally associated with nausea or vomiting</p>	<p><i>Nonspecific</i>—Localized tenderness in area of pain and/or in cervical region</p>	<ul style="list-style-type: none"> <li>In cases where neurologic signs or symptoms are predominant, CAT scan or MRI may be needed to rule out other causes.</li> </ul>	<ul style="list-style-type: none"> <li>Trial of CAT.</li> <li>Feverfew or other supplementation.</li> <li>Maintain regular sleeping and eating patterns.</li> <li>Avoid known triggers.</li> <li>Referral for acupuncture if ineffective.</li> <li>Referral for medical management with sumatriptan or similar serotonin update inhibitors.</li> </ul>
<b>Migraine Variant Includes Cluster Headache &amp; Allergic Headaches</b>	<ul style="list-style-type: none"> <li>Cluster headaches are particularly painful and psychologically difficult for the patient to handle; suicide is contemplated by many patients.</li> </ul>	<p><i>Age of Onset</i>—Most common onset is 30s to late 40s; male predominant</p> <p><i>Onset Characteristics</i>—Often same time each day; clusters over days or weeks. Smoking may initiate; alcohol exacerbates</p> <p><i>Location</i>—Unilateral, orbital</p> <p><i>Severity</i>—Very severe</p> <p><i>Duration</i>—Lasts for 45 minutes to 2 hours</p> <p><i>Associated S &amp; S</i>—Unilateral lacrimation, rhinorrhea; generally associated with nausea or vomiting; generally not responsive to over-the-counter pain medication</p>	<p><i>Neurological</i>—During attacks, a temporary Horner's syndrome may be present in a minority of patients</p> <p><i>Nonspecific</i>—Localized tenderness in area of pain and/or in cervical region</p>	<ul style="list-style-type: none"> <li>In cases where neurologic signs or symptoms are predominant, CAT scan or MRI may be needed to rule out other causes.</li> </ul>	<ul style="list-style-type: none"> <li>Trial of CAT.</li> <li>Feverfew or other supplementation.</li> <li>Maintain regular sleeping and eating patterns.</li> <li>Avoid known triggers.</li> <li>Referral for acupuncture if ineffective.</li> <li>Referral for medical management with O<sub>2</sub> therapy, intranasal lidocaine, or sumatriptan.</li> </ul>

Diagnosis	Comments	History Findings	Positive Examination Findings	Radiography/Special Studies	Treatment Options
<b>Cervicogenic Headache</b>	<ul style="list-style-type: none"> <li>Used only when patient does not have clear indicators of one of the primary headache types, such as migraine or tension-type, and it is suspected that the headache is purely cervicogenic in origin.</li> </ul>	<p><i>Onset</i>—May be posttraumatic or have an insidious onset</p> <p><i>Symptoms</i>—Pain is localized to neck or occipital region; however, may radiate to various areas of the head and face</p>	<p><i>Palpation</i>—Tenderness in neck musculature or changes in tone, contour</p> <p><i>Ortho</i>—Headache may be exacerbated or reproduced by head/neck movements</p> <p><i>ROM Findings</i>—Limitation or resistance to neck movements</p>	<ul style="list-style-type: none"> <li>Radiographs indicate one or more of the following: movement abnormalities of flexion/extension, abnormal posture, or fractures/dislocations, congenital abnormalities, RA, tumors, or other distinct pathologies.</li> </ul>	<ul style="list-style-type: none"> <li>Mobilization, manipulation (need corresponding subluxation code).</li> <li>Stretching, postural exercises.</li> <li>Myofascial therapy.</li> <li>Physiotherapy.</li> </ul>

# CHAPTER 18

## Dizziness

### Context

In most studies of primary care,<sup>1</sup> internal medicine,<sup>2</sup> and emergency departments,<sup>3</sup> dizziness ranks among the top three patient complaints. Statistics for chiropractic clinics are not as clear.<sup>4</sup> In the context of chiropractic practice, probably the most frequently seen cases are those associated with motor vehicle cervical spine/head injuries and in the elderly. Dizziness may be one of the top three symptoms reported after acceleration/deceleration injury to the neck.<sup>5-8</sup> It is unclear how many cases are due to insult to neck proprioceptors versus the vestibular apparatus or vascular supply to the head and neck.

Dizziness may occur in as many as 50% of the elderly.<sup>9</sup> In nearly 20% of all older persons, the dizziness is severe enough to consult a health professional. Although it appears that there are age-related declines in vestibular, visual, auditory, and somatosensory functions in normal older individuals, these changes correlate weakly to actual changes in gait and balance.<sup>10</sup>

At a dizziness and balance clinic for patients over age 65 years, the distribution of cause for dizziness was 32%, due to benign paroxysmal positioning vertigo;<sup>11</sup> 22% was due to either fear of falling or disuse equilibrium, and 13% was due to vestibular loss. All other causes accounted each for 5% or less of cases. Although dizziness is a frequent complaint,<sup>12</sup>

only a little more than half of patients receive treatment.<sup>13</sup> The elderly population in particular is more prone to the vertiginous effects of medications and the lack of compensation that a younger population has for dysfunction of one of the components of balance. Vision, proprioception, and vestibular function are all integral to balance. When one is dysfunctional, the nervous system may accommodate through input and adaptation from the other systems. In the elderly, there may be a general deterioration of all neural systems, perhaps complicated by other diseases such as diabetes or atherosclerosis, making adaptation less effective and dizziness more disabling.

As with many patient complaints, the chiropractor must ask the patient to further describe a complaint of dizziness in order to gain a clearer understanding of which body systems are involved. Often this simple step in evaluation will narrow down the cause into a general category (**Exhibit 18-1**). Dizziness may be perceived as spinning of the room or self, motion imbalance or lack of coordination while walking, or simply lightheadedness or the sensation of almost fainting (i.e., presyncope). The sensation of spinning or motion is generally attributed to dysfunction of the vestibular and central processing systems, whereas a sensation of imbalance or lack of coordination is more likely due to cerebellar or proprioceptive dysfunction. In the senior, it is important to remember that myelopathy due to spinal stenosis is a common cause of a sense of imbalance. Lightheadedness or a sense of almost fainting suggests a vascular or psychologic cause. Some studies indicate a psychologic component in as many as 37% to 40% of patients with chronic dizziness, depending on the facility.<sup>14, 15</sup>

## General Strategy

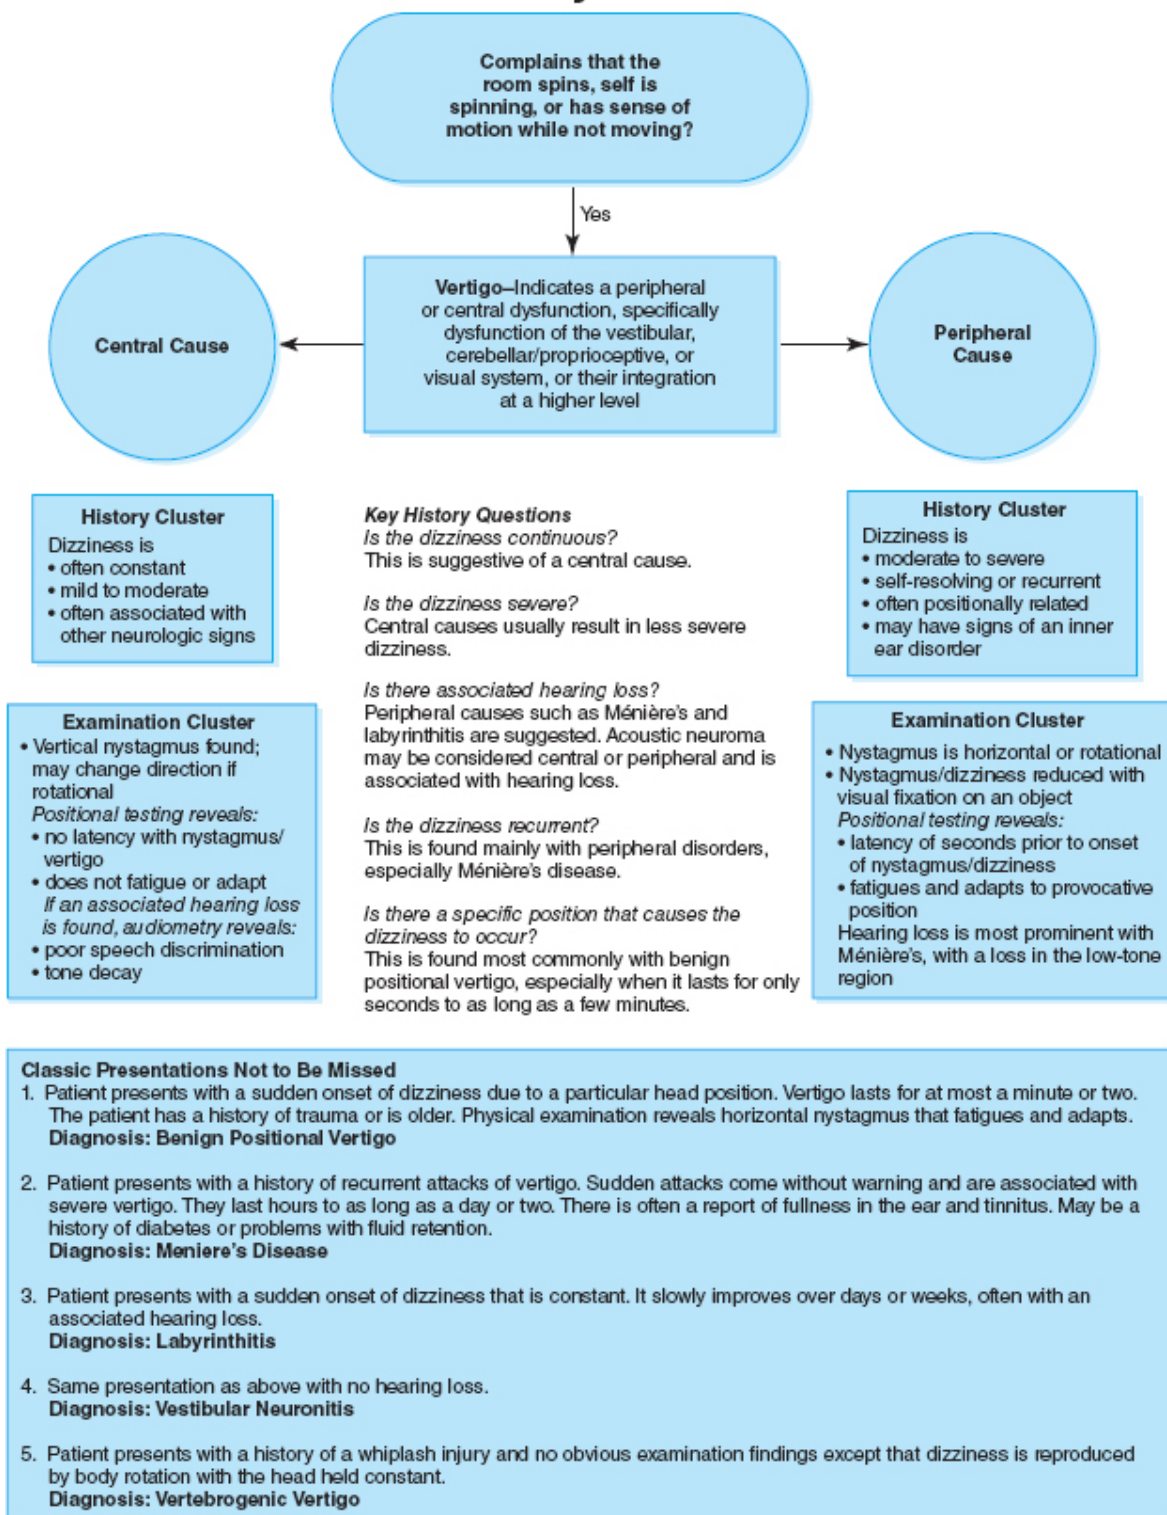

# History

- Obtain a more detailed description of a patient's complaint of "dizziness."
- Differentiate vertigo from nonvertiginous causes of a dizziness complaint.
- Determine onset and length of attacks and whether they are recurrent to help differentiate further.

## **Exhibit 18-1 Narrowing the Cause of Dizziness**

# The Dizzy Patient

- Determine whether the patient senses any hearing loss.
- Ask about associated neurologic or systemic complaints.
- Ask about current medications.
- Differentiate between peripheral and central causes if vertigo is likely.

## **Narrowing the Cause of Dizziness**

# **Evaluation**

Screen with a battery of tests to:

- Determine whether there are any objective hearing deficits.
- Determine whether there are any associated systemic or neurologic problems.
- Determine the patient's vascular, endocrine, and psychologic status if nonvertiginous, particularly diabetes.
- Determine to what degree cervical spine dysfunction may be contributory.
- Evaluate seniors for signs of myelopathy.

# **Management**

- Consider referral or comanagement in the following scenarios:
  - The patient has had head trauma and is demonstrating other associated neurologic signs, or a skull fracture is suspected.

- Prescription medication is suspected as the underlying cause (refer to the prescribing physician if possible).
- The dizziness is incapacitating, requiring medication during the symptomatic phase (comanagement may be possible).
- The dizziness appears to have a strong psychologic component.
- The patient appears to have a cardiopulmonary cause such as an arrhythmia, heart block, or congestive heart failure.
- The patient is suspected of having a perilymphatic fistula.
- The patient needs further audiologic or special imaging evaluation, especially in the consideration of brain tumors, cerebrovascular accidents, demyelinating diseases (e.g., multiple sclerosis), or cerebellar or extrapyramidal disorders (e.g., Parkinson's disease).
- The patient has hearing loss.
- Treat peripheral vertigo with chiropractic manipulative techniques, habituation exercises, and other conservative approaches.
- Refer if treatment is ineffective or the dizziness creates significant functional impairment.

## **Relevant Anatomy and Physiology**

Balance and spatial orientation are maintained by an integrated, neuronal feedback loop. A slow adjustment can be made to compensate when input from any component is dysfunctional unless more than one component is involved. The components of this system are: (1) vestibular, (2) visual, and (3) proprioceptive. The vestibular labyrinth

sends information to the vestibular nuclei in the medulla and lower pons via the vestibular branch of cranial nerve VIII. The cerebellum, receiving input from the spinocerebellar tracts (proprioception), also sends information to the vestibular nuclei. Conscious proprioception is conveyed through the posterior column/medial lemniscus (PCML) pathways. These may be adversely affected directly through myelopathy often due to the compressive effects of spinal stenosis or commonly at distal receptors affected by diabetes. The midline cerebellar structures have a strong inhibitory effect on the vestibular nuclei. In turn, the vestibular nuclei project to the cerebellum to all spinal levels through the vestibulospinal tracts, and to the medial longitudinal fasciculus (MLF) and the pontine reticular formation. Fibers in the MLF project to nuclei of the third, fourth, and sixth cranial nerves, stimulating reflex conjugate eye movement in reaction to head position change. The cerebral cortex, although not part of the vestibular system per se, modulates motor activity and coordination as a result of information supplied from various sensory inputs.

The vestibular receptor at each end of each semicircular canal is referred to as the ampullae (i.e., crista ampullaris). Within the ampulla is the cupula. Displacement of hair cells implanted in the neuroepithelium of the cupula occurs with angular movement (e.g., rotation) as a result of endolymphatic fluid movement. This component of equilibrium is often referred to as kinetic. In addition to the semicircular canals are the utricle and saccule. Together the utricle and saccule are referred to as otolith organs. They contain a small patch of sensory epithelium referred to as the maculae. Again, as with the ampullae, hair cells are sensitive to displacement through contact with a gelatinous material containing calcium carbonate crystals (i.e., otoliths). The utricle and saccule are sensitive to gravity and linear acceleration. This is often referred to as static

equilibrium. Specifically, the utricle is more sensitive to forward and backward movement, whereas the saccule is more sensitive to vertical movement. A high rate of tonic firing from the vestibular sensory organs occurs, and when a unilateral disorder disrupts this tonic firing a sense of dizziness (and clinically manifested nystagmus) occurs. When there is bilateral damage to vestibular sensory organs, there is often no “imbalance” and the individual may not experience vertigo. A slow process such as an acoustic neuroma may not cause vertigo, because damage occurs gradually and compensation by the central nervous system is able to accommodate. Dislodging of otolith crystals may cause stimulation with certain head positions, causing vertigo that usually lasts for seconds to minutes. Any ipsilateral increase or decrease in labyrinth discharge will create a sense of movement.

Proprioception is conveyed through the integration of muscle spindles, joint receptors, and cutaneous mechanoreceptors that transmit external and internal information about the body that results in both conscious and non-conscious perspectives about where the body is in space. Information specific to the cerebellum travels in the spinocerebellar tracts as non-conscious information that the cerebellum can use to compare with descending information sent from the cerebrum in the corticospinal tracts (collaterals sent through the pons to the cerebellum through the middle cerebellar peduncle) allowing fine adjustments to movement. This information and that from the posterior columns (i.e. conscious proprioception) may be interfered with through compression of the spinal cord; in particular, in elderly patients with spinal canal stenosis and subsequent myelopathy. Loss of proprioception in the feet often results in a perception of unsteadiness or being off-balance. This is common with diabetes. Proprioceptive information from the upper cervical musculature and joints may play a major role in a patient’s perception of balance. The high density of

receptors in the upper cervical region<sup>16</sup> participates in several reflexes. Although many assume that these are primarily capsular afferents, the scientific basis for this assumption has been questioned. The original study<sup>17</sup> used the vertebral joints of quadrupeds for examination. It was found that in addition to nociceptors, the capsules contained proprioceptive type I afferents (tonic discharge; static position detection) and type II afferents (discharge only with movement). However, recent studies<sup>18-20</sup> indicate that human facet joints contain mainly nociceptors with only a few type I or type II proprioceptors. It appears that perhaps the majority of proprioceptors are located in other tissue, in particular the deep cervical muscles such as the interspinales, multifidus, rotator spinae, intertransversarii, and longus cervicis. The cervico-ocular reflex causes the eyes to rotate to the opposite side of head rotation. It becomes especially significant as a compensation for damage to the vestibular apparatus. The vestibulocollic reflex is more of an effector reflex, allowing vestibular information to modulate cervical muscle activity. To complete the interaction, input from the neck can also modulate vestibular reflexes.<sup>21</sup>

Theoretically, trauma or dysfunction in the cervical spine may have effects on these reflexes, or if there is damage to the vestibular apparatus, these reflexes may help compensate. Cervicogenic vertigo is believed to be a result of cervical joint dysfunction, muscle strain, or injury from trauma such as a whiplash-like accident. The basic science support for this possibility comes from numerous studies that have shown ataxia, nystagmus, and/or disequilibrium with local anesthetic injection<sup>22</sup> into the deep posterolateral neck, electrical stimulation<sup>23</sup> of strained muscles, and transection of suboccipital muscles or upper cervical root section in animals. Vibration of muscle tendons or the head can create a postural illusion leading to nystagmus and motion sickness.<sup>24</sup> Overstimulation from joint dysfunction or

muscle spasm or damage to the upper cervical proprioceptors theoretically may result in an imbalance of proprioceptive information. Through vestibular reflexes the result may be a sense of disequilibrium.

The vascular supply to the ear and the vestibular apparatus and nuclei may be compromised, leading to the perception of dizziness. Although it was once believed that a sympathetically mediated vascular reflex could be the cause of vertigo in patients with cervical dysfunction, it appears that vertebral blood flow is minimally responsive to sympathetic stimulation.<sup>25</sup> The main vascular supply to the head is from branches off the vertebral or basilar arteries (the basilar artery is formed by the two vertebral arteries). The main artery is the anterior inferior cerebellar artery. The caudal portion of the vestibular nuclei is supplied more specifically by the posterior inferior cerebellar arteries via the lateral medullary or posterior spinal arteries. The vestibular and basilar arteries supply more than the vestibular nuclei; as a result, other symptoms accompany vertebrobasilar insufficiency, including diplopia, ataxia, “drop attacks,” dysarthria, and various forms of body paralysis or weakness (although dizziness is often a prominent symptom).

Generally, dizziness is caused by decreased cerebral, cerebellar, or brainstem perfusion or dysfunction of one or all of the neural balance systems: (1) visual, (2) vestibular, and (3) proprioception/cerebellar. This dysfunction is usually due to trauma, vascular compromise, infection of the labyrinths, or neural inflammation or degeneration both centrally and peripherally (such as in multiple sclerosis). For less common causes of dizziness see **Table 18-1**.

<b>Table 18-1</b> Differential List of Less Common Causes of Dizziness
--

--	--	--

Disorder	Clinical Clues	Management
<b>Acute Ramsey-Hunt Syndrome</b> —varicella virus infection of cranial nerves VII and VIII	In addition to facial paralysis (Bell's palsy) there is also possible hearing loss, tinnitus, and dizziness. Important to check otoscopically on all patients with signs of varicella infection.	Medical management includes acyclovir and possibly prednisone within first few days
<b>Brainstem infarct</b> —vertigo due to infarcts in posterior fossa structures that contain vestibular pathways		
<ul style="list-style-type: none"> <li>• Anterior inferior cerebellar artery—branches including the cerebellar, pontine, and labyrinth</li> </ul>	Infarct of anterior inferior cerebellar artery—vertigo, nausea/vomiting, and imbalance. Common cochlear or labyrinth artery presentation is same, plus hearing loss/tinnitus. Infarction of pontine branch—central signs including dysarthria, Horner's, peripheral facial paralysis, trigeminal sensory loss, and contralateral pain/temperature loss.	MR arteriography used to assess posterior circulation with transcranial Doppler for basilar artery flow. Warfarin often used. Management includes decrease in risk factors for cerebrovascular disease and vestibular exercises. Central compensation may not be complete if the infarct involves the vestibular portion of the cerebellum.
<ul style="list-style-type: none"> <li>• Posterior inferior cerebellar artery—</li> </ul>	Lateral medulla infarct results in	Same as above for anterior, inferior cerebellar artery

supply to posterior inferior cerebellum and dorsolateral medulla	Wallenberg's syndrome—crossed sensory findings, ipsilateral lateropulsion ataxia, Horner's sign. Nystagmus may be pure torsional or mixed.	
<p><b>Chronic vestibular hypofunction</b>—chronic vestibular loss may be the residual of vestibular disease or when bilateral due to ototoxicity (e.g., gentamicin).</p> <p>The most common is idiopathic likely due to degeneration with age.</p>	Patients may complain of unsteadiness while walking, oscillopsia with head movements (i.e., false sense of movement). There is no spontaneous nystagmus, positive on head thrust tests and negative Romberg.	Vestibular rehabilitation is key to treatment. A programmed sequence of vestibular training allowing for central compensation is often effective. A supervised program is more effective than handing the patient an instruction sheet.
<p><b>Disuse disequilibrium and fear of falling</b>—in the elderly, a combination of lack of exercise and mobility in general can lead to disuse disequilibrium. Fear of falling may result from disuse disequilibrium and exacerbate the problem by the patient's unwillingness to ambulate.</p>	Patient expresses fear of falling especially with eyes closed and walking in areas where no support is evident. Past history of a fall is likely. The vestibular examination is normal. Tandem walking is often abnormal, as is Romberg's with eyes closed. The Tinetti risk assessment questionnaire may be helpful to determine risk and strategy for management.	Daily home program that includes exercise for endurance, balance, and lower extremity strength. Balance exercises are modeled after vestibular rehabilitation exercises.
<b>Leukoaraiosis</b> —white matter disease of the	Gait and balance problems similar to	Because features overlap with Parkinson's, including age,

<p>brain due to significant small vessel disease seen most frequently in older patients with diabetes and hypertension</p>	<p>Parkinson's and normal pressure hydrocephalus. Positive retropulsion test. Patient asked to take one step backward when examiner pulls back on patient's hip. Positive is either falling backward like a log or taking several steps backward.</p>	<p>nonresponse to carbidopa/levodopa (Sinemet) indicates possibility. MRI reveals leukoaraiosis. Only available management is prevention of further progression and an attempt at vestibular training exercises, which have variable success.</p>
<p><b>Spells of dizziness</b> Central positioning vertigo—caused by lesion near the fourth ventricle near the cerebellum, including tumors, multiple sclerosis, and strokes</p>	<p>Patient complains of onset with change of position. Hallpike maneuver response is usually an up- or downbeat nystagmus with no latency and no fatigue to repeated positioning.</p>	<p>Imaging, often using MR with or without gadolinium, reveals lesions. Surgical correction is likely.</p>
<p><b>Perilymphatic fistula</b> —a hole connecting the inner and middle ear due to barotrauma (e.g., scuba diving), head trauma, tumor (cholesteatoma), or movement of a prosthetic middle ear bone into the inner ear</p>	<p>A history of barotrauma such as scuba diving or heavy weight lifting may be found. Also, lifting weights may cause oscillopsia and vertigo. Pressure changes provoke dizziness due to flow of fluid between the two compartments. Valsalva maneuver may also provoke oscillopsia, as will blowing out through pinched nostrils. Using the insufflation device of the otoscope</p>	<p>Surgical exploration with patching of round or oval window with autogenous tissue is usually effective. Patient usually ambulating after one week postsurgery.</p>

	may also provoke. Hallpike maneuver may or may not provoke a peripheral type of response.	
<b>Superior canal dehiscence</b> —less than 1% of the population is born with a thin bony top of the superior semicircular canal. Mild head trauma or pressure change may cause an opening with contact between the membranous canal and overlying dura.	Patients may complain of a “rumbling” sensation in the head with talking or coughing. Dizziness occurs with changes of position, Valsalva maneuver, or with loud noises (Tullio’s phenomenon). An ocular tilt response may occur with blowing out through a pinched nose, resulting in one eye moving up and in and the other down and out.	Petrous bone CT will usually reveal the loss of bone. Treatment usually involves surgically placing a bone plate over the superior SCC or, if not surgically possible, having patient avoid pressure changes and using earplugs to avoid the Tullio phenomenon.
<b>Transient ischemic attacks (TIA)</b> —TIAs of the vertebrobasilar vascular area will often cause transient symptoms.	TIAs of the vertebrobasilar area may be due to dissection or thrombus. The attacks generally last only a few minutes and, in addition to sudden dizziness, may also include “drop attacks,” visual disturbances, and/or weakness. Risk factors for cerebrovascular disease are evident in those with repeated spells of dizziness.	MR arteriography is the diagnostic tool of choice. Transcranial Doppler may reveal decreased blood flow in the basilar artery. Warfarin is often used when there is vertebral or basilar artery stenosis.

<p><b>Migraine</b>—a variant of migraine; may be the “aura” prior to headache</p>	<p>Some patients with migraine experience vertigo. Dizzy spells generally last 45 minutes to 60 minutes and do not always result in a subsequent headache. The dizziness may appear vestibular because it is provoked by head movement.</p>	<p>Management is similar for migraine headaches in general. Avoidance of triggers, regular lifestyle maintenance (e.g., regular sleeping and eating habits). Chiropractic manipulation should be considered when serious causes of dizziness have been ruled out.</p>
<p><b>Psychogenic/anxiety</b>—commonly associated with anxiety, bouts of attacks that include dizziness as one of a complex of symptoms</p>	<p>When the patient uses multiple terms to describe the dizziness (vague), depression or anxiety is likely. Common descriptions include floating and rocking. There is often a history of stress. Associated complaints including shortness of breath or chest tightness, paresthesias, and sweating are not uncommon. They often occur together, escalating over about 10 minutes when in a stressful or uncomfortable situation.</p>	<p>Behavioral modification may be very effective. If not, selective serotonin reuptake inhibitors (SSRIs) are often prescribed. Alprazolam (Xanax) is an anti-anxiety medication that may also be prescribed.</p>

## Evaluation

# History

The most important step in the evaluation of a complaint of dizziness is to ask the patient to qualify or more clearly describe his or her complaint. The patient may be reluctant or unable to describe the complaint further, and it may be necessary to prompt him or her with some common descriptions (**Tables 18-2** and **18-3**). Patient descriptions correlate well with four general categories of dizziness: (1) vertigo, (2) syncope or presyncope, (3) disequilibrium, and (4) psychogenic (hyperventilation, depression).

If the patient feels as though the room or he or she is spinning, one would be more likely to think of classic vertigo. Vertigo includes any abnormal sensation of motion when there is no motion or an exaggerated sense of motion in response to a body movement. The next step in evaluation would be to determine causes that are central and those that are peripheral. *Peripheral vertigo* refers to dysfunction of the labyrinths or vestibular nerve. *Central vertigo* refers to disorders affecting the central connections to the cerebellum and brainstem.

A distinction among the various types of peripheral vertigo may be evident through a comparison of common history elements with regard to onset, duration, recurrence, and associated hearing loss (90% accurate for the most common disorders).<sup>26</sup>

- Benign paroxysmal positional vertigo (BPPV) is suggested when there are brief episodes of moderate to severe vertigo associated with specific provocative head positioning; it gradually diminishes over a month or two without associated hearing loss.

**Table 18-2** History Questions for Dizziness

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Do you or the room spin?	Vertigo. Peripheral or central causes.	Is it continuous or intermittent, coming and going?	Continuous indicates central; recurrent indicates peripheral.
Does it feel like you are about to faint or are lightheaded?	Vascular or endocrine cause.	Does this occur when you stand?	Orthostatic hypotension. Ask about medications.
		Does this occur when you haven't eaten?	Hypoglycemic reaction.
		Does this occur when you cough?	Cough syncope (glossopharyngeal).
		Does this occur when you are "stressed out"?	Anxiety. Adrenal disorder.
		Does this occur when you turn your head?	Subclavian steal, atherosclerotic cause.
		Does it occur when you wear a tight collar?	Sick sinus syndrome.
Are you "dizzy" only when you walk?	Cerebellar or proprioception problem.	Are you diabetic?	Patient may not know. Need to evaluate with lab.
		Is it worse with your eyes closed or in a dark room? Do you fall always to the same side?	Proprioceptive problem, probably dorsal columns. Cerebellar cause should be investigated.
Are you taking medication?	Side effect or indication of underlying disorder that could cause dizziness.	Are you taking muscle relaxants, medication with codeine, or barbiturates?	Central nervous system depression.
		Are you taking cimetidine (Tagamet), pain medications, or high blood pressure medications?	Common drugs that may cause dizziness.

**Table 18-3** Specific History Questions for Vertigo

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Is the dizziness continuous or progressive?	If yes, a central cause is likely. If no, suspect a peripheral cause.	Is the dizziness relatively mild and not affected much by position?	Central cause such as acoustic neuroma, multiple sclerosis.
Is the dizziness recurrent?	Most commonly benign positional vertigo and Ménière's disease.	Is the onset abrupt and related to a specific position change? Does it last for seconds to a couple of minutes? Is it abrupt but lasts for hours to a day or so? Is there associated fullness and a ringing in the ear during attacks?	Benign paroxysmal positional vertigo (BPPV). BPPV. Ménière's disease is likely. Ménière's disease is likely.
Is there associated hearing loss?	Peripheral causes include labyrinthitis and Ménière's disease. Central causes include acoustic neuroma and other pontine tumors.	Have you had this for weeks with a gradual decrease in dizziness? Are these recurrent attacks with associated hearing loss?	Labyrinthitis. Ménière's disease.
Was there a somewhat fast onset with a slow decrease in dizziness?	Labyrinthitis and vestibular neuronitis.	Is there hearing loss?	Labyrinthitis more likely (no hearing loss with vestibular neuronitis).

- Ménière's disease is suggested if there is an abrupt onset of severe vertigo lasting for several hours to one day that is recurrent and associated with attack-related tinnitus (cause of most severe tinnitus; roaring sound), hearing loss, and a sensation of fullness in the ear.
- Vestibular neuronitis or labyrinthitis is suggested if there is a rather abrupt onset of severe vertigo (cause of most severe vertigo and nausea) associated with a prior respiratory infection lasting for several days and gradually diminishing over weeks; the distinguishing factor is whether hearing loss is evident, suggesting labyrinthitis.
- Chronic bilateral vestibulopathy results in nonspecific dizziness or disequilibrium. Often it creates the illusion that the environment is moving when the head is moved (i.e., oscillopsia). The most common cause is ototoxicity due to aminoglycoside use (i.e., certain antibiotics).

- Migraine-associated vertigo is suggested if vertigo precedes a headache. However, isolated vertigo attacks may also occur (i.e., migraine equivalent). Benign recurrent attacks of vertigo suggest migraine-associated vertigo.<sup>27</sup> Basilar migraine is clinically evident via posterior-fossa symptoms (e.g., vertigo, ataxia, dysarthria, and tinnitus) associated with abnormal visual phenomena. Basilar migraine is more common in adolescent girls.
- Transient verteobasilar insufficiency is more common in older patients as a cause of vertigo. It is unclear whether the cause is ischemia of the labyrinth, brainstem, or both; however, the source of blood supply to these structures and the vestibular nuclei and eighth cranial nerve is the verteobasilar circulation. Transient ischemic attacks (TIAs) are typically abrupt in onset; last for several minutes; and may be accompanied by nausea, vomiting, and vertigo. If the posterior circulation is involved, visual blurring, blackouts, diplopia, drop attacks, headache, and weakness and numbness of the extremities may accompany the vertigo. Risk factors are those for atherosclerosis including hypertension, coronary artery disease, diabetes, and hyperlipidemia.

The International Headache Society classification of migraine has a subcategory referred to as benign paroxysmal vertigo of childhood. This refers to multiple episodic attacks of disequilibrium, anxiety, or vomiting in otherwise healthy children. There is no suggestion of cause or management.

Vertigo that is mild and/or constant is always suggestive of a central problem, especially if associated with other neurologic signs or symptoms.

A more rare description of rocking, swaying, or bobbing sometime occurs after prolonged travel on a cruise ship or

airplane. This is mal de débarquement syndrome. It is sometimes associated with migraine headaches.

Another description may be that the patient feels as though he or she is about to faint. This feeling also may be described as lightheadedness. This description is clearly one of decreased cerebral perfusion. It would be important then to determine whether this occurs while sitting, which would be more classically a common faint position, or whether it occurs on rising, which would be more suggestive of orthostatic hypotension. With orthostatic hypotension as a suspicion, a drug history would be the first avenue of concern. This inquiry would be followed by questioning regarding signs suggestive of diabetes, anemia, or cardiopulmonary causes such as congestive heart failure.

One of the most important context questions is, when does it occur? Lightheadedness on rising is suggestive of orthostatic hypotension, whereas difficulty with ambulation is suggestive of a proprioceptive problem. If the patient has more difficulty with dimly lit areas (especially an elderly patient), when not wearing corrective lenses, or with eyes closed a proprioceptive problem is likely. If the dizziness is apparent with certain head positions such as rotation, vertigo is more likely—more specifically benign positional vertigo.

When the patient complains of associated neurologic symptoms such as slurred speech or electric shock sensations down the arms, multiple sclerosis must be considered, especially in a middle-aged patient. Additional considerations are the use of drugs/alcohol and cervical trauma. It is important to obtain a thorough drug history to determine whether illicit use of drugs may be the cause or the side effect of a prescription medication. Medication interactions may cause dizziness, especially in the elderly. Some drugs that may cause dizziness are:

- Anticonvulsants, alcohol, and tranquilizers—through central nervous system (CNS) depression or cerebellar dysfunction
- Antihypertensives—postural hypotension
- Aminoglycosides—vertigo due to asymmetric hair cell loss, disequilibrium due to vestibulospinal reflex loss, and oscillopsia due to vestibular-ocular reflex loss

## Examination

The examination process is dictated by suspicions generated from the history. If the patient's history is suggestive of a vascular cause, evaluation of cardiopulmonary status and perhaps laboratory evaluation are warranted. If the patient's history is more suggestive of vertigo, an evaluation for nystagmus is essential, as is some form of provocative testing. If the dizziness appears to be more disequilibrium, a search for cerebellar and proprioceptive dysfunction is the focus of the examination. Given that there is some variation and ambiguity in patient descriptions, a standard battery of screening tests should be performed on most patients in an attempt to clarify or confirm historical suspicions.

Nystagmus is a jerking eye movement that represents an external observation of a disproportional stimulus from the labyrinths. There are usually fast and slow components to this jerking eye movement. Generally, when there is a normal amount of vestibular neural output in one ear, the pathologic ear with decreased output will be the side of slow beating. It is important to recognize that some degree of end-range nystagmus is possible, especially in individuals with poor vision. Observation of nystagmus is possible visually and electrically. Electronystagmography (ENG) is a helpful adjunct to the more gross visual observation used in most offices. ENG may also detect peripheral and cerebellar

nystagmus that has been hidden by gross observation because of the patient's ability to incorporate optic fixation reflexes. This is accomplished with special lenses or with the eyes closed. Gross observation can be passive, looking for spontaneous nystagmus without head movement, or active, using provocative maneuvers to elicit nystagmus. Assisting gross observation is the use of Frenzel lenses. These lenses are used to abolish the patient's ability to fixate visually on an object and have the added benefit of magnifying the patient's eyes. Generally, nystagmus accompanies a sensation of spinning. When there is no vertigo but nystagmus is present, a central neurologic cause should be suspected and a neurologic consultation should be sought.

The type of nystagmus may be helpful in distinguishing between peripheral and central causes. In general, the following statements can be made:

- A peripheral cause is suggested if the nystagmus is horizontal or horizontal-rotational, decreased by visual fixation, increased with gaze toward the fast phase of nystagmus, occurring in one direction yet bilateral, associated with position change, and associated with moderate to severe vertigo.
- A central cause is suggested if the nystagmus is variable, being often vertical, unaffected by visual fixation, present with the eyes open or closed, and associated with constant, mild vertigo.

Provocative testing can be positional or with the introduction of water into the ear—caloric testing. Caloric testing is cumbersome and is considered relatively insensitive for detecting inner ear causes.<sup>28</sup> Most chiropractors do not perform caloric testing, so the focus will be on positional, provocative maneuvers. The classic positional test is to begin with the patient in a seated or supine position and quickly place the patient in the opposite

position. The Nylen-Bárány (also called the Bárány, Hallpike, or Dix-Hallpike maneuver) test starts with the patient seated, head turned 45° to the involved side, and quickly brings the patient into a supine position with the head tilted to the side of involvement and slightly extended (**Figure 18-1**). The responses that are monitored are as follows:

- Latency—a few seconds of latency are indicative of benign positional vertigo due to delay in crystalline movement and causing stimulation.
- Severity of dizziness—peripheral causes generally produce more severe dizziness.

**Figure 18-1** Nylen-Bárány maneuver.

- Direction of nystagmus—most peripheral nystagmus is rotational or horizontal; central causes often produce a vertical nystagmus.
- Adaptation and fatigue—if the nystagmus decreases after holding the position for 10 to 20 seconds or if the response to positioning decreases in severity with repeated attempts (dispersion of crystal particles), benign positional vertigo is suggested.

A simple in-office test of the horizontal vestibulo-ocular reflex is referred to as the head thrust test.<sup>29</sup> By prepositioning the patient's head 30° downward from neutral, the sensitivity of the head thrust test is increased. The patient's head is quickly turned from a neutral (forward facing) position observing whether the eyes are facing neutral. To perform the test, have the patient look straight ahead (i.e., at the examiner), head tilted 30° downward, then quickly rotate the head 10° to the left. The patient visually focuses on the examiner's nose. The examiner observes for corrective rapid eye movements (saccades), which indicate a decreased vestibular response. In other words, the eyes move with the head rather than remaining fixed to the visual target. If these "catch-up" saccades occur after a head thrust into one position but not the other, a vestibular lesion on the same is likely (e.g., eighth cranial nerve or root's entry into brainstem). Repeat on the right. Sensitivity and specificity are in the 80% range.

Testing for cervicogenic vertigo is performed with the rotating chair test. The examiner has the patient sit on a rotating chair. The first part of the test is to have the patient rotate his or her head from side to side several times to determine whether he or she becomes vertiginous. The examiner then stabilizes the patient's head while the patient rotates his or her body. Theoretically, the second maneuver eliminates direct semicircular canal participation yet allows stimulation of proprioceptors and the vestibular nuclei. It is suggested that vertigo reproduced with the head stationary and the body rotating indicates cervicogenic vertigo.

An attempt to differentiate vascular and other causes of dizziness may be made with a battery of tests. These tests are designed to detect vascular compromise via decreases in blood pressure or auscultation of bruits. If absent, a position of rotation and extension to each side is performed in an attempt to provoke signs of vertebrobasilar

insufficiency such as dizziness, nystagmus, or visual signs such as diplopia. Unfortunately, there is no clear evidence to support the use of these “screening” procedures.<sup>30</sup> They are considered insensitive and nonspecific.<sup>31</sup> Traditionally, chiropractors have used the maneuvers to protect the patient and also themselves (in the event of a post-manipulative vascular event). Yet there is disagreement as to whether this practice should be continued. It appears as though patients with dizziness provoked by extension or extension and rotation may in fact have other causes such as cervicogenic, benign positional vertigo, or a normal variant response. Brandt and Daroff<sup>32</sup> demonstrated that even healthy individuals may experience a to-and-fro vertigo and postural imbalance with head extension. Closing the eyes or standing on foam rubber augments this effect.

Patients who complain of imbalance or unsteadiness while standing or walking should be screened with proprioceptive testing. The main test is Romberg's. If the patient sways or loses balance only when standing with the eyes closed, a proprioceptive problem is the cause (i.e., a positive Romberg test). With the eyes open, visual input compensates. The Fukuda test is an extension of the Romberg test. The patient closes his or her eyes and walks in place. A positive response occurs when the patient rotates, usually to the side of the lesion.

Given spinal stenosis is so common in the senior patient, it is important to understand and test for signs of myelopathy. If the anterior cord is involved pain, pathological reflexes and/or hyperactive deep tendon reflexes or motor weakness may be evident whereas, if the posterior cord is involved, loss of dexterity, gait abnormalities, poor coordination, clumsiness, or sensory loss may be the dominant signs and symptoms. Overlap may occur so that headache, neck stiffness, shoulder pain, paresthesia in one or both arms or hands, or other radiculopathic signs may also be present.

For patients with myelopathy, the following tests have been found to be specific but not sensitive:

- Gait or Balance—Both abnormal gait (ataxia, wide-based gait, or spastic gait) and a positive static or dynamic Romberg sign
- Pathological Signs—Hoffmann's sign, Babinski's, and clonus
- Deep tendon reflex changes—Hyperreflexia

The inverted supinator sign is probably the most sensitive test. It is similar to the brachioradialis reflex test with the patient's forearm placed in slight pronation on the examiner's knee. The examiner delivers a few quick strikes with a percussion hammer near the radial styloid process. A pathological response is slight finger flexion or elbow extension.

Specialized testing options to clarify a diagnostic suspicion further include ENG, brainstem auditory-evoked response (BAER), duplex Doppler scanning, dynamic posturography, and magnetic resonance imaging (MRI). In general, ENG is used to objectify a suspicion of vestibular pathology; BAER is used to identify a central lesion. Using surface electrodes and the delivery of a series of clicks through headphones, the neural signal can be divided into five potentials. Latency between potentials identifies the side of potential lesion. For example, latencies between I and II indicate an acoustic nerve lesion; between I and V or III and V indicates a brainstem lesion. Duplex Doppler scanning is used to determine blood flow in extracranial (and intracranial with transcranial three-dimensional Doppler) vessels, dynamic posturography is used mainly as a research tool, and MRI is used to identify a brain tumor or multiple sclerosis.

# Management

- Refer to a medical doctor if systemic disease, drugs, or psychologic dysfunction is suspected as the cause.
- Refer for further evaluation if hearing or other neurologic deficits are found, a tumor or bacterial infection is suggested, or a perilymphatic fistula is suspected.
- Treat peripheral vertigo with chiropractic manipulative techniques, habituation exercises, and other appropriate conservative approaches.
- Refer if treatment is ineffective or dizziness creates significant functional impairment.

Given that the vast majority of dizziness complaints are benign, initial referral often is not necessary. Obviously, if a tumor, infection, hearing deficit, or drug interaction is suspected, referral is requisite. In the rare but serious event of vertebrobasilar ischemia, the most common symptom following the event is dizziness. Other symptoms/signs to consider include the five “Ds”—dizziness, diplopia, drop attacks, dysarthria, and dysphagia, and the three “Ns”—nystagmus, numbness, and nausea. Never readjust the patient if the patient complains of any of the above following an adjustment. See **Table 18-4** for a capsule summary of vertebrobasilar accidents. If the patient is vomiting and disabled by the dizziness, referral for medication seems appropriate, although comanagement is often possible. Most causes of vertigo are usually due to abnormality of the vestibular nerve or labyrinth. Of these, the most common cause of vertigo is benign positional vertigo.<sup>33, 34</sup> In patient populations of both post-whiplash and the elderly, benign positional vertigo is common. Acceleration/deceleration injuries, in addition to causing a

cervicogenic form of vertigo, may simulate Ménière's disease, or in some instances cause it.

## Cervicogenic Vertigo

A history of neck trauma, muscle spasm, and restricted cervical range of motion (ROM); negative tests for peripheral or central causes of vertigo; or positive findings on the chair rotation test suggest a cervicogenic cause of vertigo. Theoretically, joint dysfunction may produce reflex muscle spasm or alter input to the vestibular nuclei.<sup>35</sup> The chiropractic approach is to reduce muscle spasm and free restricted movement through manipulation, with possible adjunctive therapy such as electrical stimulation, deep heat, myofascial therapy, or traction. Some practitioners<sup>36, 37</sup> claim a high degree of success. Generally, the research<sup>38-40</sup> supports a possible positive effect with cervical adjusting alone or in combination with other approaches such as vertigo exercises or biofeedback.

There are several difficulties with the designation of cervicogenic vertigo. It appears that there is often an overlap between cervicogenic vertigo and other peripheral vestibular vertigos such as benign positional vertigo and Ménière's disease. Second, although it is called *vertigo* it appears that many patients feel more of a disequilibrium, where they are pulled to one side, although rotary vertigo is also reported.

## Benign Paroxysmal Positional Vertigo

There are several conservative approaches to BPPV. One approach is habituation exercises (**Exhibit 18-2**). These

exercises are designed to fatigue the response to the positional stimulation of vertigo. In one study<sup>41</sup> in which patients acquired the provoking position several times every three hours, the success rate was quite high and was achieved in 3 to 14 days. A more sophisticated approach, the Vestibular Habituation Therapy test battery, attempts to identify various body and head position changes to develop an individualized series of training exercises. One study<sup>42</sup> indicated a 70% to 80% success rate in six to eight weeks of treatment with this approach.

**Table 18-4** Vertebrobasilar Ischemia (VBI)/Accident Fact Sheet

<b>Type</b>	<b>Summary Information</b>
What is known about the ability to detect risk?	<ul style="list-style-type: none"> <li>• There is no age or gender predilection.</li> <li>• Risk factors such as smoking, hypertension, alcohol consumption, or others have not been firmly established.</li> <li>• Testing is insensitive to the patient most at risk and may result in false positives for those not at risk.</li> </ul>
How does VBI occur?	Trauma to arterial wall causing damage and/or vasospasm with the following possibilities: <ul style="list-style-type: none"> <li>• Subintimal hematoma</li> <li>• Intimal tear with or without emboli</li> <li>• Dissection with subintimal hematoma (stenosis)</li> <li>• Dissection with pseudo aneurysm development</li> <li>• Perivascular bleeding</li> </ul>
What are the most common presenting signs/symptoms of impending/existing VBI?	<ul style="list-style-type: none"> <li>• Severe neck or head pain was the most common presenting complaint (often described as different than any previously experienced).</li> <li>• Dizziness is the most common symptom of VBI.</li> </ul>
What are the possible risk factors for VBI?	<ul style="list-style-type: none"> <li>• Precursor lesions</li> <li>• Fibromuscular dysplasia</li> <li>• Medial cystic necrosis</li> <li>• Behçet's disease</li> </ul>

	<ul style="list-style-type: none"> <li>• Rheumatoid arthritis</li> <li>• Giant cell arteritis</li> <li>• Osteogenesis imperfecta</li> <li>• Ligamentous hypermobility (e.g., Ehlers-Danlos syndrome, Marfan syndrome, osteogenesis imperfecta)</li> </ul>
Is VBI testing, such as George's, sensitive or specific for VBI?	<ul style="list-style-type: none"> <li>• Standard in-office testing cannot detect arterial anomalies, or pathology that predisposes to VBI.</li> <li>• Cannot detect arterial structural damage that exists prior to treatment.</li> <li>• Tests cannot be used to predict whether damage or reflexogenic spasm will occur.</li> <li>• Cannot distinguish between proprioceptive "dizziness" versus vascular "dizziness."</li> </ul>
When do the signs of VBI appear with regard to occurrence?	<ul style="list-style-type: none"> <li>• Symptoms of VBI appear in the practitioner's office 69% of the time.</li> <li>• Another 9% within 1 hour.</li> <li>• Another 14% within 24 hours (92% within first 24 hours).</li> </ul>
What are the most common symptom/sign indicators of VBI?	<b>D</b> izziness, <b>d</b> rop attacks, <b>d</b> iplopia, <b>d</b> ysarthria <b>d</b> ysphagia, <b>n</b> ausea, <b>n</b> umbness, <b>n</b> ystagmus (the 5 Ds and 3 Ns)
What is the damage associated with VBI?	<ul style="list-style-type: none"> <li>• Wallenberg syndrome—occlusion of PICA</li> <li>• Locked-in syndrome—basilar artery occlusion</li> <li>• Other brainstem injuries</li> <li>• Occipital, cerebellar, or thalamic injury</li> </ul>
What is the prognosis for those patients who suffer VBI?	<ul style="list-style-type: none"> <li>• The reported rate of death from dissections of the carotid and vertebral arteries is less than 5%.</li> <li>• 90% of stenosis resolves eventually.</li> <li>• 66% of occlusions are recanalized.</li> <li>• 33% of aneurysms decrease in size.</li> <li>• Improvement occurs primarily in the first 2-3 months after the dissection.</li> </ul>
Are there specific adjustment techniques associated more with the occurrence?	<p>Mechanisms are reported in the literature and have varied descriptions that may be overlapping or misleading.</p> <ul style="list-style-type: none"> <li>• 60%—Rotation</li> <li>• 10%—Rotation with extension</li> <li>• 4%—Rotation with flexion and hyperextension</li> </ul>

## Exhibit 18-2 General Habituation Exercises

The patient is taken through a structured, progressive program in an attempt to increase balance, increase independent eye-from-head movement, fatigue

the peripheral response of specific head positions, and increase confidence in moving in a poorly lighted area.

The exercises are performed first seated and progress to standing. The exercises are first performed slowly and progressively increased to rapid performance. Following is a general outline of some exercises:

- 1.** After determining the provocative head positions, have the patient either acquire the position and hold it for 30 seconds or repeatedly acquire the position several times until the sense of vertigo diminishes.
- 2.** The patient practices moving the eyes up and down and side to side with the head remaining stationary.
- 3.** Repeat the exercises while focusing on a finger held in front of the face.
- 4.** Bend over to pick up objects 20 to 30 times.
- 5.** Throw a ball from hand to hand while watching the ball (20 to 30 times).
- 6.** Walk across a room 10 times with eyes open.
- 7.** Walk across a room while turning the head slowly from side to side, attempting to focus on pictures or cards placed on the wall.
- 8.** Walk across a room 10 times with eyes closed.

Based on a theory of cupulolithiasis and canalolithiasis, therapeutic maneuvers have been designed to “reposition” debris in the canals in an attempt to decrease inadvertent stimulation. One theory is that debris gets stuck to the cupula, making it heavier and more responsive to head movement. This is referred to as cupulolithiasis. The canalolithiasis theory is similar; however, the debris supposedly is floating in the long arm of the posterior semicircular canal, influencing the flow of endolymph and causing a secondary movement effect on the cupula. When a patient is sitting, a congealing of crystals occurs at the most dependent section of the posterior semicircular canal. Moving the head back and to the side (in the plane of the posterior canal) allows the crystalline clot to have a plunger effect. Standard maneuvers have been developed with numerous variations employed. Several reports indicate a relatively high rate of success, often with a single treatment. The average rate of success is between 66% and 92%, depending on the type of maneuver used and the time frame in which it is measured.<sup>43, 44</sup> Some argue that,

because BPPV will resolve spontaneously in about one month in many cases, results measured after this time would not appear to be different from results with no treatment at all.<sup>45</sup> For the vertiginous patient, however, an earlier relief of symptoms is welcome. Two maneuvers are discussed below.

The modified Epley maneuver (**Figure 18-2**) attempts to move debris from the long arm of the posterior semicircular canal to the common crus.<sup>43</sup> The patient sits on the examination table with the head turned 45° toward the involved side. The examiner quickly lays the patient on his or her back, maintaining the head in 45° rotation. The patient is maintained in this position for 20 seconds, at which time the doctor rotates the patient's head to the opposite side over a 20-second period. Then the entire patient is rolled onto a side-lying position with the head turned 45° down (toward the floor) and left in the position for 20 seconds. With the head deviated toward the side that is not affected, the patient slowly sits up. Instructions are given following the maneuver to prevent otoconia movement. The use of a soft collar is a reminder not to quickly move the head, especially into neck extension.

The second approach is called the Semont maneuver (**Figure 18-3**). The attempt is to remove debris from the cupula (i.e., cupulolithiasis). The patient begins seated. The patient turns the head 45° away from the affected side. The patient is quickly brought down on his or her side, maintaining the previous head position. Vertigo is often experienced. The patient is maintained in this position for about four minutes, at which time he or she is quickly brought onto the opposite side, maintaining the same head position. If vertigo does not occur, move the patient's head through a few quick, short-arc ROM oscillations. After four minutes, the patient is brought back to the seated position slowly.

**Figure 18-2** Modified Epley maneuver.

Following either maneuver the patient should be given the following instructions:

- Wait 10 minutes before leaving the doctor's office; avoid sudden head movement; have another person drive you home.
- Sleep in a half-reclined (recumbent) position either in a recliner or propped up on pillows on the couch for the

following two to three days; avoid sudden movements; avoid sleeping on the “bad” side.

- Avoid movements that will reproduce the vertigo; especially avoid head extension maneuvers such as looking to the ceiling, looking up to shave your chin (men), extension positions at the hairdresser or dentist, sporting activities (especially aerobics, sit-ups, swimming).
- Try to move slowly into the provoking position after one week; if still dizzy see the doctor for habituation exercises.

## **Ménière's Disease**

The basic premise for management of Ménière's disease is that there is an imbalance in the production of endolymph. A recent study<sup>46</sup> suggests a dysfunction of antidiuretic hormone (ADH)-dependent control at the inner ear. Medical treatment has focused on the reduction of excess endolymph with the prescription of diuretics and salt-reduction diets. With this approach, approximately two-thirds of patients improve.

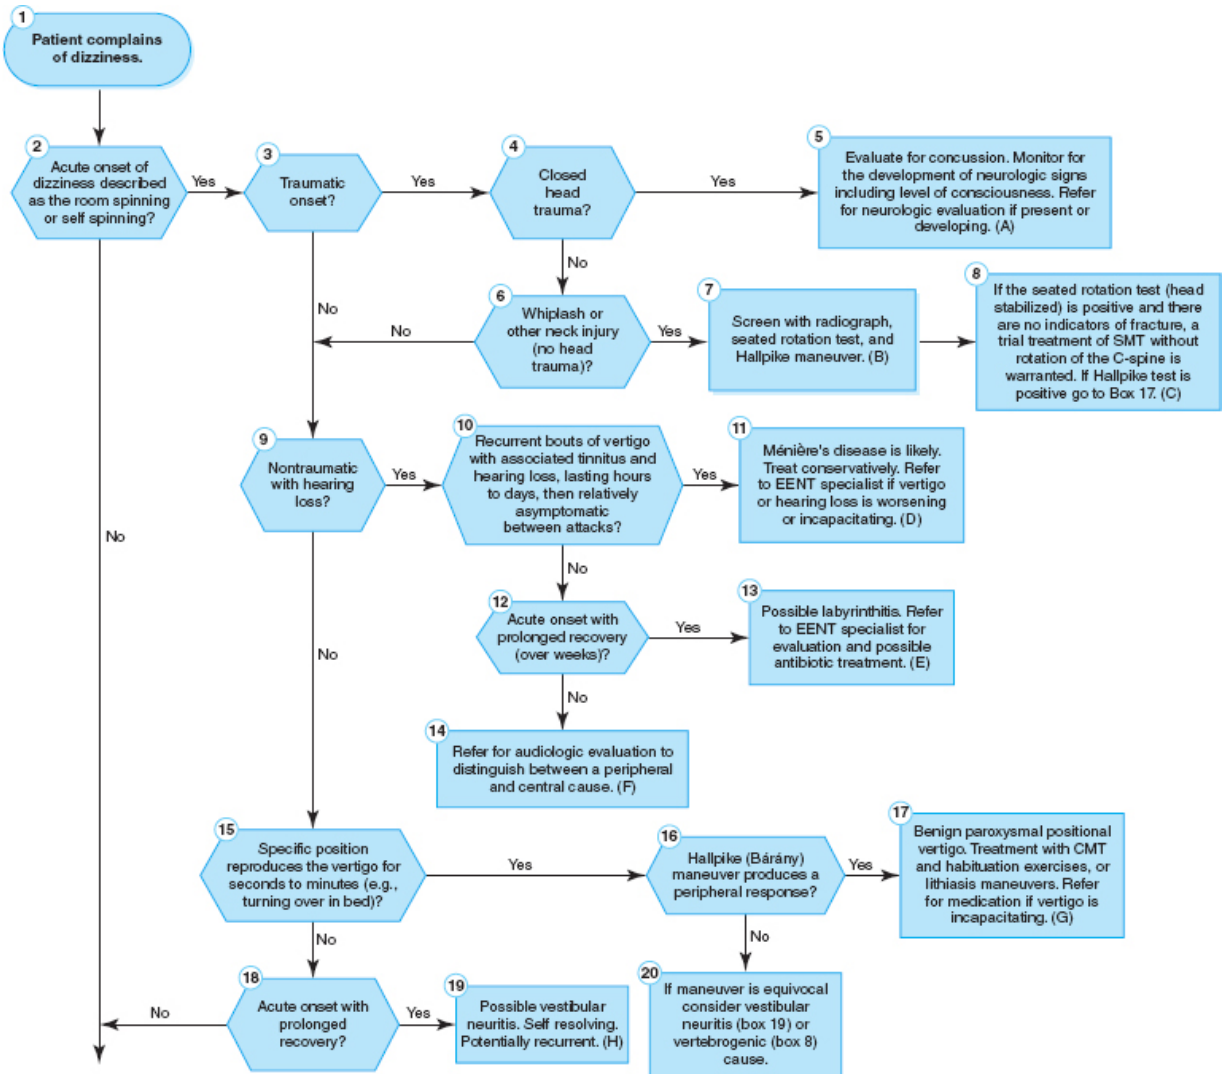

**Figure 18-3** Semont's maneuver.

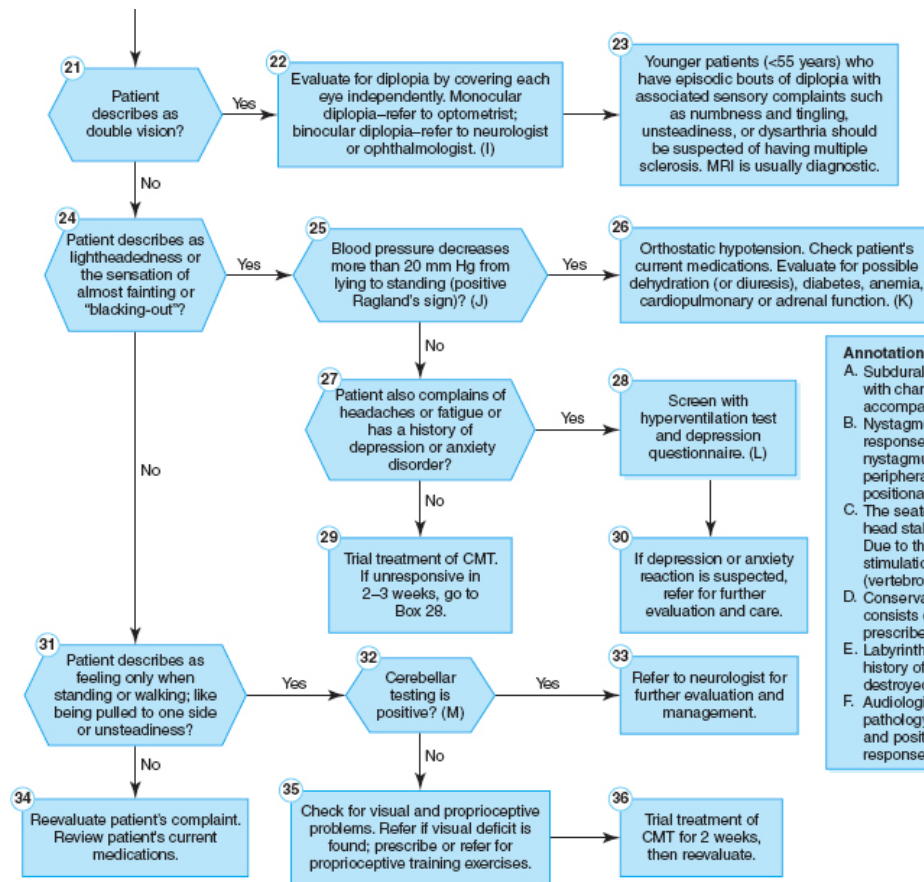

The natural course of Ménière's disease is gradually to "burn out" over months to years; however, the patient is often left with permanent hearing loss. Chiropractically, a course of nonmedical (herb) diuretic therapy coupled with a low-sodium diet may be helpful, combined with chiropractic manipulative therapy (CMT) for a short course to determine effectiveness. Some studies indicate the possibility of improvement with CMT.<sup>47</sup>

Medications used in the treatment of vertigo are usually one of several types, including antihistamines (meclizine, cyclizine), anticholinergics (scopolamine), and sedative/hypnotics (diazepam). These drugs are rarely needed except with severe attacks. It is worth mentioning that there is evidence that using these drugs in cases where there is vestibular disease decreases the ability of the CNS to compensate.

## Algorithm

An algorithm for evaluation and management of dizziness is presented in **Figure 18-4**.

#### Annotations

- A. Subdural hematoma may develop slowly over days with changes in mood, consciousness, or accompanying clumsiness or slurring of speech.
- B. Nystagmus/vertigo latency of a few seconds, response fatigues/adapts, horizontal/rotational nystagmus, and severe vertigo suggest a peripheral disorder; specifically benign paroxysmal positional vertigo.
- C. The seated test is performed with the patient's head stabilized while he or she rotates in a chair. Due to the vestibular apparatus being stationary, stimulation is assumed to be proprioceptive (vertebrogenic).
- D. Conservative treatment of Ménière's disease consists of a salt-restriction diet, diuretic (herbal or prescribed), and CMT.
- E. Labyrinthitis is usually associated with a prior history of otitis media or meningitis; the inner ear is destroyed in the bacterial form.
- F. Audiologic testing may show signs of a central pathology with decreased speech discrimination and positive tone decay. Brain stem auditory response testing is also used to localize pathology.

**Annotations (continued)**

- G. Habituation exercises require the patient to maintain the head in the provocative position or repeatedly acquire the position to fatigue the response. Lithiasis maneuvers attempt to reposition degenerative debris in the posterior semicircular canal.
- H. Vestibular neuritis is thought to be due to a viral infection. There is no associated hearing loss. Recovery may be assisted with proprioceptive or habituation types of exercise.
- I. Monocular diplopia suggests a refractive error or cataract (diplopia disappears when involved eye is covered; persists when uninvolved eye is covered). Binocular diplopia represents more often a neurologic cause such as extraocular muscle weakness due to tumor, diabetes, or myasthenia gravis (double vision disappears when either eye is covered; is present only when both eyes are open).
- J. The normal sympathetic response to standing is vasoconstriction of splanchnic vessels (in particular veins) to maintain cerebral blood pressure. A drop in blood pressure after standing for 2 minutes suggest orthostatic hypotension.
- K. Common drugs that may cause orthostatic hypotension include antihypertensives and antidepressants.
- L. Short depression questionnaires include the Beck Depression Inventory and the Zung Self-Rating Depression Scale. The hyperventilation test is performed with the patient supine. The patient is instructed to breathe deeply for 2 minutes as the examiner feigns auscultation. If the patient reports the same sense of dizziness, anxiety-related hyperventilation may be the cause.
- M. Cerebellar testing includes past-pointing, heel-to-shin, and quick repetitive pronation/supination of the hands. Direction of sway with Romberg's test may indicate the site of lesion in both labyrinth and cerebellar disorders. If swaying or loss of balance occurs only with the eyes closed, a proprioceptive problem peripherally or in the spinal cord (dorsal columns) should be investigated.

**Figure 18-4** Dizziness—Algorithm

# Selected Causes of Vertigo

## Benign Paroxysmal Positional Vertigo

### Classic Presentation

The patient reports episodes of vertigo that occur with certain head positions. The vertigo lasts for seconds to a couple of minutes. Common head positioning changes that precipitate attacks are head extension (“top shelf vertigo”) or rotation, bending over and straightening back up, or rolling over in bed.

### Cause

It is believed that BPPV is due to degenerative debris (otoconia) floating in the posterior semicircular canal. Either the debris sticks to the cupula, making it heavier and more responsive (cupulolithiasis), or the debris floats in the long arm of the canal, inappropriately causing endolymph to move the cupula (canalolithiasis).<sup>48</sup> Trauma and age appear to be important factors.<sup>49</sup> BPPV is the most common cause of vertigo.<sup>34</sup>

### Evaluation

In addition to the patient’s complaining of head positioning-specific onsets lasting for a few seconds, BPPV is also provoked by positioning maneuvers. The Hallpike (Nylen-Bárány) maneuver quickly positions the sitting patient into a supine posture with the head turned 45° to the same side.<sup>50</sup> A positive response is a small latency of a few seconds before vertigo and nystagmus begin. The vertigo is severe, and the nystagmus is usually horizontal-rotational to the same side. If the patient is left in the position or returned to the position several times, the vertigo fatigues.

### Management

There are two main approaches: habituation exercises and otoconia repositioning maneuvers. Single-treatment responses appear to be effective

(55% to 70%) when using a repositioning maneuver.<sup>43</sup> The intention of the maneuvers is to move the debris so that it no longer causes inappropriate stimulation. The two most commonly used methods are the modified Epley maneuver for canalithiasis and Semont maneuver for cupulolithiasis (see [Figures 18-2](#) and [18-3](#)). Habituation exercises take advantage of the fatigue and adaptation response of holding the head in the provocative position or repeatedly acquiring the provocative head position. In addition, exercises can be used to train independent eye movement and balance control. Rarely is medication or surgery considered a viable option.

## **Ménière's Disease**

### **Classic Presentation**

The patient complains of paroxysmal (sudden and recurrent) attacks of severe vertigo accompanied by low-tone hearing loss, low-tone tinnitus, and a sense of fullness in the ear. The episodes last for several hours to a day, with vertigo-free periods lasting for weeks or months. Hearing loss is progressive, while vertigo attacks appear to “burn out” over time. Some patients have sudden “drop” attacks without loss of consciousness.

### **Cause**

Distention from either overproduction or retention of endolymph appears to be the cause in most cases. Specifically, there appears to be a problem with the endolymphatic sac's (immune processing area) and/or duct's filtration and excretion function with a possible autoimmune etiology. An association between high levels of ADH and stress has been found in Ménière's patients.<sup>51</sup> Head trauma or previous infection may be factors. Pregnant females may be more prone to attacks. Ménière's disease is considered the fourth most common cause of vertigo.<sup>52</sup>

### **Evaluation**

Recurrent, sudden onset of vertigo with associated hearing loss or tinnitus is fairly diagnostic of Ménière's disease. Hearing loss is usually low tone, and the patient may also be found to have a positive recruitment phenomenon with sensitivity to loud sounds; a small increase in sound intensity is perceived as large. Both ears are affected in 30% to 50% of patients over time.<sup>53</sup> Patients who fit the vertigo pattern but do not have auditory dysfunction may have recurrent vestibulopathy. Some of these patients have basilar migraine while others progress to typical Ménière's disease.

## Management

The primary conservative approach is based on the theory that increased fluid causes distention and symptoms. Therefore, diuretic therapy (herbal or prescribed) in combination with a salt-restriction diet may be effective in managing the vertiginous component of Ménière's disease; however, there is some debate as to whether this is a natural history overlap of effect.<sup>54-56</sup> For a few patients, surgical intervention using decompression of the endolymphatic sac has been performed; however, a Cochrane review found little scientific support for its use.<sup>57</sup> Other approaches include transtympanic gentamicin, intratympanic steroid therapy, and, for intractable cases, vestibular nerve section,<sup>58</sup> although, in one study,<sup>59</sup> half of patients had residual subjective complaints but 85% were satisfied with their decision. The possibility of an overlap between Ménière's disease and cervicogenic vertigo warrants a treatment trial of cervical manipulation in patients with Ménière's disease.

## Vestibular Neuronitis (Neuritis)

### Classic Presentation

The patient complains of severe vertigo that occurred rather suddenly and lasted for days to weeks. There is often associated nausea and vomiting. The patient says that lying still may help. There is no associated hearing loss.

### Cause

The cause is unknown. However, it is postulated that there is a viral infection of the vestibular nerve because of the report of an antecedent respiratory infection in some patients.<sup>60</sup> Of patients with vestibular neuritis, 50% report having had a common cold.<sup>61</sup> There is an age-range peak at around 40 to 50 years of age. It is postulated that this disorder is a reactivation of a dormant herpes infection in the Scarpa's ganglion within the vestibular nerve. Involvement appears to be with the superior division of the vestibular nerve. The initial attack of severe vertigo, nausea, and disequilibrium generally lasts a few days. Although constant dizziness improves over days, rapid head movements will provoke vertigo and disequilibrium often for several weeks. Although often used interchangeably, labyrinthitis is usually reserved for involvement of both the vestibular and cochlear nerves. The primary differentials for vestibular neuritis are:

- Labyrinthitis, which is differentiated by also having hearing loss and often signs of bacterial infection (e.g., fever, chills, ear pain)
- Infarction or hemorrhage of the inferior cerebellum (25% of patients with risk factors for stroke who appear to the emergency department with

complaints of severe vertigo, nystagmus, and disequilibrium have an infarction of the cerebellum)<sup>62</sup>

## Evaluation

It is important to differentiate vestibular neuritis (peripheral) from cerebellar stroke (central). Nystagmus is made worse by looking in the direction of the unaffected side (Alexander's law) and is reduced by visual fixation with vestibular neuritis. Central nystagmus is not reduced by visual fixation and may change direction. There are often other neurologic signs and symptoms with cerebellar involvement such as dysarthria, ataxia, and difficulty with repeated supination/pronation or finger-to-nose testing and the patient's complaint is usually one of disequilibrium; not vertigo. Caloric testing demonstrates hyporesponsiveness or nonresponsiveness with vestibular neuritis.<sup>63</sup>

## Management

Central compensation occurs, and the condition resolves over time. Even when nystagmus is present, it is important to begin vestibular training with having the patient focus on a target with head movement in all directions, and eye-head coordination exercises. Helpful exercises are to have the patient focus on a target while moving the head up and down and side to side. Balance exercises are incorporated as soon as possible. Medication may be needed during the acute phase. Antihistamines such as meclizine or cyclizine or anticholinergics such as scopolamine are often prescribed. The most effective medications for suppression of vestibular symptoms are the benzodiazepines such as lorazepam (Ativan) or diazepam (Valium). However, their use should be restricted to those who are able to stay home. Sublingual benzodiazepines are a good first-line approach. The caveat for the use of any vestibular suppressants is that it delays central compensation so symptoms may last longer.

## Labyrinthitis

### Classic Presentation

The patient complains of an acute onset of vertigo with (bacterial) or without (viral) hearing loss. Although the vertigo may improve over a week, sudden head movements may provoke the vertigo for weeks.

## Cause

The distinction between labyrinthitis and vestibular neuritis is often not clear in the literature. One distinction is to call labyrinthitis that is bacterial, suppurative labyrinthitis. Another distinction is to call viral labyrinthitis serous. It is believed that either a viral or bacterial infection causes damage to the inner ear. Common viral causes include cytomegalovirus, mumps, varicella, or rubella. Common bacterial causes include *Streptococcus pneumoniae*, *Haemophilus influenza*, and *Neisseria meningitidis*. Bacterial infection may follow otitis media or meningitis, leading to complete destruction of the inner ear. Viral infection is less fulminant and may be reversible.<sup>64</sup>

## Evaluation

The findings are the same as for vestibular neuritis plus there is some hearing deficit. Otoscopic evaluation may reveal an otitis media.

## Management

Antibiotic therapy is beneficial with bacterial labyrinthitis. With viral causes, a tapered course of oral prednisone may be helpful, but results are varied. Physical therapy training for balance control may be utilized during the recovery period.

## Perilymphatic Fistula

## Classic Presentation

There is no classic presentation because the onset, intensity, and frequency vary. However, many patients have a history of barometric pressure changes, as with diving or air flight, or internal pressure development through intense weight lifting.<sup>65</sup>

## Cause

An opening develops between the middle and inner ear (oval or round window rupture), allowing leakage of perilymph. Perilymphatic fistulas are a rare cause of vertigo.

# Evaluation

Findings are variable; however, there is often a response to bearing down and provocation with pressure created by a pneumatic otoscope, which causes increased pressure in the ear.<sup>66</sup>

# Management

Surgical management is often corrective.

## Cervicogenic Vertigo

# Classic Presentation

The patient complains of vertigo that is associated with maintaining certain head positions (not acquiring the position). There may be associated complaints of neck or suboccipital pain. There appears to be a history of trauma (such as a whiplash injury) in about one-third of patients.

# Cause

It is believed that either overstimulation of upper cervical proprioceptors or degeneration of these proprioceptors or their pathways may cause an imbalance of information leading to a perception of vertigo or dysequilibrium.<sup>37</sup>

# Evaluation

Findings of upper cervical soft tissue involvement and restricted movements are possible. The Fitz-Ritson rotation test may help differentiate.<sup>33</sup> The examiner stabilizes the patient's head while the patient rotates his or her body in a chair. If the patient becomes dizzy, a vertebrogenic source is suggested because it is believed that vestibular stimulation is eliminated with this maneuver.

# Management

Chiropractic manipulation may be beneficial and should be applied as a treatment trial.<sup>67</sup> It is important to consider that because of the proprioceptive input of the upper cervical area, chiropractic manipulation may serve to benefit other causes of vertigo or that there may be an overlap between cervicogenic vertigo and other types.

## **Acoustic Neuroma**

### **Classic Presentation**

A patient in his or her 50s or 60s presents with a complaint of mild but constant hearing loss and dizziness sometimes with associated tinnitus. The onset is gradual and may be ignored initially. There are rarely acute attacks. Dizziness may be described as spinning but more often as off-balance.

#### **Cause**

A benign schwannoma of the vestibular nerve is called an acoustic neuroma. It is located in the cerebellopontine angle, where other cranial nerves are susceptible to compression. Most commonly this involves the facial nerve. As the tumor grows it may cause brainstem compression. Ninety-five percent of the time these are unilateral (bilateral may occur with neurofibromatosis). Associated risk factors may be smoking, pregnancy, and epilepsy.

### **Evaluation**

Unless the tumor is large and pressing on other cranial nerves, there are likely to be no additional clinical findings. Auditory testing may reveal poor speech discrimination. Hearing loss is sensorineural. Stacked auditory brainstem response (ABR) is 95% sensitive and 88% specific for lesions < 1 cm (standard ABR only for lesions > 1 cm). When the suspicion is high, an MRI should be ordered. It is the definitive diagnostic tool.

### **Management**

Age and growth rate need to be considered prior to a decision for surgical excision. Growth is about 5 mm in the first year of detection but less than 1 mm in the fourth year following detection.<sup>68</sup> Fifty-seven percent of neuromas shrink and 70% of extracanalicular lesions grow less than 2 cm per year.<sup>69,70</sup> Preservation of hearing is better with conservative management than with radiotherapy or surgery. A distinguishing factor is speech discrimination. Sixty-nine percent of patients with 100% speech discrimination on initial detection maintain their hearing 10 years after detection.<sup>71</sup> Options that are

nonconservative include gamma-knife single-dose stereotactic surgery and three standard surgical approaches including retromastoid/retrosigmoid, middle cranial fossa, and translabyrinthine that use microscopic approaches.

# CHAPTER 19

## Seizures

### Context

It is important to remember that not all seizures are epileptic<sup>1</sup> and not all epilepsy results in convulsive activity. Patients diagnosed as epileptic often are subject to restrictions (sports, driver's license, etc.) and biases. Therefore, it is incumbent on the evaluating doctor to make an effort to distinguish epilepsy from other causes of "seizures." Epileptic seizure activity may be benign or cause death through status epilepticus (an uninterrupted seizure) or cause the deaths of others if the patient is operating a car or other potentially lethal machinery. Those with true epilepsy often can be helped through medication or surgery.

Epilepsy and unprovoked seizures affect approximately 2.3 million Americans.<sup>2, 3</sup> Approximately 3% of individuals will have epilepsy during their lives. Although approximately 6% of adults will experience at least one afebrile seizure in their lifetime, only half of these adults will have recurring seizures (epilepsy).<sup>4, 5</sup> This must be considered prior to initiating medical management decisions. About 60% of childhood-onset epilepsy is due to birth and neonatal injuries, 15% to central nervous system (CNS) infections, and 12% to head trauma. With adult-onset epilepsy, 60% is due to CNS infarcts or hemorrhage, 10% to tumors, and 9% to CNS infections. Approximately 60% of seizures do not recur after one year, with 15% resolving some time later.

Unfortunately, 25% are intractable. There appears to be a higher incidence in black men and in the elderly. Most of the black male occurrence is in middle-aged groups, possibly reflecting consequences of trauma or cerebrovascular disease.<sup>6</sup> Tumor accounts for the majority of seizures in patients between ages 25 and 64 years.<sup>7</sup> Other causes include cysts and vascular malformations. In the over-65-years age group, stroke, cardiovascular disease, tumor, and Alzheimer's disease are the main causes of seizures. Twenty-four percent of epileptic patients are elderly, with 38% of new cases occurring in the elderly (with stroke accounting for one-third of cases).<sup>8</sup> If an adult has a seizure following moderate to severe head trauma, he or she is likely to develop epilepsy. Most will develop seizures within two years of the incident. Fortunately, about one-half will experience only a single seizure, 25% will have two to three future seizures, and the remaining 25% will have multiple seizures.

The incidence of a single, nonepileptic (nonrecurrent), unprovoked convulsive episode in children appears to be between 0.5% and 1%.<sup>9</sup> Most occur within the first year of life. Twenty percent of epileptic cases develop before age 5 years; 50% develop before age 25 years. Absence epilepsy (petit mal) accounts for 10% to 15% of childhood epilepsy, myoclonic epilepsy for 5%, and idiopathic localization-related epilepsy for 10%.

If a patient has a family history, the chance of a second seizure within the next two years is 35%. Even without a family history, the chance of a second seizure within the following 24 hours of a first seizure is about 15%.<sup>10</sup> These important facts must be kept in mind by the chiropractor, who with the best of intentions is trying to save the patient from the potential side effects of medication.

The direct and indirect costs for epilepsy in the United States were estimated at \$3.6 billion in 1975.<sup>11</sup> The total cost to the nation in 1995 was estimated at \$12.5 billion.<sup>3</sup>

The impact on individuals with regard to educational achievement, employment, and psychological stresses is significant and sometimes insurmountable.

Patients do not often present to chiropractic offices with a complaint of seizures. However, there is the occasional patient who has anecdotally heard of or spoken to someone with seizures who felt that he or she had been helped by chiropractic care. Such patients usually are unhappy with the side effects of medication or are not completely controlled by their medication. They present as “last hope” patients. Although the author has heard from colleagues of resolution of seizures with chiropractic care, there are unfortunately few case studies and no large studies to help support the anecdotal “miracle” cures. One of the difficulties with interpretation of therapeutic effect is that the outcome measure has been eliminated. In other words, if the outcome measure is a reduction or elimination of seizure activity, the patient on medication is often well-controlled, eliminating the outcome to be measured. It is to be hoped that, within the next few years, those chiropractors who feel that they have had an effect will join together in publication to help generate interest in larger studies.

The context of a seizure patient’s entering a chiropractic setting is fraught with difficulty. Often the patient is being controlled by medication and is dissatisfied with the drug’s effect on his or her general sense of well-being. The chiropractor is in the position of not being able to withdraw medication gradually to determine a therapeutic effect with manipulation. If a sudden withdrawal does occur, there is a strong risk of a rebound effect with an increased severity or frequency of attacks, including status epilepticus. It is imperative that the patient understand that any changes in medication are dictated only through consultation with the prescribing physician. Neither the patient nor the chiropractor should attempt withdrawal or reduction of seizure medication.

Realistically, the chiropractor may be especially helpful if he or she is at the scene of an epileptic occurrence. With his or her knowledge of different seizure types, the chiropractor may assist in management of an acute seizure. A list of “do’s and don’ts,” as recommended by the Epilepsy Foundation of America, is given in **Table 19-1**.

**Table 19-1** Seizure Recognition and First Aid

Type of Seizure	Symptoms	First Aid	Don'ts
Tonic/clonic (grand mal)	Sudden cry, fall, rigidity (grand mal) Followed by muscle jerks, shallow breathing, bluish skin, possible loss of bladder or bowel control Usually lasts a couple of minutes Person may be confused and/or fatigued, followed by return to full consciousness	Look for medical identification Protect from nearby hazards Loosen tie or shirt collar Protect head from injury Turn on side to keep airway clear Reassure when consciousness returns If brief, single seizure, ask if hospital evaluation desired If multiple seizures or if one seizure lasts longer than 5 minutes, call an ambulance If person is pregnant, injured, or diabetic, call for aid at once	Don't put any hard implement in the mouth. Don't try to hold tongue; it can't be swallowed. Don't try to give liquids during or just after a seizure. Don't use artificial respiration unless breathing is absent after muscle jerks subside, or unless water has been inhaled. Don't restrain.
Single partial	Jerking may begin in one area of body, arm, leg, or face Patient stays awake and is aware Jerking may proceed from one area of the body to another, sometimes becoming a convulsive seizure May not be obvious to an onlooker Patient experiences a disturbed environment	No first aid necessary unless seizure becomes convulsive, then first aid as above No immediate action needed other than reassurance and emotional support Medical evaluation recommended	
Complex partial	Often starts with blank stare Followed by chewing, then random activity Person appears unaware of surroundings, dazed, mumbling Actions clumsy, not directed May run, appear afraid, and struggle or flail at restraint Lasts a few minutes, but postseizure confusion can last substantially longer	Speak calmly and reassuringly to patient and others Guide gently away from obvious hazards Stay with person until completely aware of environment Offer to help getting home	Don't grab unless sudden danger (such as cliff edge or approaching car) threatens. Don't try to restrain. Don't shout. Don't expect verbal instructions to be obeyed.

## General Strategy

Look for causes other than epilepsy (**Exhibit 19-1**):

- Determine whether the patient lost consciousness or whether there was convulsive activity of a body part without loss of consciousness—nonepileptic causes often result in loss of consciousness due to hypoxia with associated convulsive activity.
- Determine whether the patient was given information from any witnesses detailing the length of time that he or she was unconscious or length of any convulsive activity.

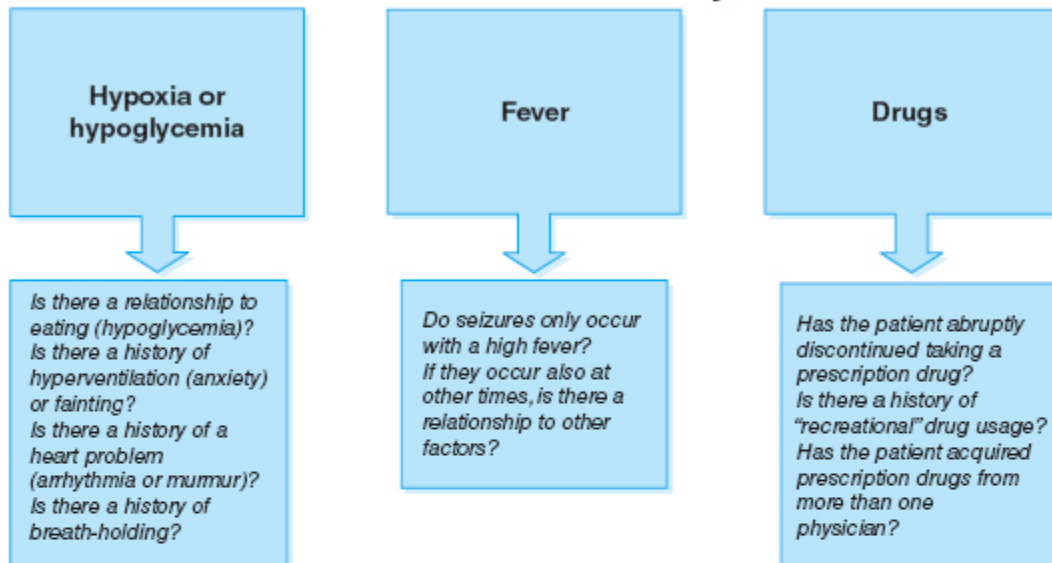

### **Exhibit 19-1 Differentiating between Epilepsy and Other Causes of Symptoms**

Patient presents with a history of a “seizure.”

Differentiate between epilepsy and other causes of convulsive activity.

Differentiate among known causes of epilepsy.

1. Vascular (includes arteriovenous malformation, aneurysm, hemorrhage)
2. Tumor
3. Head trauma
4. Metabolic

If the patient has associated neurologic symptoms such as headache, dizziness, change in personality, changes in level of consciousness, or obvious neurologic deficits such as paralysis, weakness, or persistent numbness and tingling, an organic brain lesion is likely. Are there triggers that the patient can identify, such as use of a computer, watching a fan, specific sounds or smells, etc.?

Differentiation requires a thorough neurologic examination. Referral to a neurologist should result in an EEG, CT, or MRI evaluation, and possibly an angiogram.

- Determine whether the patient had any pre- or postictal signs or symptoms.
- Determine the position and environment that the patient was in and whether these are consistent with

any previous episodes.

- In an infant or child, determine whether there was an associated fever.
- Always determine the patient's use of medications and alcohol, and any sudden stopping of the medication regimen.
- Is there any history of toxic exposure (specifically, lead intoxication in children)?
- Is the patient diabetic?

If epilepsy is suspected, attempt to determine the cause and any triggers.

- Is there a family history? There may be a genetic predisposition (especially with generalized absence seizures or febrile seizures).
- Did the seizures begin before age 2 years? Ask about birth trauma and metabolic causes. Specifically determine whether there is a history of cerebral palsy, mental retardation, tumors/cysts, or hydrocephalus (all are often associated with epileptic seizure activity).
- Did the seizure activity begin between ages 2 and 20 years? Idiopathic epilepsy is likely.
- Did the seizures begin later than age 30 years? If yes, consider tumor; if over age 60, consider a vascular event or Alzheimer's.
- Is there a recent or past history of head trauma?
- What accompanies the seizure? Any auras? Any automatisms (i.e., purposeless repetitive movements such as scratching)? Any postictal findings such as extreme tiredness, headaches, or incontinence during the attacks?

Determine whether further testing is necessary.

- If a nonepileptic cause is suggested, lab testing may be necessary.
- For a firm diagnosis of epilepsy, an electroencephalogram (EEG) is necessary; often several 24-hour EEGs are needed using provocation such as strobe light stimulation or hyperventilation.
- If a tumor is suspected, refer for neurologic consultation, which is likely to include magnetic resonance imaging (MRI).

## Definitions and Classifications

Specifically, an epileptic seizure is an event characterized by excessive electrical discharge due to a hyperexcitable group of neurons. The diagnosis of epilepsy is reserved for a recurrent history of such attacks. A seizure, however, is any attack of cerebral origin regardless of the cause. It becomes clear, then, how difficult it is to use these terms discriminately. Convulsions are involuntary contractions of muscles. They may be the result of epilepsy or a host of other causes. Convulsions do not always occur with epilepsy. Unfortunately, a patient could easily be mislabeled without a search for other causes.

Epilepsy that is inherited, without a known cause, is termed idiopathic. When associated with a suspected disorder or lesion, epilepsy is labeled symptomatic. Cryptogenic epilepsy refers to seizures that are secondary to a disorder or lesion, but whose cause is unknown. The most common classification system used is that proposed by the International League Against Epilepsy (ILAE).<sup>12</sup> This revised classification system is complex; however, there are some general points that would be useful to the nonspecialist. There are generally two classifications of epileptic seizures (see **Table 19-2**):

1. Generalized—simultaneous involvement of all or large parts of both cerebral hemispheres. Generalized seizures are often metabolic in origin.
2. Localization-related, also known as partial seizures—initiated in a discrete cortical site accompanied by related focal EEG and clinical manifestations. Partial seizures are the most common seizure disorder in adults, usually due to small, focal lesions such as scars or pressure effects from head trauma, strokes, and tumors. These seizures are further divided into simple partial seizures, in which consciousness is unimpaired, and complex partial seizures, in which consciousness is impaired. Complex partial seizures (psychomotor or temporal lobe epilepsy) account for 40% of all epilepsies.

Epilepsy is often classified based on clinical features such as complex partial seizures and generalized tonicclonic seizures. Given that these are more syndromes than specific types of seizures, another classification scheme is based on type of seizure, the association or lack thereof of neurological or developmental abnormalities, and electroencephalogram (EEG) findings.

**Table 19-2** Specific Aspects of Some Selected Types of Epilepsy

<b>Classification</b>	<b>Clinical Features</b>	<b>Possible Mechanism/Cause</b>
<b>Generalized</b>	Begins between age 4–8 years, but may occur as late as age 20 years. Rapid onset. Often	It is now believed that the mechanism is an abnormal circuit that causes rhythmic activation of the cortex (same as

Absence epilepsy (petit mal)	after relaxing following physical or mental activity individuals stare, stopping other activity for up to about 10 to 30 seconds, then return to normal without memory of the event. This may occur tens or hundreds of times/day. May be confused with daydreaming or attention deficit disorder. The classic EEG pattern is three/second, generalized spike-waves. Seizures are provoked by hyperventilation in most individuals.	non-REM sleep), a thalamocortical circuit dysfunction. The reason for this dysfunction is not known. Theories include problems with T-type calcium channels, GABA receptor dysfunction, or brainstem modulation problems. Each may be targeted by specific medications, such as ethosuximide and valproic acid for T-type calcium channel blockade, or benzodiazepines inhibiting GABA receptors.
Generalized epilepsy with febrile seizures plus	A genetic (autosomal dominant with incomplete penetrance) disorder that results in febrile seizures plus one other type, such as absence, myoclonic, atonic, or tonic-clonic.	A mutation in the gene for voltage-gated sodium channel $\beta 1$ subunit (SCN1B) associated with chromosome 19q. Leads to hyperexcitability of cortical neurons.
Benign familial neonatal convulsions	Autosomal dominant, single-gene mutation syndrome. Seizures begin within a few days of birth and	Mutations in genes for potassium channels on chromosomes 20q and 8q, resulting in prolonged depolarizations that increase neuronal hyperexcitability.

	resolve in a few weeks with or without treatment. There are no associated neurological or metabolic abnormalities.	
Primary generalized tonic-clonic seizures (grand mal)	<p>Loss of consciousness either without warning or preceded by myoclonic jerks. There is first stiffening (tonic stage) for about one minute followed by clonic jerks (i.e., convulsions involving all four limbs) that may last on average 1-3 minutes. Individual is slow to recover with possible tongue biting or incontinence during the seizure. Individuals are disoriented and recover slowly. Sometimes individuals are combative. Routine EEG (no seizure) reveals spike-wave patterns at 3-5 Hz.</p>	Complex inheritance patterns.
<b>Partial</b>	Consciousness is not impaired. Signs and symptoms are	Lesions or pressure cause altered neuronal function. This may include scarring from infection, vascular

Simple partial seizures (focal)	motor, sensory, autonomic, or psychic, indicating seizure generation area. When motor-dominant and spreading down a limb, referred to as a Jacksonian seizure. When this persists as weakness or paralysis that lasts hours to days, it is referred to as Todd's paralysis. Routine EEG (no seizure) reveals focal slowing and/or sharp-wave activity.	malformations, tumor, and trauma.
Complex partial seizures such as medial temporal-lobe epilepsy or psychomotor	Seizures usually begin with olfactory or gustatory hallucinations and epigastric rising sensations, or psychic symptoms such as déjà vu. If the seizures progress to a disconnection with the environment, the individual may stare blankly, speak incoherently, or exhibit automatisms such as lip smacking, or picking at clothing. Routine EEG (no seizure) reveals focal slowing and/or	The most common lesion found is hippocampal sclerosis. There is some debate as to whether this is the cause or an effect of seizures.

	sharp-wave activity.	
Secondary generalized partial seizures (tonicclonic or grand mal)	<p>Same as primary except preceded by motor, sensory, autonomic, or psychic signs and symptoms, indicating seizure generation area. Then there is a loss of consciousness either without warning or preceded by myoclonic jerks. Tonic increase in muscle tone followed by clonic jerks that may last on average 1-3 minutes. Individual is slow to recover with possible tongue biting or incontinence during the seizure. Individuals are disoriented and recover slowly. Sometimes individuals are combative. Routine EEG (no seizure) reveals focal slowing and/or sharp-wave activity.</p>	

When epilepsy results in loss of consciousness, there are two defined phases. The seizure itself is termed the *ictal*

*phase*. The time following the seizure is referred to as the *postictal phase*.

Hallucinatory visual, auditory, olfactory, or other sensory aberrations are common. When they occur preceding loss of consciousness and last a few seconds, they are referred to as an aura. When they last longer than a few seconds, they are classified as a complex partial seizure. Additional signs of a complex partial seizure are referred to as automatisms. These include repetitive activity such as scratching an area of skin, lip smacking, or any repetitive movement.

Status epilepticus is a prolonged seizure that lasts longer than 30 minutes and may lead to death if not interrupted by medical intervention. The risk for permanent injury increases when the seizure lasts longer than five minutes. In children, about one-third who suffer from an episode of status epilepticus will have permanent neurologic damage (i.e., hemiparesis, microcephaly, mental retardation).<sup>13</sup>

## **Relevant Anatomy and Physiology**

A seizure involves a sudden, abnormal electrical discharge in the brain. The normal asynchronous interaction of the cortical neurons suddenly becomes synchronous. Although the etiology of seizure activity is often unclear with epilepsy, generally it can be said that a decrease in either oxygen or glucose, an imbalance in electrolytes, or generalized toxic events may lead to a seizure episode. Other causes are direct damage through pressure or scarring of an area of the brain. Pressure is often due to either a tumor or vascular event, whereas scarring is often due to infection. The result is a dysfunctional cortical area that is, in many instances, hyperexcitable. With infection or trauma, it is not uncommon for the seizure to occur six months to as much

as several years later, after scar tissue has formed. During a seizure, electrical impulses increase. For example, impulses of 80 per second are suddenly increased to 500 per second. In addition, this increased activity is uncoordinated. The resulting seizure activity is dependent on the specific area affected. Therefore, an epileptic “seizure” runs the gamut of emotional, motor, and sensory manifestations with and without loss of consciousness.

## **New Models of Epilepsy**

Some new theories of partial epilepsy are:<sup>14</sup>

- *Neurogenesis*: Based on animal models, it appears that seizures can trigger increased mitotic activity in the dentate gyrus (specific to temporal lobe epilepsy), increasing differentiation and creation of new dentate granule cells.
- *Mossy-fiber sprouting*: Found with temporal lobe epilepsy, these extend to pyramidal neurons as part of the hippocampal output pathway.
- *Cortical malformations*: These may be involved with partial or generalized epilepsy. Theory is based on a disruption of development in the cerebral cortex classified as disorders of neuronal proliferation, neuronal migration, or disruption or reorganization of the cortex. These may be involved more with refractory epilepsy and specifically in cases once believed to be cryptogenic. Neurons within dysplastic areas may lack potassium channels or GABA-mediated inhibitory mechanisms.
- *Glial cell*: Glial cells, although primarily supportive, also serve functions of buffering that help maintain uptake of potassium and glutamate (among other metabolic balances). The result may be increased levels of

extracellular potassium, decreasing the threshold for neuronal firing (hyperexcitability).

## Evaluation

# History

There appears to be an age-related association to epilepsy. The following list is based on age:

- Infancy-childhood: developmental, infection, trauma, cerebrovascular disease (CVD)
- Adult: brain tumor, trauma, developmental disorder, infection, CVD
- Late adulthood-elderly: CVD, brain tumor, degenerative disease, trauma

Important aspects of the history that might suggest a nonepileptic form of seizure include the following (**Table 19-3**):

- Loss of consciousness that was brief, with no postictal complaints
- No aura prior to loss of consciousness
- History of arrhythmias, diabetes, use of antidepressants and other medications, use of recreational drugs, psychologic problems, or possible electrolyte imbalance

**Table 19-3** History Questions for Seizures

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Did you lose consciousness?	Epilepsy, hypoxia, head trauma, syncope	Were you out for less than a minute? Did you hit your head? Did you feel any unusual feelings before passing out? How did you feel after regaining consciousness? Were you out longer than a couple of minutes? Were there any witnesses? Any history of irregular heart rhythm or do you feel any chest symptoms? (For a child) Did the child hold breath before passing out?	Syncope. Seizure due to hypoxia. Posttraumatic seizure or subdural/epidural hematoma. Warrants neurologic referral. An epigastric sensation or confusion would suggest epilepsy; lightheadedness suggests syncope. Extreme fatigue, soreness, headache, incontinence, tongue bleeding suggest grand mal seizure. Epileptic attack usually lasts 3–5 minutes. Describe sequence; especially how the person fell; any automatisms. Arrhythmia may cause LOC with convulsions due to hypoxia. Breath-holding is possible with children when they are angry.
Are you taking medications?	Side effect, withdrawal symptom.	Have you had a recent change in your prescription? Have you recently stopped taking the medication? Do you use recreational drugs or alcohol? How much?	Check Physicians' Desk Reference for side effect of medication. Antiseizure medication will often cause seizures when abruptly stopped. If abuse is suggested, refer to a counseling or specialized center.
(For infants or children) Did this occur with a high fever?	Febrile seizures.	Do they occur only with fever or at other times?	Febrile seizures usually do not indicate progression to epilepsy.
Is there a family history?	Epilepsy, inherited metabolic problems.	Any known metabolic disorders?	These usually occur in infancy. If epilepsy, chance of more seizures is increased.
Did this occur while you were conscious?	Partial epileptic seizures.	Did the seizure happen in your arm/leg?	Especially if it moves slowly up the arm it is suggestive of partial seizure.

Key: LOC: loss of consciousness.

There are generally two history findings that confuse the distinction between epileptic and nonepileptic seizures: (1) loss of consciousness (LOC), and/or (2) convulsions. Obtaining an eyewitness account and the patient's recollection of presyncope and postsyncope events goes a long way in differentiating between epilepsy and other causes. If LOC occurred upon standing, after prolonged standing (especially in a hot environment), or after feeling lightheaded and nauseated, the cause is less likely to be epilepsy. If the patient collapsed as opposed to falling stiffly when passing out, the cause again is less likely to be

epileptic. Finally, if the patient did not experience significant ictal or postsyncopal signs or symptoms such as tongue biting, urinary or fecal incontinence, extreme fatigue, headache, or persistent achiness, the cause probably is not epileptic. Movement disorders such as shuddering attacks, nonepileptic myoclonus, tics and spasms, and paroxysmal choreoathetosis may be mistaken for epilepsy. Betts<sup>1</sup> feels that as many as 20% of patients referred to specialist centers for intractable epilepsy have nonepileptic seizures.

Febrile seizures are alarming to parents. However, only about 1% of cases proceed to tonic-clonic seizures, and only 5% of children will have status epilepticus.<sup>15</sup> Although the cause may be direct, such as with meningitis, most seizures are benign and do not indicate a propensity for future epilepsy or other neurologic dysfunction.<sup>16</sup> A family history is often found. With generalized absence seizures a family history is also found, often suggesting an inherited tendency toward a low-seizure threshold reaction to physiologic stresses such as sleep deprivation, fever, psychic stress, and repetitive stimulation (e.g., light flashes/photosensitivity).<sup>17</sup> One study<sup>18</sup> of inducing factors found that in adolescents common triggers were fatigue after exercise (15.2%), sleep disturbance (9.1%), and psychic stress and emotional change (15.1%).

The following are important facts about seizures and related causes or triggers:

- One rare but significant cause of seizure activity is an arrhythmia such as ventricular tachycardia of the torsades de pointes type. It is identified on an electrocardiogram as a P/long or prolonged QT interval (idiopathic QT syndrome).<sup>19</sup>
- Although antidepressants (and other drugs) have been targeted as causes of seizures, the rate is only 0.3% to 0.6%.<sup>20</sup> Predictive risk factors include a previous

history of seizures, alcohol or sedative withdrawal, or multiple drug usages.

- One of the causes of nonepileptic seizures is a response to sexual abuse in childhood.<sup>21</sup> Two reactions have been studied. One is referred to as a “swoon,” considered a cutoff reaction. The other is referred to as an abreactive type that may represent an acting out of the memory of abuse.
- Although video games have been accused of increasing the occurrence of epileptic seizures, one study<sup>22</sup> indicates that the risk is no greater than that for the general population.
- Seizures that are likely to be epileptic are those that are recurrent and often stereotypic for that patient.
- Recent evidence<sup>23</sup> suggests a relationship between migraine headache and epilepsy. Migraine is particularly prevalent in patients with centrottemporal epilepsy (63%; rolandic epilepsy). In patients with absence seizures, 33% had migraine, 7% had partial epilepsy, and 9% had a history of cranial trauma.<sup>24</sup>

## Examination

The examination of a seizure patient should focus on nonepileptic causes first. This would include a cardiovascular examination, including blood pressure after lying down for three minutes and then standing (check for orthostatic hypotension), auscultation for any obvious chronic lung or heart abnormalities, and a thorough neurologic evaluation to determine any underlying neurologic disease. Further evaluation would include laboratory testing to determine the possibility of a metabolic association. Electrolyte, glucose, and blood cell evaluation should be used as an initial screen. Further evaluation is warranted when a specific metabolic disorder is suggested;

this evaluation is best performed by the medical specialist. More and more, a reaction to use of or discontinuation of illicit drugs and alcohol is found, especially in the adolescent, young, and middle-aged adult in whom no other obvious cause has been found. Laboratory evaluation is often helpful. When pseudoseizures are suspected (due often to psychologic factors), a postictal prolactin estimation may help clarify whether a “true” seizure has occurred. After a major tonic-clonic seizure, there is usually a significant rise in serum prolactin levels.<sup>25</sup> This is not as noteworthy with partial seizures. If a baseline can be established and a subsequent level taken postseizure, an elevated level would be more suggestive of a true seizure.

The primary diagnostic tool in evaluating seizures is EEG. EEG coupled with clinical findings is likely to distinguish between generalized and localization-related (partial) seizures. Epileptiform EEG patterns (spikes and sharp waves) are characteristic of epileptic seizures. Although only 29% to 50% of patients with epilepsy show abnormalities on the first EEG, multiple testing yields abnormal findings in 59% to 92% of patients. This is increased with the use of provocative techniques such as hyperventilation or strobe light stimulation. Also sleep EEG and sleep deprivation-induced procedures are sometimes employed. Indications for the site of a source of initial seizure activity are sometimes represented by focal slowing in the form of delta waves indicating the presence of a mass or lesion. Another indicator is what is referred to as phase reversal between two adjacent electrodes, which helps localize specifically where the initiating ictal focus is originating from, again suggesting a mass or lesion.

When structural brain disorders are suspected (often based on the finding of localization-related seizures), MRI and other specialized imaging procedures may be helpful. MRI is usually more sensitive than computed tomography (CT) scan in uncovering cerebral lesions as causes of

epilepsy.<sup>26</sup> Positron emission tomography (PET) may demonstrate abnormalities in about 70% of patients with temporal lobe epilepsy.<sup>27</sup> However, its use is probably more valuable for research purposes because it is generally unavailable and does not provide information beyond that gained from other imaging techniques.

## Management

If the patient is having a seizure, based on a knowledge of the most common seizure types, quickly determine intervention needs based on recommendations from the Epilepsy Foundation of America (see [Table 19-1](#)).

If the patient is not having a seizure but has had a past diagnosis of epilepsy, review the history to determine whether the patient has had a full evaluation to differentiate between nonepileptic and epileptic seizures. If the patient has had a recent episode that has not been evaluated prior to presentation in your office, obtain a thorough history to determine any indicators of seizure type and refer the patient with your recommendations. If the patient wants chiropractic care, it is important to comanage the case with the prescribing physician to avoid patient misinterpretation and resultant changes in medication schedule.

The majority of epileptic cases are managed with medication. Those that are unresponsive and fit other criteria may be successfully treated with a variety of surgical procedures. The only predictors of seizure intractability are short-term unresponsiveness to medication, history of status epilepticus, and an initially high seizure frequency.<sup>28</sup> Many cases will resolve over time; however, 66% of patients remain on lifetime medication, in particular those who have seizures later in life. Some studies<sup>29, 30</sup> indicate that when epilepsy was untreated or minimally treated in some societies, the remission or

inactivity rate was quite high (44%). With medical care, about 50% of children on medication for two years will remain seizure-free with gradual withdrawal of the drug(s) over a period of six weeks to one year. In four years, this rate increases to 70%.<sup>31</sup> Those who do not have remission over time are usually patients for whom the following factors apply:<sup>32</sup>

- There is a high frequency of seizures.
- There was a long period of time before medical therapy was initiated or before the seizures could be controlled through medication.
- There are associated neurologic problems such as mental retardation.

The primary drugs used in the treatment of epilepsy include carbamazepine, phenytoin, phenobarbital, and valproic acid. With the understanding that seizure activity represents, in part, hyperexcitability, the mechanism of action for many of the medications prescribed for epilepsy becomes more evident. The development of effective medications is premised on the basis that neurotransmitters that are primarily excitatory need to be diminished or blocked and those that are inhibitory need to be enhanced. Following are some common examples:

- Phenytoin (e.g., Dilantin) and carbamazepine (e.g., Tegretol) are part of a medication category termed glutamate antagonists. They block glutamate ionotropic receptors rendering ion channels less permeable to sodium and/or calcium.
- Benzodiazepines and barbiturates used in the management of many disorders are used as therapy for seizures due to their glutamate inhibition by GABA through hyperpolarization.

- Sodium valproate is able to effectively block the conversion of GABA to glutamate by blocking the transaminase enzyme responsible for this conversion.
- Ethosuximide is a specific T-channel blocker affecting the excitability of thalamic relay neurons. This then blocks these neurons from entering a burst-firing mode.

Note that anti-epileptic medications are used for other disorders based on these neuronal inhibitory effects, including prophylactic management of chronic headache and neuralgias such as trigeminal neuralgia and postherpetic neuralgias.

The major concern with medical management of epilepsy is the chronic effect on psychomotor and cognitive function.<sup>33</sup> Phenytoin and phenobarbital are of particular concern with long-term usage. A possible problem with AEDs is CNS toxicity, including sedation, dizziness, imbalance, diplopia, and nausea. Usually these are transient. Morbilliform rashes occur in 5% to 7% of patients. Common side effects for the three primary drugs include:

- Valproic acid (Depacon): tremor and weight gain
- Phenytoin (Dilantin): in young patients, gingival hyperplasia and hirsutism
- Carbamazepine (Carbatrol, Tegretol, Tegretol-XR) and oxcarbazepine (Trileptal): hyponatremia in patients who drink large amounts of fluids or are on diuretics

The specific prescription must account for several other variables, however, including seizure type, age of patient, ability to control with one medication, and other concomitant systemic or neurologic disorders (other medications, diabetes, other diseases). Partial seizures are managed with carbamazepine, phenytoin, phenobarbital, primidone, or valproic acid. Valproic acid is effective for

most patients with generalized seizures. Valproic acid and ethosuximide are used for absence attacks.

Another concern with anti-epileptic medication is the risk to pregnant patients of having malformed infants. Although 90% of all pregnancy outcomes are unremarkable, the remaining 10% are abnormal and may be attributed to the possible teratogenic effect of seizure medication.<sup>34</sup> Unfortunately, none of the four major medications has been identified as the single culprit. There has been a suspicion that the birth defects were, in part, due to the seizures themselves or inherited tendencies from the mother. A recent study indicates that the cause is the AED when comparing mothers with epilepsy taking AEDs and those who did not.<sup>35</sup> The defects include major malformations, microcephaly, growth retardation, and some minor abnormalities of the face and fingers. It appears that supplementation with folic acid did not have an effect on decreasing these malformations. Suggestions for pregnant epileptics are to seek monotherapy drug treatment at the lowest effective dosage and to adhere to a diet with adequate amounts of folate (or supplement).

In addition to the standard primary medications, other medications are also being used. These include:

- Ethosuximide (Zarontin) and valproic acid (Depacon) as first-line treatment of childhood absence seizures
- Lamotrigine (Lamictal) and oxcarbazepine as initial treatment of partial-onset epilepsy
- Lamotrigine as an alternative treatment for absence seizures
- For patients who do not respond well to first-line therapy, topiramate (Topamax), levetiracetam (Keppra), gabapentin (Neurontin), tiagabine (Gabitril), and zonisamide (Zonegran)

Only about 50% of newly diagnosed epilepsy patients become seizure-free with first-line medical treatment.<sup>36</sup> About two-thirds will achieve good seizure control.

A generally held concept is that if the patient is seizure-free for two years, the patient can be gradually withdrawn from epileptic medication. More recently, with increasing data regarding risk of recurrence, it has been suggested that perhaps for some children, withdrawal could begin as early as six months or one year if the patient is seizure-free.<sup>37</sup> This is a complex decision; however, it is known that patients with partial seizures, neurologic abnormalities, epileptiform activity on EEG, or patients who have siblings with seizures have a much higher risk of recurrence. The parent and patient must be reminded that the prescribing physician must direct any decrease in medication use and that sudden withdrawal, in particular, could result in an increase in seizure occurrence or even status epilepticus.

For intractable childhood seizures, a diet developed in the 1920s, referred to as the ketogenic diet, may be of benefit. This radical diet is almost the antithesis of the “healthy” diet. The positive effects appear to be due to ketone body accumulation in the brain. A ketogenic approach consists of a diet high in fat and low in protein and carbohydrate.<sup>38</sup> A standard ratio is 4:1, which represents the ratio of grams of fat to grams of protein and carbohydrates. There is a very strict protocol, which includes a gradual introduction to the diet in a supervised, hospital environment and continued use at home after extensive training of parents coupled with a strong supporting staff of experts. Two recent large studies<sup>39,40</sup> reported the success rate in intractable patients to be about 55% if success is based on a 50% or more reduction in seizure occurrence. Both studies showed similar dropout rates after one year: about half of the starting number. They were due to ineffectiveness or the difficulties that arise from this extremely precise, restrictive diet. About one-fourth of the

patients had a 90% reduction, and 10% actually became seizure-free. The subjects were patients for whom drug therapy was not effective. Apparently the diet must be strictly followed for long periods of time for the effect to be significant.

Experimentation with a new Food and Drug Administration-approved therapy shows some promise. The therapy, called vagal nerve stimulation (VNS), uses a small programmable pulse generator to deliver short bursts of electrical energy to the vagus nerve.<sup>41</sup> The device is implanted under the skin of the left upper chest, and the patient or partner can use a magnet to activate the generator if a seizure onset is perceived. The only known side effects at this time are hoarseness or change in voice quality.

Surgery is reserved for a special subgroup of epileptic patients. If it appears that the cortical area that is the cause of the seizure is identifiable and that surgical excision can safely remove this epileptogenic region without significant neurologic impairment, surgery may be an option. Most often these patients will be those with complex partial seizures and unilateral temporal lobe seizures.

For refractive epilepsy several options are available depending on the age, location, and type of lesion. Following is a list of current surgical options with related types that may be treated:<sup>42</sup>

- Resective surgery: The epileptogenic area must be delineated using several approaches to a convergent localization that allows accuracy in resection. Temporal lobe epilepsy is one example of epilepsy that may be responsive to resection.
- Multiple subpial transections: This is based on the knowledge that functional cortical organization is primarily vertical. Intracortical fibers that are generally responsible for seizures are horizontally oriented.

Small parallel cortical slices are made perpendicular to the long axis of the gyrus in an effort to spare function. This procedure is used alone or in combination with resective surgery for seizures arising in or around motor, sensory, or language cortical areas.

- Gamma-knife surgery: This is a stereotactic delivery of radiation to a very specific point in the brain that has been identified using MRI. A delay effect in results may occur as much as one to three years post-procedure. Currently, three types of epilepsy are being evaluated for success using this treatment: hypothalamic hamartomas, vascular malformations, and mesial temporal lobe sclerosis. In selected cases, success rates for cessation of seizures are around 75%.
- Vagal nerve stimulation: This is an adjunctive therapy with an effect of desynchronizing the EEG of the left vagal nerve stimulation through a subcutaneous lead. The device may decrease frequency of seizures by about 25%, but is not used as a cure-all.
- Deep brain stimulation: Experiments have been done to stimulate areas including the anterior thalamus, the centromedian thalamic nucleus, the caudate nucleus, the posterior hypothalamus, and hippocampus. Multicenter studies are now under way to determine effectiveness.

With correct patient selection, about half of patients remain seizure-free while another quarter or more have a significant reduction in seizure activity.<sup>43</sup>

Debate over the recommendations for driving privileges will continue. In 1994, the Joint Commission on Drivers' Licensing of the International Bureau for Epilepsy and the ILAE made joint recommendations.<sup>44</sup> They recommended against physicians being required to report all cases of epilepsy. They suggested an individual case-by-case assessment with the general recommendation that there be

a seizure-free period of one to two years. However, they felt that physicians should report those patients whom they believe pose a danger to themselves and to public safety. Risk factors for seizure-related motor vehicle crashes have recently been studied.<sup>45</sup> Only 54% of patients who crashed were driving legally. These individuals were not seizure-free. Twenty-five percent of patients had more than one seizure-related crash. Having a 12-month or longer seizure-free period reduced the odds of having a crash by 93%. Staying on or modifying medication and having reliable auras (fair warning to pull off the road) also aid in decreasing the odds of an accident.

**Table 19-4** Anti-seizure Medications

Drug Class	Examples	General Mechanism	Interactions/Side Effects
GABA Agonists Benzodiazepines and barbiturates	Clonazepam	A benzodiazepine derivative that potentiates GABA and acts to inhibit seizure activity. Used alone or in combination with other medications for absence seizures, myoclonic seizures, Lennox-Gastaut, akinetic seizures, restless legs syndrome.	Palpitations, dry mouth, anorexia, drowsiness, ataxia, sedation, respiratory distress, GI symptoms, diplopia, facial edema, hallucinations and other psychogenic problems.
	Klonopin Rivotril		
	Diazepam	Drug of choice for status epilepticus; however, used as an anti-anxiety, sedative, muscle relaxant also. A long-acting benzodiazepine acting at the limbic, hypothalamic areas producing sedation.	Vertigo, dizziness, fatigue, laryngospasm, thorax or chest pain, incontinence or urinary retention, hiccups, hypotension, cardiovascular collapse.
	Apo-diazepam		
	Valium		
	Diastat		
	Diazemuls		
	Novo-Dipam		
	Vivrol		

Drug Class	Examples	General Mechanism	Interactions/Side Effects
	<b>Phenobarbital</b>	A long-acting barbiturate used primarily for the management of epilepsy (grand mal). Inhibits the reticular activating system, causes CNS depression, and raises the threshold for stimulation of the cerebral cortex. Also used for pre- and postoperative sedation in pediatrics and pylorospasm in infants.	Causes CNS depression with possible extreme of coma and death. May cause usual GI symptoms, hyperkinesia, insomnia, nightmares, headaches, bradycardia, syncope, megaloblastic (macrocytic) anemia, agranulocytosis, thrombocytopenia, folic acid or vitamin D deficiency, if taken during pregnancy, birth defects (10%).
	Barbital		
	Luminal		
	Solfoton		
	<b>Gabapentin</b>	Related to gamma aminobutyric acid (GABA). Used as an adjunctive treatment of seizures; also used for herpes zoster.	May cause tiredness, ataxia, dizziness or other CNS effects.
	Neurontin		
	<b>Topiramate</b>	May affect GABA or kainite/AMPA receptors. Used in the treatment of partial seizures.	May cause ataxia, dizziness, speech and psychomotor impairment.
	Topamax		
	<b>Valproic acid</b>	Possible augmentation of GABA neurotransmission by blocking conversion to glutamate; blocks transaminase. Used in the treatment of all seizure types.	Severe hepatotoxicity possible, thrombocytopenia, and hyperammonemia.
	Depacon		
	<b>Glutamate Antagonists</b>	<b>Carbamazepine</b>	CNS toxicity including sedation, dizziness, imbalance, and nausea/vomiting. Agranulocytosis or aplastic anemia. Also possible cause of birth defects.
	Carbatrol	Sodium, potassium, and calcium currents are reduced across neuronal membranes decreasing neuronal transmission. Has an antidiuretic effect. Used in the treatment of seizures and facial neuralgias, also sometimes schizophrenia.	CNS toxicity including sedation, dizziness, imbalance (ataxia), nausea, diplopia (nystagmus); also birth defects, hepatotoxicity, bone marrow suppression, and GI disturbances. Usually these are transient. Morbilloform rashes occur in 5% to 7% of patients; in young patients gingival hyperplasia and hirsutism
	Tegretol		
	Tegretol-XR		
	<b>Phenytoin</b>		
	Dilantin	Sodium, potassium, and calcium currents are reduced across neuronal membranes decreasing neuronal transmission. Used in the treatment of epilepsy (except absence seizures).	CNS toxicity including sedation, dizziness, imbalance (ataxia), nausea, diplopia (nystagmus); also birth defects, hepatotoxicity, bone marrow suppression, and GI disturbances. Usually these are transient. Morbilloform rashes occur in 5% to 7% of patients; in young patients gingival hyperplasia and hirsutism
	<b>Lamotrigine</b>	May have an effect on glutamate/aspartate release and help in stabilizing neurons. Used in the treatment of seizures; in particular, partial seizures.	May cause dizziness, headache, nausea, diplopia, blurred vision, ataxia, tiredness.
	Lamictal		
<b>T Channel blocker</b>	<b>Ethosuximide</b>	A succinimide anticonvulsant used in the treatment of seizures. Specifically, absence seizure, myoclonic and akinetic epilepsy. Acts to depress the motor cortex and elevate CNS threshold for stimulation.	May cause drowsiness, hiccups, ataxia, dizziness, headaches, lethargy, sleep disturbances, myopia, nausea, vomiting, epigastric discomfort, eosinophilia, thrombocytopenia, positive direct Coombs test, hirsutism, pruritic skin rash, gingival hyperplasia, and weight loss.
	Zarontin		

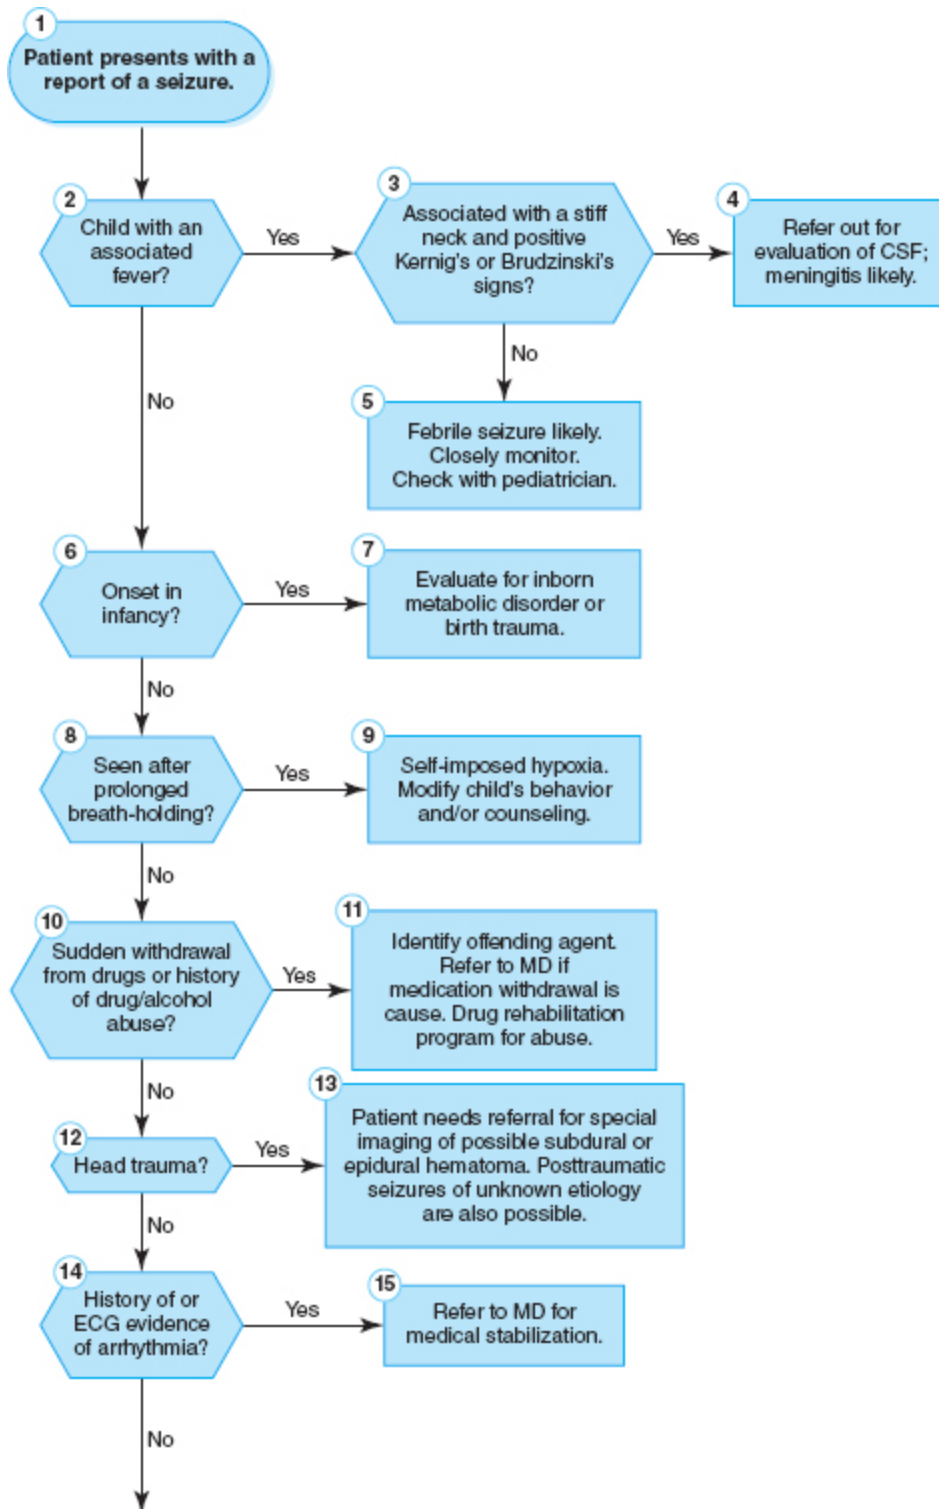

With regard to sports participation, it is known that the following are risk factors and should either be avoided or the activity modified:

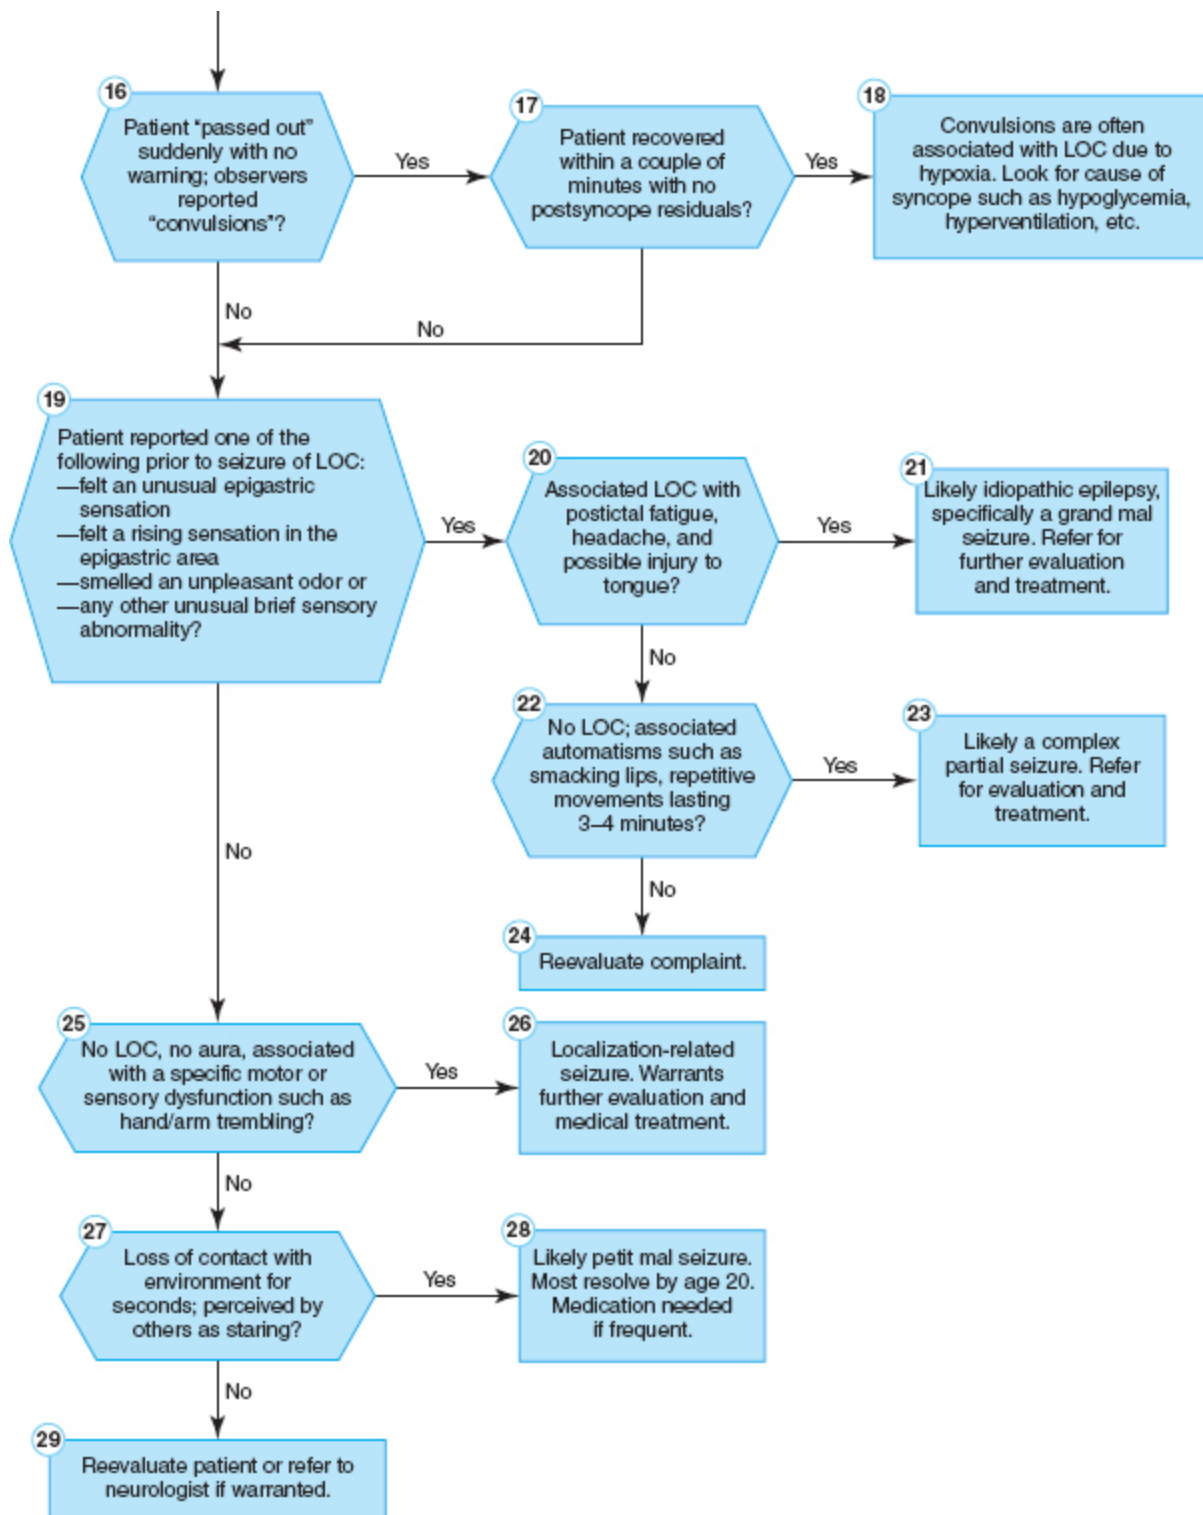

- Sleep deprivation or excessive fatigue
- Hypoglycemia associated with a poor diet (especially before activity)
- Hyponatremia (electrolyte loss) and hypernatremia (dehydration)
- Hypothermia (i.e., physical exhaustion and heat)
- Hypoxia associated with high altitudes

Sports participation should be avoided with high-contact sports. Solo participation or unsupervised participation in sports that involve speed or potential drowning should be performed in tandem or with supervision.<sup>46</sup>

## Algorithm

An algorithm for evaluation and management of seizure is presented in **Figure 19-1**.

Part III

General Concerns

## CHAPTER 20

# Depression

## Context

Most individuals think of depression as a reaction to an unfortunate and emotionally painful occurrence in their life. However, this is not the clinical entity referred to as major depression. The physician expecting his or her patients to complain of depression or to account for a “sad” feeling with a cause-and-effect narrative will miss the diagnosis in many cases.<sup>1</sup> Following hypertension, depression is the next most common chronic condition seen in an average primary care medical office.<sup>1</sup> Of these patients, approximately 10% suffer from major depression. Approximately 10% of men and 20% of women are affected by depression at some point in their life.<sup>2</sup> A recent large-scale study rated the lifetime prevalence for a major depressive disorder at 16.2% in the United States.<sup>3</sup> Major depressive episodes last an average of eight months. If onset of major depression occurs during childhood or adolescence, the risk of recurrence after a single episode is 40% in the next two years and 72% in five years.<sup>4</sup> Prevalence of depression in children is 1% and in adolescents it is 5%. Twenty percent of these cases are at risk for bipolar disease. In people with medical illness, depression is as high as 36% with conditions such as chronic fatigue syndrome, fibromyalgia, stroke, diabetes, rheumatic diseases, heart disease, certain forms of cancer, and renal impairment at the top of the list. Depression also appears to

be a risk factor for coronary heart disease.<sup>5</sup> Another study indicated that depression is a possible risk factor for Alzheimer's disease.<sup>6</sup> With depression the chance of being affected by other medical illnesses and the use of medical services increases. The prognosis for these diseases is often less optimistic for depressed individuals. Almost half of adult patients with a major depression are not diagnosed by their primary care physician. It is obvious that it is difficult to diagnose a disorder for which one does not understand the criteria. Patients with a major depressive disorder will account for between 5% and 13% of patients seen in a primary care setting.<sup>7</sup> (Zung<sup>8</sup> reports this estimate to be as high as 30% of patients.) There are a number of questionnaires available to evaluate patients with possible depression. A recent review of these questionnaires was performed by researchers. Their conclusion was that a clinical interview by a mental health professional or a semi-structured interview made by a primary care physician is able to diagnose major depression with high reliability.<sup>9</sup> A list of websites for many of these questionnaires is given at the end of this chapter.

Chiropractors may feel that depression is outside their scope of practice. The chiropractor, however, can play an important role in developing a diagnostic impression of depression and perform an appropriate referral. Although it would seem logical that patients would complain of depression to their caregiver, most patients with depression actually complain of physical symptoms. This transference from mental to physical is an unconscious process referred to as somatization. The chiropractor is key in identifying a somatizing complaint given musculoskeletal complaint, in particular spinal pain, is commonly reported by patients with depression. It may be that the treatment of major depression is the domain of the medical specialist, but comanagement may be appropriate when associated with musculoskeletal complaints. More important, when treating

a depressed patient for a musculoskeletal complaint, the outcome of treatment may be seriously affected by underlying depression.

Depression has a major impact on the quality of life and the productiveness of the individual. Suicide is more common in depressed patients, with a suicide rate eight times that of the general public.<sup>10</sup> The societal impact of depression can be enormous. The annual indirect and direct costs of depression have been estimated at \$44 billion.<sup>11, 12</sup>

## General Strategy

# History and Evaluation

- Ask the patient about mood disturbance: feeling “blue,” “sad,” “low,” “not right.”
- Determine whether the patient can associate a life event with this feeling, such as loss of a loved one, moving, divorce, leaving home, getting married, lack of social support, or occupational or school stress.
- Screen with questions regarding sleep disturbances, appetite changes, energy level, and loss of interest in previously enjoyed activities if depression is suspected.
- Look for a cluster of complaints that appear unrelated and reported as mild but persistent such as headache, dizziness, increased effort to breathe, and multiple joint complaints in patients who are somatizing.
- Observe all patients for suggestive signs in appearance, behavior, and thought content.
- Determine any past history or family history of mental illness and any past suicide attempts.
- Determine whether there are any current medical conditions that have been diagnosed. Some disorders

associated with depression include chronic fatigue syndrome, fibromyalgia, rheumatoid arthritis, multiple sclerosis, chronic heart conditions, acquired immunodeficiency syndrome (AIDS), stroke, diabetes, renal failure, and Parkinson's disease.

- Determine whether the patient has given birth within the last year.
- Obtain a thorough drug history. Some drugs that may cause affective changes are glucocorticoids, anabolic corticosteroids, oral contraceptives, antihypertensives (especially methyldopa, guanethidine, and clonidine), H<sub>2</sub> antagonists such as cimetidine, anticonvulsants, antiparkinsonian drugs, and digitalis. Always investigate the possibility of alcohol abuse (CAGE questions, discussed later). Always check for use of any stimulants; they may cause depression upon withdrawal.
- Consider using a questionnaire for patients suspected of having depression. Choose from the Beck Depression Inventory (BDI), Center for Epidemiologic Studies Depression Scale (CES-D), or the Zung Self-Rating Depression Scale (SDS).

## Management

- Patients who appear to have a reactive depression should be referred for counseling if the depression appears to be disabling or causing a major disruption in job performance.
- Patients who appear to have a major depressive disorder, bipolar disorder, or mood disorder or those who have possible depression secondary to another illness or drug or alcohol abuse should be referred for

medical evaluation and management of the depression.

## **Terminology and Classification**

# **Relevant Anatomy and Physiology**

With the advent of more sophisticated neuroimaging tools, some of the neurochemical/endocrine and structural relationships to depression are becoming evident. Some of these new advances in understanding relate to the nervous system's response to stress. Although the effects of depression and stress are better understood, the underlying cause of depression is only recently addressed through a genomic approach matched with a theory of genes and environment.

There is a vicious cycle initiated with stress:

- The cortex sends signal to the amygdala (a preconscious signal may arrive first).
- The amygdala is prompted to release corticotrophin-releasing hormone (CRH).
- CRH stimulates the brainstem to activate the sympathetic nervous system.
- Sympathetic activation causes the adrenals to release epinephrine, and a separate pathway causes the release of glucocorticoids.
- If the stress is chronic, glucocorticoids prompt the locus coeruleus to release norepinephrine.
- Norepinephrine stimulates the amygdala to release even more CRH.

The effects of chronic stress on the brain include:

- Release of glucocorticoids, epinephrine, and norepinephrine, which increases the risk of depression through dopamine depletion.
- Decreased stimulation of the raphe nucleus, which then decreases the release of norepinephrine from the locus coeruleus; this decreases attentiveness and possibly memory.
- Decreased secretion of serotonin from the raphe nucleus and possibly decreased number of receptors in the frontal cortex; this effects sleep and mood.
- Possible cell death and shrinkage of the hippocampus; those with serious depression have been shown to have a 10% to 20% decreased hippocampal volume.

There is mounting evidence that an individual's susceptibility to depression following stress is genetically related. One study recently found that individuals with one or two copies of the short allele of the 5-HTT promoter polymorphism exhibit more depressive symptoms than individuals homozygous for the long allele when exposed to stressful situations.<sup>13</sup> It appears that an individual's response to environmental factors coupled with genetic predisposition plays an important role in whether depression results from exposure to stressful life situations.

The terminology and criteria used to describe mental illness may be confusing. Terminology is often updated with new terminology; however, the older terminology is still used. Many psychologic disorders are overlapping, making distinct diagnosis difficult. An attempt at standardization has been made by the American Psychiatric Association (APA) through a task force that has provided updated classification and criteria for mental disorders in a manual called *Diagnostic and Statistical Manual of Mental Disorders*

(DSM). The fifth (latest) edition (DSM-V) was published in 2012.<sup>14</sup>

Depression fits under a broad category of mood disorders characterized by disturbances in emotional, behavioral, cognitive, and somatic function. Depression is further divided into the following main types:

- Adjustment disorders with depressed mood
- Depressive disorders
- Bipolar disorders
- Organic mood disorders

## **Adjustment Disorders**

*Adjustment disorder* is the new terminology for what was called exogenous, reactive, or situational depression. This is a common occurrence when a stressful life situation such as moving, divorce, job stress, or physical illness is “reacted to” with depression. This is considered a maladaptive reaction when the degree of response and type of response are out of proportion to the stressor. Depression is usually mild and lacks some of the diagnostic criteria for major depression.

Another similar type of depression is bereavement or grief reaction. Although it is a normal reaction to be depressed at the loss of a loved one, there appears to be a natural course of incapacitation that does not usually exceed six months. A prolonged grief reaction is disabling for more than six months. The patient demonstrates signs of a major depression disorder (loss of sleep, loss of weight, overwhelming sadness with crying, and isolation from friends/relatives) indicating the need for medication and psychotherapy.

## **Depressive Disorders**

Depressive disorders are divided into major depression disorder (MDD) and persistent depressive disorder (which includes chronic MDD and the previously termed *dysthymia* for milder signs/symptoms). Major depression may occur as a single episode or recurrently. The hallmark of MDDs is a major depressive episode (MDE). Major depression is believed to be due to an imbalance in neurotransmitters, possibly genetically determined. The diagnostic criteria for MDE require that an individual experience a minimum of five out of nine symptoms almost continuously for two weeks; the nine symptoms are as follows:

- 1.** Depressed mood that lasts most of the day, often worse in the morning; felt by the individual or observed by others
- 2.** Loss of interest in previously enjoyable activities; unable to have fun, disinterest in sex or previously enjoyed hobbies
- 3.** Disturbed appetite or change in weight; involuntary loss of more than 5% of weight in a one-month period
- 4.** Fatigue or loss of energy felt every day
- 5.** Disturbed sleep indicated by insomnia or hypersomnia; the classic pattern is terminal insomnia—the person wakes up several hours early and cannot get back to sleep
- 6.** Psychomotor retardation or agitation
- 7.** Feelings of guilt, worthlessness, or self-reproach
- 8.** Suicidal thoughts or focus on death
- 9.** Inability to concentrate or make decisions

The major required criteria are depressed mood and loss of interest or pleasure in life. The criteria are also exclusive in that the patient must also not have an underlying secondary cause such as hypothyroidism, drug effect, stress at work, another mental illness, or bereavement. An MDE is also seen with bipolar disorders.

A more chronic condition in which many of the same symptoms for MDE are present in a milder form for at least two years in adults or one year in children and adolescents is called persistent depressive disorder (previously termed *dysthymia*). Other types of major depression are seasonal affective disorder (SAD) and postpartum depression.<sup>15</sup> SAD appears to be a dysfunction of circadian rhythms occurring more frequently in the winter. These patients respond to full-spectrum light. Postpartum depression must be differentiated from postpartum blues. Postpartum blues (“baby-blues”) occur in the majority of new mothers, peaking around the fourth day post-delivery and resolving after 10 days. Although of concern, this common problem does not usually affect the mother’s functional ability. Within the first month post-delivery there are large fluctuations of hormones in the mother. These fluctuations may lead to periods of sadness and emotional lability; however, the condition is self-resolving within weeks. Postpartum depression, however, is more likely to occur weeks or months after delivery and is characterized by thoughts about harming the baby or feelings of incompetence with regard to taking care of the infant. This disorder may occur in varying degrees of severity in approximately 13% of pregnancies. Postpartum depression is possibly more related to neurotransmitter imbalance than hormonal imbalance and requires medical management. Postpartum depression occurs in susceptible women as a result of withdrawal of gonadal steroids. However, other factors, such as a family history of mood disorders, a stressful life event, and past history of depression, are all risk factors and predictive of those at risk.<sup>16</sup>

## **Bipolar Disorders**

Bipolar disorders are often alternating episodes of depression and mania. Manic depression is further divided into bipolar I and bipolar II disorders. Bipolar I is dominated by manic episodes that may alternate with depressive episodes. Bipolar II is dominated by depressive episodes that alternate with less severe manic periods that cause less impairment. Manic episodes are characterized by feelings of elation or euphoria, overactivity, constant offerings of plans or new ideas, and easy distractibility. Although these are not inherently bad traits, the individual is prone toward lability with regard to mood and can become easily agitated. Quick decisions and commitments are often regretted and abandoned, leaving a trail of alienated friends and relatives. The onset of bipolar disorders is generally at an earlier age than unipolar depression. Spring and summer appear to be periods when manic episodes surface. When the cycle of mania and depression occurs four or more times per year, the patient is referred to as a “rapid cycler.” Substance abuse is often found in manic depressives in an attempt to keep the “highs” of the disorder.

For children who present with persistent irritability and frequent episodes of extreme behavioral dyscontrol, a new diagnosis called disruptive mood dysregulation disorder is used in an attempt to caution medical doctors on over-diagnosing manic depression in children with the associated prescription of related medications and their effects. Like major depression, bipolar disorders may manifest as a milder, yet more chronic, dysfunction. For manic depression this has been called a cyclothymic disorder or, more currently, hypomania. Like persistent depressive disorders, the symptoms are milder, yet are constant for a period of at least two years.

## **Organic Mood Disorders**

Organic mood disorders have an identifiable cause. The major categories are concurrent illness and medication induced. Many illnesses, especially chronic illnesses, can cause depression. Disorders such as rheumatoid arthritis, multiple sclerosis, cancer, AIDS, Parkinson's disease, and chronic heart disorders are commonly associated with depression. Depression may also occur in response to hormonal changes.

Drugs are an important cause of depression. Drugs may cause depression as part of normal usage or as part of a substance abuse pattern. Common medications that have been noted as potential causes of depression are corticosteroids, oral contraceptives, antihypertensives, antiparkinsonian drugs, and digitalis. All stimulant drugs potentially can cause a limited cycle of depression associated with withdrawal, including caffeine.

## Evaluation

The Agency for Healthcare Research and Quality (AHRQ), through the Depressive Guideline Panel, has developed *Clinical Practice Guidelines: Depression in Primary Care*.<sup>2</sup> It contains a suggested approach to diagnosis and management. The focus of the AHRQ approach is detection of depression via a systematic evaluation that begins with a patient's appearance, behavior, and thought process and content. Therefore, both examination and history are occurring simultaneously in the evaluation of depression.

## History

Patients with the following conditions may present with depression as a chief complaint.

- Hypothyroidism
- Hyperthyroidism
- Neurosyphilis
- Premenstrual disorder
- Postpartum blues/depression
- Dementia

Also take a thorough medication history cognizant that the following (among others) affect mood:

- Glucocorticoids
- Anabolic corticosteroids
- Oral contraceptives
- Antihypertensives
- H<sub>2</sub> antagonists such as cimetidine
- Anticonvulsants
- Antiparkinsonian drugs
- Digitalis

Noting current comorbidities is important because depression is more prevalent for patients who have Parkinson's, myocardial infarction (MI), stroke, endstage renal disease, cardiac disease, and cancer.

It is important for primary care or first-contact physicians to be cognizant of the symptoms of depression. Although patients reporting to mental health specialists will likely report feeling depressed, those reporting to primary care physicians usually report other symptoms due to somatization. Somatization is an *unconscious* psychological process that expresses psychological distress as physical symptoms. Suspicion should be raised when a patient presents with multiple complaints, especially if these include complaints of coexisting fatigue, sleep disturbances, mild headaches, dizziness, chest pains, and multiple joint pains. Depression is more common in women and in those who are single, divorced, or separated or who have a

serious disease or a personal or family history of depression.<sup>17</sup> It is equally important to realize that patients may not voluntarily report the symptoms of depression, and a subtle fishing expedition is often needed. One opening approach is the HATAH question: **How Are Things At Home?** This often reveals issues related to the fatigue and agitation often associated with depression.

The assumption by physicians is that patients who are depressed will say so, yet asking that one question is estimated to rule in depression with a yes answer to only around a 20% to 37% post-test probability and a negative answer (no answer) leaving the post-test probability still at 6% to 12%. The characteristic indicators are mood depression and a loss of enjoyment of activities that used to be enjoyable (anhedonia). Asking two history questions regarding depressed mood and anhedonia (loss of life's pleasures) has a sensitivity of 96% but a specificity of 57%, which means that additional questions are needed if the patient indicates a depressed mood or anhedonia.<sup>18</sup> Absence of these positives virtually rules out depression (assuming the patient is being honest). The application of a questionnaire based on the DSM-V criteria for depression is called the PRIME-MD.<sup>19</sup> A simplified, two-question approach is the basis for the PRIME-MD2 used for the purpose of screening for depression. The focus is on sadness and anhedonia. The questions are prefaced with "over the last two weeks ...." The next sequence in the evaluation is the Patient Health Questionnaire 9 (PHQ-9),<sup>20</sup> which utilizes the DSM-V criteria (nine elements) as questions with one additional question regarding the effect of these symptoms on work, home environment, or getting along with people. The patient is asked "over the last two weeks ...?" The patient rates each element by choosing:

- Not at all = 0 points
- A few days = 1 point

- Half of days = 2 points
- Nearly every day = 3 points

An example of how this could be applied in practice would be, if there were a prevalence of depression of around 7% in a given practice, the following would be how probability would be estimated. If there is a positive response to the PRIME-MD questions and a score >10 on the PHQ-9 increases the post-test probability of depression to 49% to 59% whereas a PHQ-9 score of <10 decreases the likelihood to 1% to 4%.<sup>21</sup>

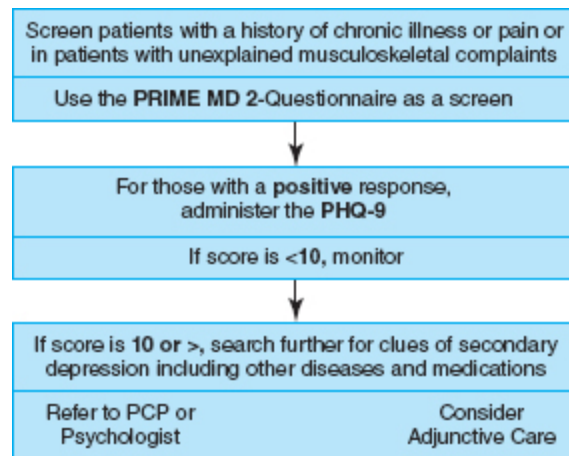

Factors that increase the likelihood for depression by 1.5 to 3.5 times are being female, having a chronic medical illness or chronic pain syndrome, recent life changes or stressors, rating personal health as fair or poor, or unexplained symptoms. **Figure 20-1** is a basic approach to utilizing the PRIME-MD and PHQ-9 in the screening and referral points for patients with suspected depression.

Attempts to determine if the patient meets the criteria for an MDE are set forth by the DSM-V (see Depressive Disorders above) including effects on sleep, appetite (weight loss), fatigue, memory/concentration, psychomotor retardation, and suicidal thoughts. While interviewing the patient, statements indicating a sense of guilt or worthlessness may surface. The patient may also be slow to respond and have difficulty concentrating or even remembering information. This finding has led to the term *pseudodementia*, which should be considered as an alternative to Alzheimer's disease as a cause of "forgetfulness" in the elderly.

When depression is suspected, a distinction among the various types should be made when possible. Questions regarding life stressors such as relationships and occupation are good beginning points. Common causes include loss of a loved one, postpartum periods, moving, leaving home, performance expectations at work, loss of money/property,

and being a victim of abuse or violence. Reactions to these adverse situations may become over-reactive or prolonged, requiring psychologic counseling, or evolve into major depression requiring medical care.

**Figure 20-1** Algorithm for applying PRIME-MD and PHQ-9.

In looking for secondary causes, it is important to ask about coexisting disease and to perform a review of systems to determine the possibility of an undiagnosed condition. Questioning regarding substance or alcohol abuse is important. The CAGE questionnaire<sup>22</sup> should be considered if alcohol abuse is suspected. It includes the following questions:

- Have you ever felt you ought to Cut down on your drinking?
- Have people **A**nnoyed you by criticizing your drinking?
- Have you ever felt bad or **G**uilty about your drinking?
- Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (Eyeopener)?

A medication history is important in determining a side effect of medication or a reaction from withdrawal of stimulants. An endogenous source is suggested when there

are indicators for depression but no identifiable cause. A familial tendency may be evident.

A caution is warranted for detecting depression in specific groups:

- Men may mask their depression through the use of alcohol, drugs, or even working excessively long hours. Unlike women who may admit feelings of hopelessness, men tend to be more irritable, angry, and discouraged.
- Depression in the elderly is often manifested as physical symptoms and complaints.
- Children who are depressed may pretend to be sick or worry about a parent leaving them or dying. In older children, depression is more difficult to detect due to childhood/adolescent stages; however, getting into trouble at school, constant negativity, sulking, and antisocial behavior may be indicators.<sup>23</sup>

In addition to the above approaches for screening for depression, those patients with bipolar disorder require additional screening. Bipolar I (BP-1) is characterized by at least one manic or mixed episode that often alternates with episodes of major depression, whereas, bipolar II (BP-2) is a mood disorder that results in at least one episode of major depression and one episode of hypomania (milder form of mania). Three or more findings on a screening approach list called “DIG FAST” is helpful. These include:

- Distractibility—distracted often to irrelevant or trivial stimuli
- Insomnia—requires little sleep; often as little as three hours per night
- Grandiosity—inflated self-esteem and sense of infallibility

- Flight of ideas—the individual reports that their mind is “speeded-up” and racing and that the individual cannot slow down their thoughts
- Agitation or an increase in goal-directed activity
- Speech—individuals are overly talkative not leaving any opportunity for interruption
- Taking risks—individuals are excessively involved in seeking pleasurable activities that often carry a high potential for catastrophic consequences

Also, for self-assessment, individuals can take the Mood Disorder Questionnaire, which is easily accessible on-line.

## **Suicide**

Given that depressed individuals have a higher incidence of suicide attempts, it is important to know the following about suicide attempts during a depressive episode:

- Risk factors include coexisting substance abuse, impulsivity and aggression, a history of abuse (physical and/or sexual), same-sex attraction and sexual activity, a personal or family history of suicide attempt, and access and/or plan for suicide.
- For children and adolescents, girls are more likely to attempt suicide; however, boys are more likely to succeed.
- 25% to 50% of BP-1 individuals attempt suicide, and 15% are successful

Even with treatment, it appears the risk for suicide may differ based on the type of medication used. For example, a recent study indicated that patients treated for bipolar disorder had a lower risk for suicide while being treated with lithium versus those treated with the most commonly

prescribed mood-stabilizing medication in the United States, divalproex.<sup>24</sup>

## Examination

The initial part of the examination begins while interviewing the patient. If the patient appears to be unkempt, and if his or her movements demonstrate either a slowness or conversely a restlessness or agitation, depression should be suspected.

The examination of a patient suspected of having depression is largely a search for underlying secondary causes. Thyroid screening may be appropriate when physical signs and history are supportive. Also, anemia, vitamin deficiency, cancer, or endocrine disorders may be unmasked by appropriate laboratory examination.

## Management

For untreated major depression, 40% of patients will improve in six months to one year.<sup>2</sup> However, in 40%, symptoms last longer than one year, and in 20%, the improvement is not complete. Unfortunately, half of all patients with one depressive episode are likely to have at least one other. Also, with each recurrence, the chance of another recurrence dramatically increases (70% for those with two episodes, and 90% for three). Seventy-five percent of these recurrences were related to a provoking life event that caused major distress.<sup>14</sup> Many patients report a prodromal phase of both anxiety and mild depression prior to the recurrence.

The following are suggestions with regard to suspected depression.

- When the depression appears to be a reaction to an outside stressor and the symptoms are prolonged or acute, psychological counseling is warranted.
- If the depression appears to be the result of a medication, referral to the prescribing physician is imperative with a letter of explanation.
- When the cause is a secondary disorder, referral to the primary physician, if already diagnosed, is needed. If undiagnosed but suspected, referral to the appropriate specialist is necessary for proper management.
- If the suspected problem is major depression or manic depression, referral to a psychologist first may facilitate the referral to a psychiatrist. Many patients are reluctant to see a psychiatrist immediately.

The type of depression dictates the form of medical management. The types of management include psychotherapy, pharmacologic therapy, electroconvulsive shock therapy, and light therapy. Drug therapy alone is not a complete treatment for depression. Some form of psychotherapy should be combined with drug therapy or used as an initial approach with dysthymia. Psychotherapy approaches vary; however, the intention is to provide a supportive environment for management of the emotional component of dealing with depression. Cognitive and behavioral therapists use a directed approach, guiding the patient through assignments that target negative behavior and help direct appropriate responses. Psychoanalytic approaches attempt to focus the patient's attention on the past in order to interpret his or her current feelings in the context of his or her whole life experience. **Table 20-1** is a list of medications based on these categories.<sup>25</sup>

The basis upon which medical management has evolved follows the hypothesis development over several decades that is related primarily to the function of mainly three neurotransmitters: serotonin, norepinephrine, and

dopamine. Also called the monoamines, these neurotransmitters are crucial to proper function related to, among others, emotion, sleep, appetite, sexuality, and reactions to stress. Medications either increase one or more of these monoamines, decrease their breakdown (e.g., monoamine oxidase inhibitors), or normalize receptor sensitivity. Although the neurotransmitters are often increased within hours of ingestion, it may take weeks for the effects to be felt by the patient. This delay may be due to a hypothesized receptor sensitivity reaction. Up-regulation may occur when decreased neurotransmitters are available leading to increased receptor sensitivity or an increased number of receptors. Medications may decrease this hypersensitivity or decrease the number of receptors through down-regulation. This may take several weeks, partially explaining the delayed effects of antihypertensive medications. The permissive hypothesis restates the cause of depression through a proposed *imbalance* of neurotransmitters versus their actual levels. For example, low levels of serotonin may allow proportionately high levels of norepinephrine to cause mania.

Following are examples of drug categories and mechanisms of action.

- Tricyclic (e.g., amitriptyline [Elavil, Endep] and doxepin HCl [Adapin, Sinequan]) and heterocyclic antidepressants (e.g., trazodone HCl [Desyrel])
- Selective serotonin reuptake inhibitor (SSRI; e.g., fluoxetine HCl [Prozac], paroxetine HCl [Paxil], and sertraline HCl [Zoloft])
- Monoamine oxidase (MAO) inhibitors

When stress reaction is managed medically, drugs such as Valium and Librium are used. These benzodiazepines inhibit the stimulation from the locus coeruleus to the amygdala, thereby decreasing subsequent sympathetic

stimulation. These drugs are effective; however, due to their sedative and addictive properties they should be used with caution.

Lithium is still the standard for manic depression; however, patients with thyroid, kidney, or heart disorders should not take lithium. Other medications include two anticonvulsants, carbamazepine (Tegretol) and valproate (Depakote), and lamotrigine (Lamictal) and gabapentin (Neurontin). However, the role of gabapentin was apparently misrepresented, and although effective for other disorders it has not been shown to be effective for depression.

Newer drug approaches being tested include:

- Substance P: Mixed results have been found in clinical trials regarding substance P blockade as an indirect approach to managing anxiety and depression.
- Corticotropin-releasing hormone (CRH): Because CRH is released from the amygdala in response to stress, attempts are being made to block CRH receptors in the brainstem, breaking the cycle that is initiated by CRH.
- Brain-derived neurotrophic factor (BDNF): Injection of BDNF is being tested as a way of decreasing the neurological damaging effects of glucocorticoids.
- Gene therapy: For depression, genes placed in the hippocampus could create proteins that break down glucocorticoids.

For major depression without mania, most physicians will begin with a single tricyclic medication. It takes a minimum of three to four weeks and as much as six to eight weeks for the medication to be effective. If not effective, a second tricyclic or SSRI is used. Failing a response or for those patients with atypical depression (i.e., excessive sleep and weight gain), MAO inhibitors are prescribed. Antidepressants do work in approximately 80% of cases. The argument against drug therapy is that major depression may resolve

without therapy in 6 to 12 months. Therefore, in those cases, drug therapy is simply assisting the person through a very difficult emotional period. Given that major depression may be self-resolving, it is recommended that the prescribing physician gradually reduce medication starting 6 to 12 months after symptoms have resolved. It should be noted that sexual dysfunction may be a side effect with many antidepressant medications. Some other possible side effects of these medications include:

- Drowsiness and sedation—tricyclics
- Insomnia and anxiety—SSRIs
- Orthostatic hypotension and cardiac arrhythmia—tricyclic and heterocyclic agents
- Weight gain—tricyclics, heterocyclics, and MAO inhibitors
- Delirium—interactions between tricyclic and heterocyclic compounds and SSRIs may cause what has been coined “serotonin syndrome,” which results in excess cerebral serotonin stimulation

It is not unusual for a patient with a depressive disorder to have accompanying anxiety or a panic disorder. Up to 20% of patients with an MDD have a panic disorder. The panic disorder precedes MDD in about half of cases. It appears that these individuals are less responsive to therapy and are more prone to suicide attempts. Antianxiety drugs are often used as an adjunct to antidepressant medication. For patients with manic depression, the standard medication is lithium. [Table 20-1](#) lists commonly prescribed medications for depression and manic-depression.

Electroconvulsive shock therapy (ECT), although sounding barbaric, is often an effective, painless approach to recalcitrant, disabling depression. ECT is delivered after the patient is given a muscle relaxant and placed under

short-term anesthesia. Surface electrodes deliver electrical impulses to the patient's head with the patient anesthetized. Although the electrical stimulation usually results in seizure activity for about 30 seconds, there appears to be no damage. ECT is typically given three times per week for several weeks to be effective. The effects are often not permanent, and relapse is likely; therefore, antidepressant drugs are still used. The most common side effects are some transient memory loss, posttreatment malaise, and interactions between the ECT and current drug therapy.

**Table 20-1** Anti-Depressive Medications

Drug Class	Examples	General Mechanism	Interactions/Side Effects
Duloxetine	Cymbalta	Used in the management of depression, acts as a selective serotonin and norepinephrine reuptake inhibitor (SSNRI). Caution with narrow-angle glaucoma or patients taking MAOIs.	Fatigue, hot flashes, rashes, nausea, dry mouth, constipation, decreased appetite, decreased libido, insomnia, tremor
Aripiprazole	Abilify	A psychotropic drug used in the management of schizophrenia, bipolar disorder, and adjunctive therapy for major depressive disorder.	Not for elderly with dementia-related psychosis, also warnings for tardive dyskinesias, orthostatic hypotension, seizures, worsening of suicidal risk, neuroleptic malignant syndrome, hyperglycemia, and diabetes, cognitive impairment and body temperature regulation, nausea, vomiting, constipation, headache, dizziness, anxiety, insomnia
Imipramine	Impril Tofranil	Used for major depression and sometimes adjustment disorders, works by blocking reuptake of norepinephrine and serotonin by presynaptic neurons (classified as a tricyclic antidepressant). Reduces REM sleep and increases stage 3 NREM sleep.	Hypersensitivity reactions (anaphylaxis), drowsiness, extra-pyramidal symptoms, orthostatic hypotension, heart block, blurred vision, dry mouth, urinary retention
Alprazolam	Xanax	A benzodiazepine sedative causing CNS depression. Suggested sites of action are the limbic, thalamus, and hypothalamus. Used in the treatment of anxiety, panic attacks, insomnia, and muscle spasms. Also used as adjunctive therapy with depression (associated anxiety).	May cause lethargy; some concern over dependency/abuse and withdrawal problems

<b>Amitriptyline</b>	Elavil Endep	Increases levels of serotonin and to a lesser degree norepinephrine through inhibition of reuptake at the presynaptic neuron in the brain. It is used for depression and associated insomnia, restlessness, and nervousness. Also used for fibromyalgia and chronic pain.	May cause drowsiness, sedation, dizziness, orthostatic hypotension, tachycardia, increased appetite, weight gain, urinary retention, or constipation
<b>Bupropion</b>	Wellbutrin Zyban Wellbutrin SR	Inhibits the reuptake of dopamine, serotonin, and norepinephrine with the major effect on dopamine. Wellbutrin is used in the treatment of depression, while Zyban has been approved as an aid for smoking cessation.	Possible problems with seizures, hepatotoxicity, nausea, vomiting, headache, agitation, tremor, and anticholinergic effects
<b>Citalopram</b>	Celexa	A selective serotonin reuptake inhibitor (SSRI) (prevents reuptake at presynaptic neuron) making more serotonin available in the CNS. Used in the treatment of depression.	May cause fatigue, fever, arthralgia, myalgia, postural hypotension, anorexia, paresthesia, tremor, agitation, anxiety, migraine
<b>Manic Depression</b>			
<b>Chlordiazepoxide</b>	Libritabs Librium Medilium Novo-Poxide Seren	A benzodiazepine that affects sleep by suppression of REM and increasing stage 4 NREM with an increase in total sleep time. Has a mild anxiolytic effect. Used primarily for anxiety and tension and assisting sleep in these individuals.	May cause drowsiness, lethargy, depression, orthostatic hypotension, dry mouth, vertigo, syncope, photosensitivity or urinary frequency
<b>Chlorpromazine</b>	Chlorpromazine Largactil Ormazine Promapar Promaz Somazina Thorazine Thor-Prom	A phenothiazine derivative that has alpha-adrenergic blocking effects, an anti-emetic effect through depression on chemoreceptor trigger zone, and antipsychotic effects through actions (blocks postsynaptic dopamine receptors) in the hypothalamus and reticular formation. Used in the management of manic phase of manic depression, for psychotic disorders such as schizophrenia, and for severe nausea and vomiting. Also, sometimes used for behavioral disorders in attention deficit disorder in children.	Many side effects; may cause neuroleptic malignant syndrome, sudden death, extrapyramidal symptoms, dizziness, tremors, drowsiness, EEG changes, pancytopenia, hypothermia, enlargement of parotid glands, infertility, reduced REM sleep dyskinesias, or seizures
<b>Diazepam</b>	Valium	A benzodiazepine. Binds to benzodiazepine site on GABA receptor complex. May cause dyskinesia inhibition through enhancement of GABA mediated chloride influx. Used for anxiety, nervous tension, and psychosomatic illness. May be used as an anticonvulsant or muscle relaxant.	May cause drowsiness, decreased consciousness, and other CNS effects
<b>Doxepin</b>	Adapin Sinequan Triadapin Zonalon	A tricyclic antidepressant that acts as a serotonin reuptake inhibitor and to a lesser degree norepinephrine also. Used in the management of depression and anxiety.	May cause drowsiness, orthostatic hypotension, dry mouth, metallic taste, photophobia, urinary retention, or weight gain
<b>Lithium</b>	Cibalith-S Lithonate Lithane Lithobid Eskalith	Competes with other ions and as a result accelerates catecholamine breakdown, inhibits the release of neurotransmitters, and decreases the sensitivity of postsynaptic receptors. Used in the treatment of acute mania and manic phase of mixed bipolar disorder.	May cause headache, lethargy, fatigue, recent memory loss, nausea, vomiting, abdominal pain, nephrogenic diabetes insipidus, fine hand tremors, muscle weakness, and reversible leukocytosis; rare peripheral vascular collapse

<b>Lorazepam</b>	Ativan	A benzodiazepine used for anti-anxiety. Acts to enhance the effects of GABA particularly in the thalamus, hypothalamus, and limbic areas. It is the most potent of the benzodiazepines but has fewer interactions and less toxic than most other benzodiazepines. Also used for insomnia and panic attacks.	Many side effects disappear with continued use including anterograde amnesia, weakness, dizziness, sedation, restlessness, hallucinations, hyper- or hypotension, blurred vision, or depressed hearing
<b>Nortriptyline</b>	Aventyl Pamelor	Tricyclic antidepressants that act as a serotonin reuptake inhibitor and to a lesser degree norepinephrine also. Used in the management of depression and anxiety.	May cause drowsiness, orthostatic hypotension, dry mouth, metallic taste, photophobia, urinary retention, or weight gain
<b>Paroxetine</b>	Paxil	A selective serotonin reuptake inhibitor (SSRI) making more serotonin available in the CNS. Used in the treatment of depression and obsessive-compulsive disorders.	May cause nausea, vomiting, weakness, dizziness, agitation, insomnia, headaches, or abnormal ejaculation
<b>Phenelzine</b>	Nardil	A monoamine oxidase (MAO) inhibitor in the management of depression. Increases available levels of serotonin and norepinephrine. Also may affect the hepatic microsomal enzymes that metabolize drugs, prolonging the effects of these drugs.	May cause orthostatic hypotension, dry mouth, dizziness, constipation, anorexia, blurred vision, tremors, or muscle twitching; caution for hypertensive crisis when ingesting foods containing tyramine
<b>Prochlorperazine</b>	Compazine Stemetil	A phenothiazine derivative that has alpha-adrenergic blocking effects, an anti-emetic effect through depression on chemoreceptor trigger zone, and antipsychotic effects through actions (blocks postsynaptic dopamine receptors) in the hypothalamus and reticular formation. Used in the management of manic phase of manic depression, for psychotic disorders such as schizophrenia, and for severe nausea and vomiting. Also, sometimes used for behavioral disorders in attention deficit disorder in children.	Many side effects; may cause neuroleptic malignant syndrome, sudden death, extrapyramidal symptoms, dizziness, tremors, drowsiness, EEG changes, pancytopenia, hypothermia, enlargement of parotid glands, infertility, reduced REM sleep, dyskinesias, or seizures
<b>Sertraline</b>	Zoloft	A selective serotonin reuptake inhibitor (SSRI) making more serotonin available in the CNS. Used in the treatment of depression and obsessive-compulsive disorders.	May cause nausea, diarrhea, dry mouth, dizziness, insomnia, fatigue, or impotence
<b>Tranylcypromine</b>	Parnate	A monoamine oxidase (MAO) inhibitor used as a last-choice treatment for those unresponsive to other MAOs in the management of depression.	May cause orthostatic hypotension, dry mouth, dizziness, anorexia, blurred vision, tremors, or muscle twitching; caution for hypertensive crisis when ingesting foods containing tyramine
<b>Trazodone</b>	Desyrel	Inhibits the reuptake of dopamine, serotonin, and norepinephrine with the major effect on serotonin. Used in the treatment of depression and also for aggressive disorders.	May cause a decrease in appetite, rash, hypertension, or shortness of breath

Lifestyle modification may be important in the management or comanagement of depressed patients. Studies indicate that routine exercise, in particular aerobic exercise for three hours per week, may have a positive effect for depressed individuals.<sup>26,27</sup>

Two Cochrane reviews<sup>28,29</sup> conclude that there is effectiveness for the use of exercise in the management of major depression. Some studies<sup>30,31</sup> indicate that aerobic

exercise is as effective as sertraline, an SSRI. It would seem the benefits are a combination of effects including endorphin release and perhaps a placebo effect. The placebo effect, though, is considered quite strong for patients taking antidepressant medications also.

Fairly recently, new studies are indicating a potential protective feature for coffee, green tea, caffeine, and moderate amounts of wine. In one study<sup>32</sup> of Japanese participants, there was a 51% lower prevalence in depression for those drinking four or more cups of green tea per day compared to one or fewer. For coffee, the effect was less robust but was still moderate for those drinking two or more cups per day. The results from two studies<sup>33,34</sup> indicated that there is a moderate benefit to drinking two to seven drinks per week and that this effect seems stronger in women.

Some studies<sup>35,36</sup> indicate that food allergies may trigger depression; therefore, an elimination-diet approach may be suggested in an attempt to determine any particular culprit. For patients with mild to moderate depression, various herbal and nutritional supplementation recommendations have been made. It is important to remember that patients who are severely depressed or suicidal should never be managed with these approaches. Also, with the use of any management strategy, it must be remembered that for some patients, self-resolution occurs in 6 to 12 months no matter what the intervention. The primary recommendations have been for St. John's wort and 5-hydroxytryptophan (5-HTP), both proposed to assist in normalizing serotonin levels.<sup>37-39</sup> St. John's wort (*Hypericum perforatum*) is often recommended for depression. A 2008 Cochrane review<sup>40</sup> concluded that St. John's wort was more effective than placebo and as effective as standard medication (with fewer side effects) for the treatment of major depression. Although in the past it was believed that hypericin was the major active ingredient, it appears that

hypericin does not cross the blood-brain barrier. Hyperforin appears to be the major constituent, yet although it appeared to have similar effects on serotonin, dopamine, and other neurotransmitters, it does not seem to act like a standard SSRI. It may have an anxiolytic action. The Food and Drug Administration, concerned about the interaction between St. John's wort and medications for heart disease, depression, AIDS, and seizures among others, issued a Public Health Advisory in 2000 warning about these possible interactions. This interaction seems to be related to the effect of St. John's wort on drug metabolism through an interaction with the cytochrome P450 3A4 enzyme.<sup>41</sup>

Other recommendations include vitamin B6 for depression associated with premenstrual syndrome, vitamin B12 and/or folic acid for those with deficiency, tyrosine (amino acid) for women taking oral contraceptives, L-phenylalanine, phosphatidylserine (derived from the amino acid serine), dehydroepiandrosterone (DHEA) and other sources of omega-3 fatty acids (especially when associated with heart disease), and S-adenosylmethionine (SAM).<sup>42-52</sup> Because many depressed patients have anxiety as an associated problem, specific recommendations including kava-kava and valerian have been made. For mild bipolar disorders, short-term improvement may be seen with use of omega-3 fatty acids.<sup>53</sup> However, a Cochrane review<sup>54</sup> published in 2008 concludes that the effect is stronger for unipolar depression and less for the manic phase of a bipolar disorder. See **Table 20-2** for a more detailed recommendation list.

**Table 20-2** Nutritional Support for Depression\*

Substance	How Might It Work?	Dosage	Special Instructions	Contraindications and Possible Side Effects
5-HTP (5-Hydroxytryptophan)	Increases serotonin levels, which may decrease symptoms of pain, insomnia, depression, headache, etc.	50–100 mg, 3 times/day	Best with meals. Should be taken with pyridoxal 5 phosphate (included in recommended supplement).	Do not combine with Imitrex or other SSRI or MAOI antidepressants. Taking more than recommended dose may lead to serotonin syndrome. Safety unknown for pregnant or lactating women.

St. John's wort ( <i>Hypericum perforatum</i> )	Works synergistically with 5-HTP; also anti-inflammatory and analgesic properties.	(0.3% hypericin content) 300 mg, 3 times/day (as high as 600 mg, 3 times/day for some patients).	If taken with 5-HTP, reduce 5-HTP dose to 100 mg daily. Best taken at mealtime.	Possible mild stomach irritation; may cause photosensitivity of skin in fair-skinned individuals; rarely allergy, tiredness, weight gain, headache, or restlessness.
Omega-3s (EPA and DHA)	Omega-3 fatty acids may have a general dampening of signal transduction pathways associated with phosphatidylinositol, arachidonic acid, and other related systems.	1,000 mg of EPA and 700 mg of DHA daily for at least 2 months.	None.	Long-term use of fish oils at more than 3–4 g/day may cause problems due to elevated blood sugar, cholesterol, or glucose levels. Side effects may then include nose bleeds or gastrointestinal upset.
L-Phenylalanine	An amino acid that converts to mood-affecting substances including phenylethylamine.	3–4 g/day of phenylalanine for 1-month trial (some research indicated amounts as low as 75–200 mg/day may help).	None.	Large amounts of individual amino acids can cause nerve damage. Safe at 1,500 mg/day. Mild side effects may include nausea, heartburn, and transient headaches.
SAM (S-Adenosylmethionine)	Possibly raises levels of dopamine.	1,600 mg/day	None.	Occasional gastrointestinal upset. Some caution about patients with manic depression switching from depression to a manic episode. Apparently safe in pregnancy.
Kava-kava ( <i>Piper methysticum</i> )	Possibly effective as an anxiolytic and muscle relaxer.	60 to 120 mg/day of kava pyrones (70%) for anxiety, stress, and restlessness; for sleep, 180 to 210 mg of the extract taken 1 hour before going to bed.	Should not be taken with central nervous system depressants or ethanol.	Not habit-forming; however, may cause dizziness or a scaly skin condition if taken in excess.
Valerian ( <i>Valeriana officinalis</i> )	Unknown; however, used for anxiety and as a sleep aid.	2 to 3 g taken 1–3 times/day.	Valerian smells bad even when encapsulated. The active ingredients are unstable; therefore, use only fresh valerian.	Should not be taken during pregnancy or with drugs used to treat anxiety or as sleep enhancers.
Magnesium and malic acid (calcium/magnesium CitraMate)	Increases products of cellular energy and serotonin function, alleviating fatigue.	1 capsule 1–3 times /day (80 mg magnesium and 240 mg malic acid).	Best taken with meals.	None at recommended dosage; however, increase in magnesium dose may cause diarrhea.

\*See tables in [Chapter 55](#) for recommendations for depression related to menstrual dysfunction.

**Note:** These substances have not been approved by the Food and Drug Administration for the treatment of this disorder.

**Key:** SSRI, selective serotonin reuptake inhibitor; MAOI, monoamine oxidase inhibitor; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid

# CHAPTER 21

## Fatigue

### Context

How often do patients complain of feeling tired? It may seem to many practitioners that most do, most of the time. Some studies indicate as many as one out of four or five patients have a complaint of constant tiredness.<sup>1</sup> As a primary complaint, fatigue ranks seventh among all patient complaints in primary care. Statistically, this represents approximately 5% of patients in a primary care setting in the United States; studies<sup>2, 3</sup> in Canada indicate 7% of patients. Although patients often arrive self-diagnosed with chronic fatigue syndrome, it is extremely important to realize that this diagnosis is a difficult one, even for the physician; however, there are defined criteria. It is also important to note that some studies indicate that 50% to 80% of patients with chronic fatigue have a psychiatric problem, most often depression.<sup>4</sup>

The causes of fatigue are generally divided into organic and psychogenic. Each accounts for up to half of all cases (20% to 45% have an organic cause; 40% to 45% have a psychogenic cause).<sup>5, 6</sup> In approximately 10% to 30% of cases, however, no cause is identified. The good news is that approximately 75% of patients improve within a one- to three-year period.<sup>7, 8</sup> These are not necessarily the patients for whom a diagnosis was made. One study<sup>9</sup> provided interesting insight into the psychology of the doctor-patient

relationship with regard to diagnosis of chronic fatigue syndrome (CFS). Seventy-five percent of doctors were reluctant to give their patients a diagnosis of CFS because of the uncertainty of the scientific understanding of the etiology and treatment. They also feared that the diagnosis might be a self-fulfilling prophecy if patients believed they had the disorder. Patients, however, felt that the negative effects of not having a diagnosis outweighed the negative effects of the diagnosis of CFS.

## **General Strategy**

# **History**

Determine what the patient means by a complaint of fatigue. Determine the following:

- Is the complaint more of tiredness (relieved by rest) as opposed to fatigue?
- Is the fatigue or tiredness disabling? Does it interfere with more than 50% of daily activities? If so, consider CFS.
- What is the timing of the fatigue or tiredness? If felt more in the morning it is suggestive of a functional cause; if it is worse as the day progresses it is more suggestive of a physiologic cause.
- Is the sense of fatigue only with exertion? A physiologic cause is suggested.
- What is the patient's typical daily schedule, including eating habits, work habits, and sleep habits (not enough or interrupted sleep, skipping breakfast, drinking large amounts of coffee in the morning, a large lunch, alcohol consumption during the day, athletic training schedule is excessive, etc.)?

- Are there any signs of infection such as fever or upper respiratory symptoms (e.g., sore throat or cough)?
- Is the patient taking medication(s)?
- Have there been any past diagnoses for the fatigue by any other physicians?
- Are there signs or symptoms suggestive of endocrine disorders such as thyroid problems, diabetes, cancer, anemia, or depression?
- Is depression a possibility? Consider the use of a depression questionnaire if suspected.

## Evaluation

- Perform a focused examination based on the history.
- Order laboratory studies based on history and examination findings; Epstein-Barr testing is not recommended.

## Management

- Management is based on the underlying cause.
- Half of all cases of CFS will self-resolve in two years; supportive advice and recommendations involve diet, rest, and exercise.
- Patients suspected of endocrine or oncologic causes should be referred to the appropriate specialist.
- For anemia, see [Chapter 52](#).

## General Discussion

The more common causes of tiredness and fatigue are usually easily recognized by patients. These include strenuous activity, lack of sleep, flu, pregnancy, and

overwork. Often, though, patients do not associate fatigue with stress. Although the first list illustrates situations of increased demand or lack of rest (physiologic), stress borders the categories of physiologic and functional causes. Physiologic stress is often more acute and therefore more easy to associate with a specific cause. Functional or psychologic causes are often without an identifiable match (**Exhibit 21-1**).

CFS is a popular label for patients who feel fatigued or who have no other identifiable cause for their complaint. There are, however, specific criteria that may help separate CFS as a cause.<sup>10, 11</sup> The case definition requires that the patient have a “new” onset of fatigue (not lifelong). This does not result from exertion only nor is it substantially relieved by rest. The sense of fatigue causes a significant reduction in previous levels of occupational, educational, social, and personal activities. To fit the criteria, other symptoms such as short-term memory loss, postexertion fatigue lasting more than 24 hours, sore throat, or headache must persist for six months or more. These criteria alone will eliminate the majority of patients with a complaint of fatigue in an ambulatory setting. It is important to explain to patients that there is no single laboratory or physical examination finding by which to diagnose CFS.

CFS has had many names, including Epstein-Barr virus (EBV) disease, yuppie flu, neuromyasthenia, postviral fatigue syndrome, royal free disease, Iceland disease, and encephalomyelitis; it is often confused with fibromyalgia.<sup>12</sup> There is little support for most theories for CFS. There is no clear evidence that EBV or chronic yeast infection is the cause. Evidence<sup>13</sup> does suggest a chronic immunologically mediated inflammatory process involving the central nervous system. The immune response is believed to be secondary to a number of infectious and psychiatric illnesses. Interest in human herpes virus 6 (hHV 6) is based on lymphocyte cell cultures. This finding, however, probably

is not an indication of primary infection but reactivation of a latent infection.<sup>14, 15</sup>

An association between neurally mediated hypotension (NMH) and chronic fatigue is recognized. Initially, NMH was identified as a cause of unexplained syncope in some individuals. In one study the patients had postexertional fatigue, while another study tested a sample of patients who met the criteria for CFS. Both groups had an abnormal response to the upright tilt test and good response to therapy using antihypertensive medication.<sup>16, 17</sup> The upright tilt test is designed to detect an abnormal cardiovascular reflex.

CFS and depression are related. Studies suggest that in many cases, depression precedes CFS; however, depression is found with all CFS patients. For this reason, the original criteria for CFS, which excluded patients with psychiatric disorders, have been modified to include those with nonpsychotic depression, somatoform disorders, and generalized anxiety or panic disorders.<sup>18</sup> In one study,<sup>19</sup> suicidal thoughts were found in 55% of CFS patients.

Two other interesting studies should be mentioned. The first study<sup>20</sup> illustrates a possible relationship between hypofunctioning of the corticotropin-releasing hormone neurons and CFS. The authors suggest a central deficiency of a potent arousal-producing neuropeptide. In the second study,<sup>21</sup> the authors suggest that the immunosupportive role of sleep is key to the understanding of the sleepiness associated with chronic fatigue. They point out that some viruses cause excessive sleepiness and postulate that some infections may cause a dysfunction in the sleep/wakefulness cycle.

## **Exhibit 21-1 Etiology of Fatigue**

*Acute infection:* influenza, hepatitis

*Chronic infection:* tuberculosis, infectious mononucleosis, brucellosis, subacute infectious hepatitis, subacute bacterial endocarditis, asymptomatic urinary tract infection, hookworm, parasitic infection  
*Autoimmune condition:* systemic lupus erythematosus, rheumatoid arthritis  
*Neurologic disorder:* Parkinson's disease, multiple sclerosis, posttraumatic syndrome  
*Primary muscle disorder:* polymyositis, muscular dystrophy, myasthenia gravis  
*Endocrine and metabolic disease:* adrenal or aldosterone insufficiency, panhypopituitarism, Cushing's disease, hypothyroidism, hyperthyroidism, hypogonadism, hyperparathyroidism, hypercalcemic and hypocalcemic states, hyperaldosteronism, potassium depletion, uncontrolled diabetes mellitus, hypoglycemic states, renal insufficiency Anemia or blood dyscrasia Nutritional deficiency  
*Circulatory disorder:* silent myocardial infarction, congestive heart failure, cardiomyopathy  
*Pulmonary insufficiency:* emphysema, chronic bronchitis  
*Neoplastic disorder:* lymphomas, carcinomas, occult tumors  
*Psychologic disorder:* depression, anxiety Chronic drug intoxication Lack of sleep

## Evaluation

# History

The initial focus of the history is to determine exactly what the patient means by a complaint of fatigue. Patients may describe their complaint as weakness, weariness, boredom, lack of energy, exhaustion, unwillingness or aversion to work, sleepiness, and difficulty breathing with exertion, among others. It is important for the chiropractor to listen patiently to this explanation. Although obtaining the history is time consuming, there are often valuable clues that will lead to a more expedient diagnosis with more judicious use of laboratory testing (**Table 21-1**).

The key initial distinction is between organic/physiologic causes and functional/psychologic causes. In general, the history clues that would point toward a functional cause include the following:

- Fatigue or tiredness is felt more in the morning and improves as the day progresses.
- Although the patient may feel like sleeping, sleeping does not improve his or her fatigue.
- The sense of fatigue is associated with work or situations that are perceived as stressful; improvement occurs with avoidance.
- There is a past or current history of depression, anxiety, or somatization disorder.

Clues that would point toward a physiologic cause include the following:

- Complaints of insomnia or disrupted sleep improve with napping.
- The patient feels best in the morning and feels worse with activity or as the day progresses; complaints improve with sleep.
- The patient has dyspnea or weakness on exertion.
- The patient attributes fatigue to a work or sports activity that is strenuous.
- The patient describes the fatigue as worse in the afternoon and has a history of large caffeine ingestion in the morning, a large lunch, skipped breakfast, or daytime alcohol ingestion.
- The patient is taking a medication such as antihypertensives, antipsychotics, chemotherapy for cancer, anticonvulsants (for seizure), tricyclic antidepressants, benzodiazepines, and antihistamines (antihistamines are the main ingredients in most over-the-counter sleep-inducing medications).

- The patient has a history of drug or alcohol abuse.

**Table 21-1** History Questions for Fatigue

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
How long have you had a sense of fatigue?	Fatigue of recent onset is more likely physiologic and/or transient.	Have you had the fatigue for longer than 6 months and does it significantly affect your performance of daily activities?	More likely CFS unless other condition has been diagnosed.
(For more recent onset) Are you taking any medications?	Medications may be the cause or may be prescribed for an underlying disorder that can cause fatigue.	Are you taking antidepressants, antiseizure medicine, or antihistamines? Do you use illicit drugs such as cocaine?	Side effect of medications.
Does your fatigue occur only after exertion?	Physiologic cause, likely postinfectious or cardio-pulmonary.	Have you had a recent infection that included a sore throat, fever, and/or lymph node swelling? Is it difficult for you to breathe while lying on your back at night? Are you a high-level athlete training multiple hours a week?	Postinfectious; consider mono-nucleosis. Congestive heart failure or obesity. Overtraining.
Is the fatigue more a sense of tiredness in the afternoon?	Consider dietary cause or sleep disturbance.	Do you eat a large meal at lunch or have alcohol with lunch? Do you drink multiple cups of coffee in the morning but not in the afternoon? Do you or your sleep partner notice any problems with sleep?	Postprandial hypoglycemia. Rebound effect of caffeine. Sleep disorder.
Do you feel “blue” or depressed?	Depression.	Do you relate this feeling to a specific life event (e.g., loss of a loved one)? Do you feel that activities that used to bring you enjoyment no longer do? Have you noticed a change in eating or sleeping habits (increase or decrease in either)?	Reactive depression. Depression. Depression.
Do you have a diagnosed condition?	Hyperthyroidism, cancer, depression, etc., cause fatigue.	Have you had a significant loss of weight over the last 6 months? Have you noticed a change in heat/cold tolerance, tremor, fast heart rate, or change in skin or hair?	Possible cancer, especially in an older patient. Possible thyroid disorder.

## Examination

The examination focuses on a search for systemic, metabolic, or neurologic conditions that may cause fatigue. Often the symptoms elicited with the history will be

suggestive of a particular system. Following are some of the more common causes with associated examination clues:

- Infection—fever, lymphadenopathy, associated upper respiratory complaints such as cough, urinary tract complaints such as burning on urination, and abdominal complaints such as nausea/vomiting, abdominal pain, or diarrhea; upper right quadrant tenderness or hepatomegaly suggests hepatitis; splenomegaly suggests mononucleosis
- Hypothyroidism—thyroid nodules or enlargement, coarse hair, dry skin, loss of outer third of eyebrows
- Hyperthyroidism—thyroid nodules or enlargement, moist skin, fine tremor, fine hair, occasionally pretibial myxedema
- Chronic renal failure—hypertension, cardiomegaly, edema, or pericardial friction rub
- Congestive heart failure—lower leg edema, ascites, adventitial lung sounds, hepatojugular reflux, cardiomegaly
- Chronic obstructive pulmonary disease—cyanosis, barrel chest, prolonged respiration, FEV<sub>1</sub> reduction, rhonchi, wheezes
- Cancer—weight loss, blood in stool, persistent or localized lymphadenopathy
- Anemia—tachycardia, conjunctival pallor, fatigue on exertion (step test), glossitis
- Acquired immunodeficiency syndrome (AIDS)—persistent lymphadenopathy, muscle wasting, leukoplakia

Laboratory evaluation of a fatigued patient is often unrevealing because of the high percentage of psychologically related complaints. However, a general screen often will reveal direct or indirect signs of a physiologic cause if present. The National Institutes of

Health<sup>22</sup> recommended in 1991 that the following be included on an initial laboratory examination of the fatigued patient:

- complete blood cell count with differential
- serum chemistries (including electrolytes, blood urea nitrogen, glucose, and creatinine)
- liver function tests
- thyroid function tests
- antinuclear antibody (ANA) test
- urinalysis
- tuberculin (TB) skin test

The majority of the above tests are done in a standard screening laboratory; however, the ANA test, thyroid function tests, and the TB skin test are not. The expense of adding these tests should be considered, and the decision to order should be based on relevant historical or examination clues.

Tests that should be run if clinically indicated include the following:

- serum cortisol (Addison's disease)
- immunoglobulin levels (chronic fatigue syndrome and connective tissue disorders)
- rheumatoid factor (rheumatoid arthritis)
- Lyme serology (Lyme disease in endemic areas)
- human immunodeficiency virus (HIV) antibody (AIDS)

The study did not recommend testing for EBV in evaluating a patient suspected of having chronic fatigue syndrome because 95% of adults over age 30 years have serologic evidence of a past EBV infection.<sup>23, 24</sup> The study, however, did recommend the use of screening questionnaires for depression or other psychiatric problems (see [Chapter 20](#)).

When an underlying sleep disorder is suggested, referral to a sleep laboratory for confirmation is needed to determine the degree of involvement. Many patients feel they sleep poorly; however, they are demonstrated to sleep adequately with a sleep laboratory investigation.

## Management

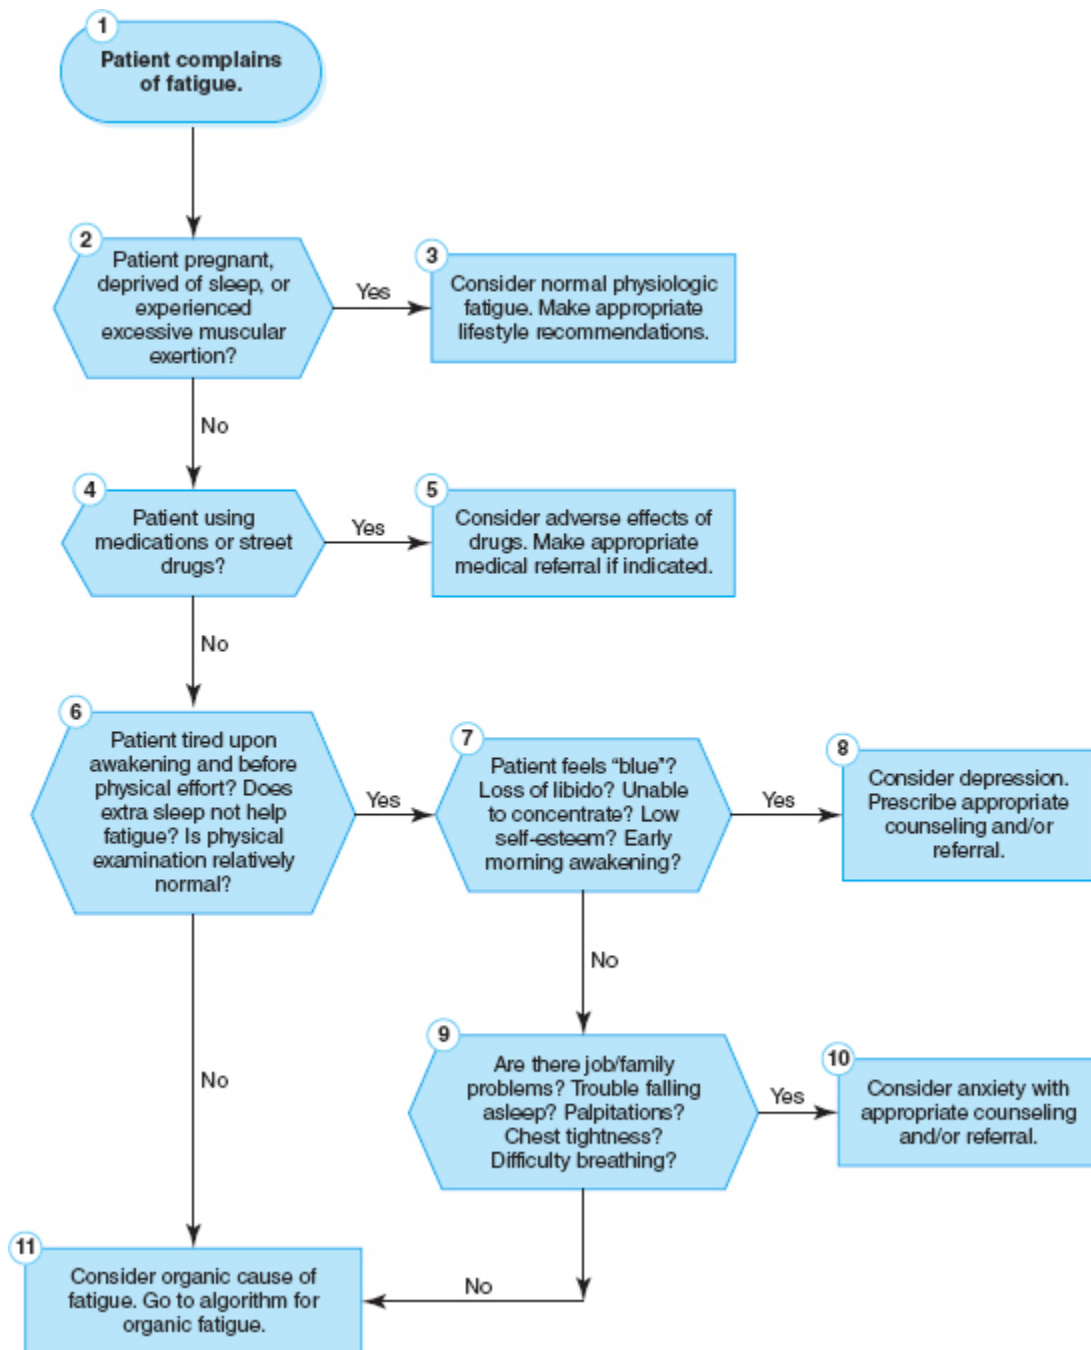

Management of fatigue is based on an identifiable cause. When there is an obvious lifestyle factor, such as diet, work, or stress, modification is often all that is needed. The chiropractor can play a clear role in advice regarding proper diet and exercise, stress management, and avoidance of excess in alcohol and drugs. When the underlying cause is suspected to be a medication, referral to the prescribing physician with a letter of explanation is necessary. All other patients with identifiable or suspected diseases should be referred to a primary care or specialist physician for comanagement.

It appears that a moderate exercise plan may be important in preventing worsening of fatigue.<sup>25, 26</sup> A number of different approaches have been used in the treatment of CFS, but there has been no consistent, reproducible benefit with any. Notably, a study<sup>27</sup> comparing immunologic therapy, psychiatric counseling, and placebo demonstrated no difference in effect among groups. The literature is full of therapeutic trials using essential fatty acids,<sup>28</sup> magnesium,<sup>29</sup> liver extract-folic acid/vitamin B12,<sup>30</sup> gamma globulin,<sup>31</sup> and acyclovir.<sup>32</sup> One gram of carnitine three times a day resulted in some improvement in a small group of patients.<sup>33</sup> Licorice that contains glycyrrhizin (not the DGL-type licorice) may cause an elevation in blood pressure and has been recommended as a possible alternative for patients with hypotension-associated CFS. One case study<sup>34</sup> used 2.5 g of licorice per day. It is important to note that these

hypertensive aspects of licorice should be taken quite seriously prior to recommending licorice as a nutritional aid to CFS. One study<sup>35</sup> indicated a role for essential fatty acid prescription. None has demonstrated a consistent effect superior to the natural course of CFS or placebo.

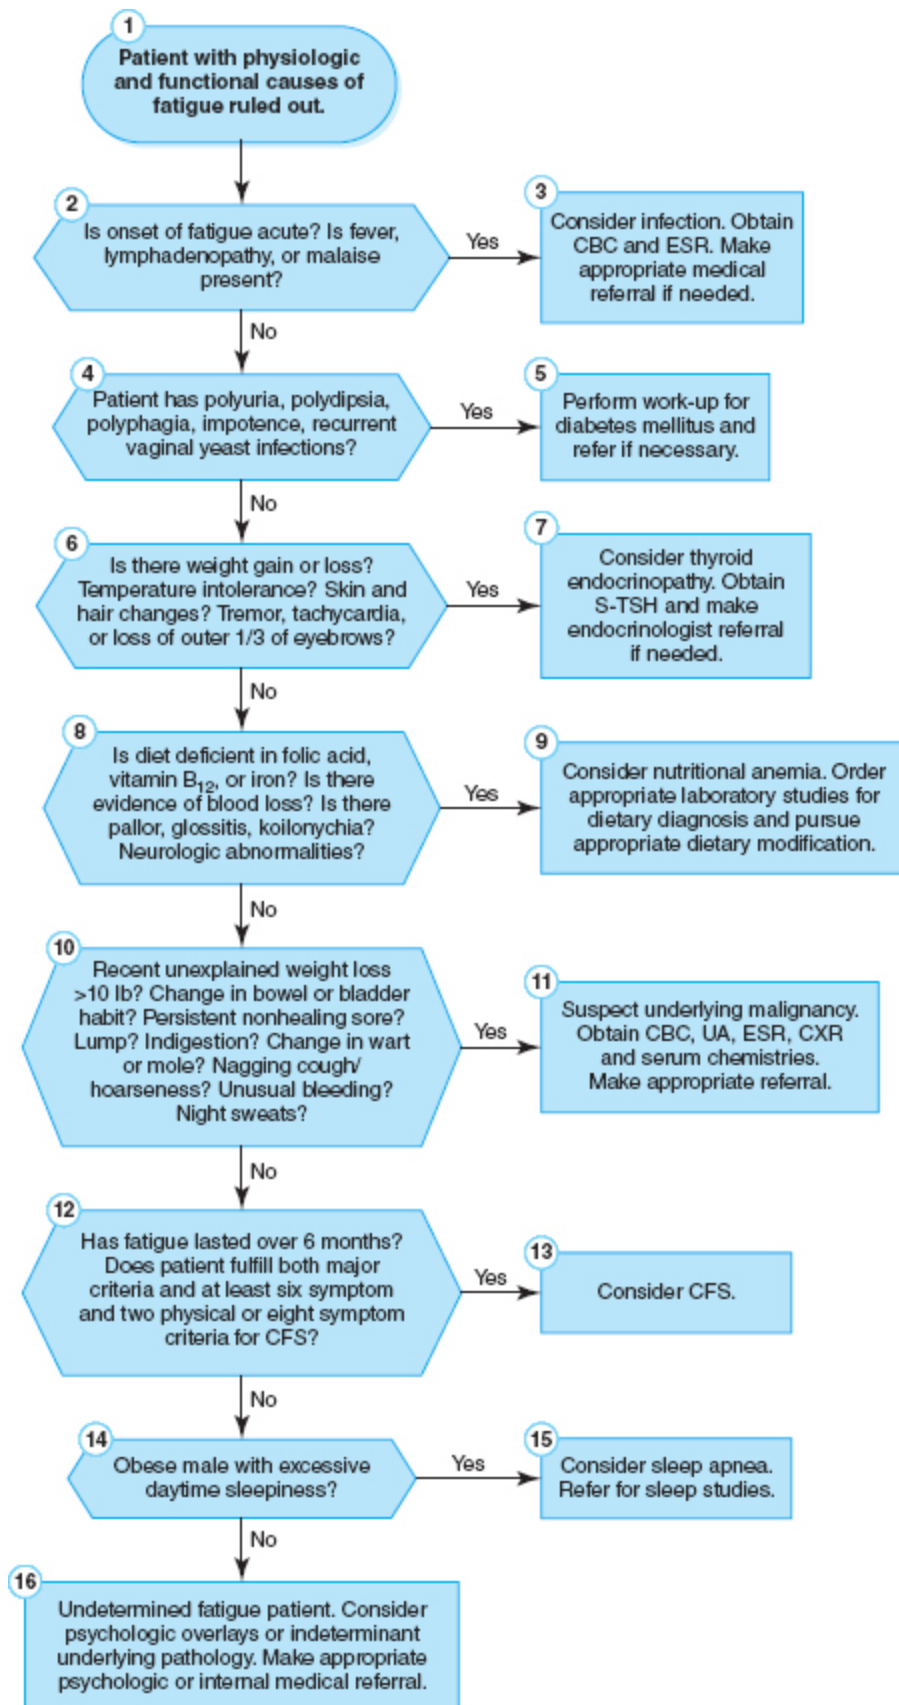

## Algorithm

Algorithms for evaluation and management of initial fatigue screening and organic fatigue screening are presented in **Figures 21-1** and **21-2**.

# Selected Disorders Presenting as Fatigue\*

## Chronic Fatigue Syndrome

### Classic Presentation

The patient complains of fatigue that has persisted for several months. This is not something felt before. It is disabling enough to interfere with normal activities of daily living. Rest feels good, but does not seem to make any difference.

### Cause

The cause is unknown. In the past there was a belief that a specific viral agent such as Epstein-Barr was the cause. However, there is no evidence that there is a single cause. It appears that the cause is a dysfunction in immune function, often in reaction to an acute illness. One finding that helps support this theory is the persistence of high levels of cytokines (i.e., interferons and interleukins) after a viral infection in patients with chronic fatigue.<sup>36</sup> Confusing the diagnostic picture is that other conditions coexist, in particular fibromyalgia (overlap with CFS is more than 50%),<sup>37</sup> depression, or other illness.

### Evaluation

The diagnostic criteria have changed. The 1988 case definition was revised in 1994 to a much more abbreviated list of criteria.<sup>11</sup> The case definition requires that the patient have a “new” onset of fatigue (not lifelong). This fatigue neither results from ongoing exertion nor is relieved substantially by rest. The sense of fatigue causes a significant reduction in previous levels of occupational, educational, social, and personal activities. To fit the criteria, other symptoms, such as short-term memory loss, postexertion fatigue lasting more than 24 hours, sore throat, and headache, must persist for six months or more. The clinical search for other causes of fatigue involves a thorough history and evaluation for possible thyroid or adrenal disease, psychologic cause or overlay (i.e., depression), somatization, Lyme disease,

mononucleosis, anemia, cancer, or any chronic disease. The choice of laboratory or imaging testing is based on the suspected cause. The clinical examination can help differentiate fibromyalgia, and questionnaires may help reveal depression. Specific laboratory testing, such as a monospot for mononucleosis, anemia panel for anemia, general screen for cancer or chronic disease, and enzyme-linked immunosorbent assay (ELISA) testing for Lyme disease, should be used only after a thorough history and examination have suggested their need. Epstein-Barr or other specific viral testing is not suggested.

## Management

It has been reported that 50% of patients will recover in two years.<sup>38</sup> However, a recent study<sup>39</sup> indicated that of those patients with severe CFS, only 4% recovered over the four years of the study. During recovery several strategies may help, including a proper diet, adequate rest periods, and mild to moderate exercise. Cognitive behavioral therapy is also important. To treat the sleep dysfunction associated with CFS, low doses of tricyclic antidepressants (e.g., doxepin hydrochloride [Sinequan] 10 mg/d) are prescribed. Low-dose hydrocortisone has only a short-term benefit.<sup>40</sup> There appears to be no benefit to either prolonged rest or immunotherapy.<sup>41</sup> It is important to help support the patient emotionally through the illness and to manage musculoskeletal complaints when necessary.

## Fibromyalgia

## Classic Presentation

The patient is often a woman complaining of both fatigue and generalized musculoskeletal pain.

## Cause

The cause is unknown. Several theories have been proposed focusing on lowered pain-threshold levels and decreased serotonin levels. It is believed that an interruption of stage 4 (nonrapid eye movement) sleep due to intrusions of alpha rhythms is also contributory.<sup>42</sup>

## Evaluation

The American College of Rheumatology set criteria for the diagnosis of fibromyalgia in 1990.<sup>43</sup> These include persistence of generalized musculoskeletal pain (both sides of the body, above and below the waist) for at least three months. There must also be tenderness at 11 of 18 sites (9 bilateral sites). These sites include the suboccipital area, the lower cervical spine (transverse processes of C5-C7), upper trapezius, supraspinatus, second rib (costochondral junction), lateral epicondyle (2 cm distal), gluteals, greater trochanter of the femur, and the medial fat pad at the knee (proximal to the joint line). The sensitivity of this approach is 88%; specificity is 81%.<sup>44</sup> Other symptoms include fatigue, sleep disturbance, persistent early morning stiffness, paresthesia, and headache. Approximately 2% of the general population has fibromyalgia (3.4% women; 0.5% men) and this incidence increases with age (7% of women aged 60–79).<sup>45</sup> Fibromyalgia is found in 10% to 40% of patients with rheumatoid arthritis and systemic lupus erythematosus (SLE). Of patients referred to Lyme disease clinics, 25% to 50% had fibromyalgia instead of Lyme disease.

## Management

Unfortunately, there is no consistent effect with any therapy. However, approximately three quarters of all patients with fibromyalgia will recover over a one-year period.<sup>46</sup> It appears that the use of low-dose tricyclic antidepressants will help approximately half of these patients. Pregabalin (Lyrica) is a new medication that may help. Although many other conservative approaches have been suggested, including the use of oral malate and magnesium, vitamin E (see [Table 21-2](#)), exercise, physical modalities, homeopathy, and manipulation, none has been demonstrated in large studies to indicate a significant difference compared with control groups.<sup>47</sup> In one study, fibromyalgia patients were randomized to either an exercise group (exercise bicycle and treadmill) or a relaxation group (stretches and relaxation exercises) for one hour, twice a week, for 12 weeks.<sup>48</sup> At the end of the trial treatment, 35% of patients in the exercise group rated feeling “much better” or “very much better” versus 18% for patients in the relaxation group. The effect seemed to be maintained at a nine-month follow-up for the exercise group (38%), with a small increase in the relaxation group to 22%. A systematic review<sup>49</sup> published in 2009 concluded that there was strong evidence for the use of aerobic exercise and cognitive behavioral therapy. They concluded there was moderate evidence for muscle strengthening, massage, acupuncture, and balneotherapy (spa therapy). There was only limited evidence for spinal manipulation, vitamins, minerals, and herbs. It appears that vitamin D deficiency is common in patients with fibromyalgia and occurs more frequently in those who also have anxiety and depression.<sup>50</sup> Although the deficiency is not necessarily causal, there appears to be a relationship that theoretically indicates the possibility of improvement with correction of the deficiency. One pilot study<sup>51</sup> using intravenous nutrient

therapy found significant improvements in pain and energy. No participants had complete or lasting resolution, but the results are an indication for further research. The patients in this study were treated once per week for eight weeks. Patients had longstanding fibromyalgia (eight years or longer) and had not responded to other therapies. Finally, acetyl L-carnitine may be of benefit. A study<sup>52</sup> combining 500 mg/day capsules and weekly injections compared to placebo demonstrated some significant difference with more improvement in the L-carnitine group after the tenth week post-treatment.

**Table 21-2** Nutritional Support for Fibromyalgia

Substance	How Might It Work?	Dosage	Special Instructions	Contraindications Possible Side Effects
5-HTP (5-hydroxytryptophan)	Increases serotonin levels, which may decrease symptoms of pain, insomnia, depression, headache, etc.	50-100 mg, 3 times/day	Best taken with meals. Should be taken with pyridoxal 5 phosphate (included in recommended supplement).	Do not combine with Imitrex or other SSRI or MAOI antidepressants. Taking more than recommended dose may lead to serotonin syndrome. Safety unknown for pregnant or lactating women.
St. John's wort (Hypericum perforatum)	Works synergistically with 5-HTP; also anti-inflammatory and analgesic properties.	(0.3% hypericin content) 300 mg, 3 times/day (as high as 600 mg, 3 times/day for some patients).	If taken with 5-HTP, reduce 5-HTP dose to 100 mg daily.	Possible mild stomach irritation; may cause photosensitivity of skin in fair-skinned individuals; rarely, allergy, tiredness, weight gain, headache, or restlessness.
SAM (5-densylmethionine)	Possibly raises levels of dopamine.	1,600 mg/day.	None.	Occasional gastrointestinal upset. Some caution about patients with manic-depression switching from depression to a manic episode. Apparently safe in pregnancy.
Vitamin E	Unknown.	100-300 IU/day.	None.	None as recommended.
Magnesium and malic acid (calcium/magnesium CitraMate)	Increases products of cellular energy and serotonin function, alleviating fatigue.	1 capsule 1-3 times/day (80 mg magnesium and 240 mg malic acid).	Best taken with meals.	None at recommended dosage; however, increase in magnesium dose may cause diarrhea.

Key: SSRI, selective serotonin reuptake inhibitor; MAOI, monoamine oxidase inhibitor.

*Note:* These substances have not been approved by the Food and Drug Administration for the treatment of this disorder.

## Mononucleosis

## Classic Presentation

The patient is usually young (age range 10 to 35 years) and complains of fever, fatigue, and sore throat.

## **Cause**

Infection by Epstein-Barr virus (human herpes virus 4) is the cause of mononucleosis. It appears to be most often transmitted via saliva, with an incubation period of 5 to 15 days.

## **Evaluation**

The patient usually has a fever, enlargement of the posterior cervical chain lymph nodes, and, in about half of cases, splenomegaly. Inspection of the throat will usually reveal an exudative pharyngitis or tonsillitis. All of the above findings may be nonspecific, yet suggest a laboratory evaluation. This evaluation may include a screen, which will reveal atypical lymphocytes, or suggest the need for specific testing including the heterophile antibody test (or the related monospot test), which will be positive for mononucleosis. It may take several weeks after acquiring the infection for these tests to become positive, however.

## **Management**

Management is largely palliative for most patients. The sore throat may last several weeks while the fatigue may last for one to three months. Rare complications occur in older or immunosuppressed patients and include enlargement of lymphoid tissue compromising breathing (refer for corticosteroids), hepatitis, myocarditis, or encephalitis. These select patients should be managed medically.

## **Lyme Disease**

## **Classic Presentation**

Presentation is dependent on the course of the disease. With early disease, the patient presents with a skin rash and flu-like symptoms following a camping or hiking trip (or simply occupational exposure for those who work in high-risk areas). Later course presentations include multiple joint pains and fatigue.

# Cause

Transmission of the spirochete *Borrelia burgdorferi* occurs from an *Ixodes* tick bite. High-risk areas include Massachusetts to Maryland, Wisconsin, Minnesota, California, and Oregon. Onset is most often in the summer or early fall. Most patients are children and young adults; however, anyone living or working in heavily wooded areas is at risk.

# Evaluation

Early manifestations are a small red macule or papule (erythema [chronicum] migrans), often at the site of a tick bite, that expands and spreads into a rash. This is often followed by mild flu-like symptoms such as malaise or low-grade fever. An inflammatory arthritis appears in about 60% of people usually over weeks or months, with the larger joints such as the knee commonly affected. Multisystem involvement may also occur including the heart, central nervous system, or peripheral nervous system. Common serologic testing is not useful in early Lyme disease due to low sensitivity.<sup>53</sup> Later in the course of disease, positive or equivocal results on an ELISA, immunofluorescence antibody (IFA), or immuno-dot assay require supplemental testing using a Western blot assay. Negative results on a Western blot or ELISA indicate no serologic evidence of *B. burgdorferi* infection at the time of testing. Some laboratories can provide culturing of skin lesions and polymerase chain reaction of skin biopsy and blood, which may be helpful in the diagnosis.

# Management

For early Lyme disease doxycycline or amoxicillin is used for 21 days or longer. With later involvement of joints, probenecid is added and the treatment is extended to 30 days. If neurologic involvement occurs, parenteral antibiotics are given. Generally, the long-term outcome is favorable for patients with Lyme disease.<sup>54</sup> A Lyme disease vaccine is available and recommended for those at high risk due to geographic location, occupation, or significant recreational exposure in high-risk areas.<sup>55</sup>

## Hepatitis A

# Classic Presentation

Although many patients are asymptomatic, some patients may present with anorexia and malaise. At some point in the illness, the patient may develop a

fever just prior to becoming jaundiced.

## **Cause**

Infection with the hepatitis A virus (HAV) is usually related to exposure by the fecal-oral route. This highly contagious viral infection is most common in daycare centers, homosexual men, and institutionalized individuals. Other means of transmission include eating undercooked shellfish, drinking contaminated water, and handling of imported chimpanzees or apes. Anywhere from 20% to 80% of the adult population has immunity (higher in lower socioeconomic group individuals). The incubation period is 15 to 45 days.

## **Evaluation**

The patient may have hepatomegaly with upper right quadrant tenderness. Another characteristic sign is dark urine. At some point the patient may develop a fever that precedes the appearance of jaundice. Interestingly, the onset of jaundice occurs when the patient begins to feel better and the fever rapidly decreases. White blood cell count and erythrocyte sedimentation rate (ESR) are generally normal. Liver enzyme levels, such as alanine aminotransferase (ALT) and aspartate aminotransferase (AST), are quite high (more than eight times the normal level when jaundice appears); bilirubin also is elevated as is alkaline phosphatase. Diagnosis is by immunoglobulin M (IgM) anti-HAV in the early stage. IgM is found during the onset of jaundice.

## **Management**

The disease is generally self-resolving; it lasts approximately six weeks with the possibility of two to three relapses. Increased calorie intake (especially in morning) and avoidance of hepatically metabolized drugs is all that is necessary. The patient is not a carrier. HAV vaccine is recommended for those at high risk.

## **Hepatitis B**

### **Classic Presentation**

Many patients are asymptomatic. If symptomatic, the patient presents with a complaint of chronic malaise or fatigue. If presenting during the prodrome,

the patient may have signs of serum sickness such as urticaria, rash, and arthralgias.

## Cause

Infection with the hepatitis B virus (HBV) is usually related to exposure by the parenteral route (needle use including infected transfused blood, contaminated needles in drug abusers, and tattoos). The most common individuals are homosexual men, drug abusers, visitors and immigrants from endemic areas, Alaska natives, neonates born to infected mothers, prisoners and the institutionalized, and medical workers exposed to accidental needle pricks. Infection at an early age in developing countries usually is unremarkable with only mild disease and no jaundice. The incubation period for HBV is 50 to 180 days. HBV is an infectious disease notifiable on the national level.

## Evaluation

The patient may have hepatomegaly with upper right quadrant tenderness. Another characteristic sign is dark urine. At some point the patient may develop a fever that precedes the appearance of jaundice. Interestingly, the onset of jaundice occurs when the patient begins to feel better and the fever rapidly decreases. White blood cell count and ESR are generally normal. Levels of liver enzymes such as ALT and AST are quite high (more than eight times normal when jaundice appears); bilirubin also is elevated as is alkaline phosphatase. Diagnosis is by IgM anti-hepatitis B core antibody (HbcAb) in the acute or early convalescent serum. IgM is found during the onset of jaundice. Hepatitis B surface antibody indicates an immunization response. Eventually, over months, anti-hepatitis B surface antigen (HbsAG) is replaced by HbcAb.

## Management

The disease is generally self-resolving; it lasts approximately six weeks with the possibility of two to three relapses. Increased calorie intake (especially in morning) and avoidance of hepatically metabolized drugs is all that is necessary. Patient is a carrier. All pregnant women should be screened for HbsAG on their first prenatal visit and later in pregnancy if at high risk. For prevention, after needle stick, within 14 days of sexual exposure, or at birth HBV, hyperimmune globulin should be administered followed by HBV vaccination. Standard immune globulin is also as effective. Due to the higher risk of liver cancer in chronic HBV individuals, immunization is recommended for all high-risk individuals. (*Note:* For chronic liver diseases, see [Table 21-3](#).)

**Table 21-3** Differential Diagnosis in Patients with Chronic Elevation of Liver Enzymes

Disease/Disorder	Definition	Clinical Features	Laboratory Findings	Treatment
Chronic hepatitis B	Either persistent carrier state with hepatitis or chronic active hepatitis.	Symptoms are nonspecific including malaise, anorexia, and fatigue. Past history of acute hepatitis B or past transfusion or IV drug abuser.	Moderate AST levels; positive for hepatitis B surface antigen and anti-hepatitis B core antibody.	Recombinant interferon-alpha; steroids are variably helpful for chronic active hepatitis B.
Hepatitis C	An acute progressive liver parenchymal infection by hepatitis C virus (HCV).	Symptoms are nonspecific including malaise, anorexia, and fatigue. Past history of acute hepatitis B or past transfusion or IV drug abuser.	ALT and AST elevation (six to eight times), bilirubin increased by five to ten times; positive for anti-HCV antibody detected by ELISA	Recombinant interferon-alpha for 6 months to reduce ALT and HCV viremia; relapse occurs 50% of time; 3- to 6-year remissions do occur.
Hemochromatosis	An autosomal recessive disorder with increased iron absorption and an accumulation of iron as hemosiderin in multiple organs including adrenals, liver, pancreas, heart, testes, kidneys, pituitary, and joints.	Family history, increased skin pigmentation, hepatomegaly and tenderness, systemic illness (e.g., heart, pancreas), arthritis (in particular hip).	Elevated serum transferrin saturation values; increased plasma iron, ferritin, liver enzymes; measurement of hepatic iron index in liver biopsy.	Weekly phlebotomy of 500 ml of blood for several months; subsequent phlebotomies are performed every 3 to 6 months; deferoxamine (iron chelating agent) is used in severe cases.
Alcoholic liver disease	Due to chronic alcohol damage fatty changes with diffuse inflammatory response and necrosis are found.	History of alcohol abuse.	High GGT, high MCV, AST:ALT ratio is greater than 2:1.	No alcohol; prednisone is used in severe cases.
Fatty liver steatonecrosis	Fat accumulation in the liver due to alcohol abuse, diabetes, and obesity.	Found with diabetes and obesity; more common in women.	Mild GGT, AST, and ALT elevation; glucose intolerance.	Control of underlying alcoholism, diabetes, or obesity.
Primary biliary cirrhosis	A disease of unknown origin with chronic cholestasis and progressive destruction of bile ducts.	Pruritus, fatigue, and jaundice; found with other disorders such as thyroiditis, arthritis, Sjögren's syndrome, scleroderma, and renal tubular acidosis.	High alkaline phosphatase and GGT; positive ANA; IgM increase.	Methotrexate and other major medications; prednisone not beneficial; supplementation of vitamins A, D, and K and calcium, pruritus treated with cholestyramine; liver transplant needed in severe cases.
Wilson's disease	A progressive and fatal disorder (unless treated) of copper metabolism inherited as a mutant gene on chromosome 13. Deposition of copper in the brain and liver is life-threatening.	Younger patient with Kayser-Fleischer rings (gold or greenish gold crescents on the cornea) confirmed by an ophthalmologist with a slit-lamp, associated with neuropsychiatric symptoms.	Deficiency of serum ceruloplasmin, excessive hepatic copper, Coombs negative hemolytic anemia, hypercupriuria.	Penicillamine, trientine, and zinc acetate are approved for treatment. Treatment must be lifelong whether symptomatic or not or death from CNS or liver pathology will occur.

Alpha-1-antitrypsin deficiency	Alpha-1-antitrypsin is produced by the liver and it inhibits proteolytic enzymes throughout the body with the most significant effects in the lungs.	Positive for family history of liver and emphysematous lung disease.	Serum protein electrophoresis (low serum globulin); measure alpha-1-antitrypsin levels.	Genetic counseling Liver transplant necessary in severe cases Counseling regarding smoking to prevent severe emphysema
--------------------------------	--	--	---	--

---

**Key:** ANA, antinuclear antibody; ALT, alanine aminotransferase (also called SGP); AST, aspartate aminotransferase (also called SGOT); ELISA, enzyme linked immunosorbent assay; IgM, gamma M immunoglobulin; GGT, gamma glutamyl transferase; MCV, mean corpuscular volume.

## Hepatitis C

### Classic Presentation

Many patients are asymptomatic. If symptomatic, the patient presents with a complaint of chronic malaise or fatigue. If presenting during the prodrome, the patient may have signs of serum sickness such as urticaria, rash, and arthralgias. There may be upper right quadrant abdominal pain during an acute attack.

### Cause

Infection with the hepatitis C virus (HCV) is usually related to exposure by the parenteral route (needle use including infected transfused blood, contaminated needles in drug abusers, and tattoos). The most common individuals are homosexual men, drug abusers, visitors and immigrants from endemic areas, neonates born to infected mothers, prisoners and the institutionalized, and medical workers exposed to accidental needle pricks. Infection at an early age in developing countries usually is unremarkable with only mild disease and no jaundice. HCV is an infectious disease notifiable on the national level. There are 40,000 new cases of chronic hepatitis in the United States each year. Two-thirds of individuals with chronic HCV are undiagnosed. The CDC recently recommended screening for HCV for all individuals born between 1945 and 1965. It is the most common cause of chronic liver disease and need for liver transplants in the United States. There has been a reduction in new cases since all donor blood has been screened since 1992.

### Evaluation

The patient may have hepatomegaly with upper right quadrant tenderness. Another characteristic sign is dark urine. At some point the patient may develop a fever that precedes the appearance of jaundice. Interestingly, the onset of jaundice occurs when the patient begins to feel better and the fever rapidly decreases. If patients do become symptomatic it is usually two weeks post-exposure, persisting for 2–12 weeks. White blood cell count and ESR are generally normal. Levels of liver enzymes such as ALT and AST are high with acute HCV; however, most liver enzymes are not greatly elevated in chronic HCV. HCV RNA is positive one to two weeks post-exposure. Anti-HCV is negative until at least two months post-exposure. For chronic HCV, ultrasound and liver biopsy may be necessary to determine the degree of liver damage.

## Management

Initially therapy was with interferon monotherapy. Recent advances have enlisted the addition of drugs that have specific effects on viral replication. With the older therapy the viral clearance rate was less than 10%. Now the rate with the addition of these new medications is around 70%. The combination of peginterferon and ribavirin leads to a 70% to 80% response against HCV for genotype 2 or 3 but only a 45% to 70% response for other genotypes. This has led to a triple therapy approach using one of two new protease inhibitors added to the standard care. There is still controversy about the effect and risk of this new approach.<sup>56</sup> New studies are necessary. Treatment within 12 weeks of exposure is highly effective. Treatment is less effective for those >60 years old. (*Note: For chronic liver diseases, see [Table 21-3](#).*)

## Chronic Myelogenous Leukemia

### Classic Presentation

The patient is usually middle-aged or older and complains of fatigue, night sweats, and a low-grade fever.

#### Cause

Overproduction of myeloid cells that are capable of differentiation is due to an abnormality of the Philadelphia chromosome (reciprocal translocation of long arms of chromosomes 9 and 22). The BCR-ABL oncogene on the Philadelphia chromosome facilitates the production of the BCR-ABL protein, which inhibits cell apoptosis and DNA repair. Sixty percent are symptomatic. Forty percent are asymptomatic and are identified only by a blood test. If allowed to progress, CML in the chronic phase progresses to an accelerated phase and then a final blast phase (becomes acute leukemia) within about three to five

years. In the accelerated phase there may be upper left quadrant pain and referred left shoulder pain due to splenic rupture.

## Evaluation

The patient will have splenomegaly at some point. The diagnosis is based on laboratory findings of a markedly elevated white blood cell count ( $> 150,000/\text{mm}^3$ ) with granulocytes in various stages of development. Blasts are less than 5%, and basophilia may be present. Uric acid levels may be elevated. Cytogenic testing can include detection of the Philadelphia chromosome  $t(9,22)$  using FISH or reverse-transcription-polymerase chain reaction.

## Management

The disease is eventually fatal unless the patient is treated with medication or has a bone marrow transplant. Tyrosine kinase inhibitors (TKI) are the mainstay of treatment. As of 2014 there were five approved TKIs including the first-generation imatinib, and more potent second-generation products dasatinib, nilotinib, bosutinib, and ponatinib. For patients in the chronic phase of CML, dasatinib and nilotinib are more effective. A decision regarding which is appropriate for each individual patient is obviously an informed decision with the managing oncologist. Of patients on TKI therapy, 71% maintain results for at least seven years. The success rate is 70% to 80% for bone marrow transplant in patients under age 40 years who have the transplant within one year of the diagnosis.<sup>57</sup> (*Note:* For other leukemias, see [Chapter 52](#).)

# CHAPTER 22

## Fever

### Context

Although fever may not be a common presenting complaint to a chiropractic office, its presence among other signs or symptoms, or lack thereof, provides an important clue in differential diagnosis.

Temperature should be measured in:

- Children on an initial visit who appear to have low energy, loss of appetite, or decreased playfulness
- All patients with signs of infection or generalized inflammation
- All seniors on initial presentation

Fever of unknown origin (FUO) is a temperature greater than 38.3° C (101° F) that is present several times over a three-week period (undiagnosed after one week) or a persistent fever for 10 to 14 days that remains undiagnosed.<sup>1</sup> It is unlikely but possible that this scenario may present to a chiropractor's office. If so, it is important to recognize the potential seriousness of this presentation. One study estimated that approximately 41% of children with true FUO had a chronic or fatal disease.<sup>2</sup> The primary focus of the following discussion is on proper assessment of temperature and a generalized approach to narrow possibilities.

There are many misconceptions with regard to fever. It is important to bear in mind the following:

- Fever is a protective response, and is not in and of itself bad.

- Fever does not always indicate infection.
- Although there is a reference normal temperature of 98.6° F, this does not represent a "fixed" normal.
- Fever is often regarded as a symptom; however, it is possible to feel "feverish" and not have a fever, or to feel normal and have a fever. It is also possible for someone with a fever to appear normal, sometimes even hyperactive; therefore, fever must be objectified.

The standard normal temperature of 98.6° F was established over 130 years ago by Wunderlich.<sup>3</sup> Recently, this has been called into question and reexamined. Mackowiak determined that the mean body temperature was not 98.6° F, but 98.2° F (close enough!).<sup>4</sup> More important is the recognition that there is a normal range of temperature that varies. Temperature is usually the lowest in the morning, highest in the late afternoon and early evening. This diurnal variation is as much as 1° F to 1.5° F. According to Mackowiak's study, fever in young and middle-aged adults is classified as a reading at or above 37.2° C (99.0° F) in the early morning; in the evening, at or above 37.8° C (100° F). There are other normal variations that must be acknowledged, as follows:

- Women have a rise in temperature at ovulation of 0.5° F to 0.75° F due to production of progesterone. The temperature returns to the normal basal reading at the beginning of menstruation.

- Children often have an exaggerated response to infection, generating a much higher temperature than adults with the same infection or cause.
- Senior patients generally have a lower mean temperature (average of 36.2° C [97.2° F]); their response to a pyrogenic stimulator is often less remarkable than that of a younger adult; seniors often do not feel that they have a fever when, in fact, they have one.
- Exercise can raise the body temperature.

FUO is a worrisome phenomenon. The medical criteria are fever higher than 38.3° C on several occasions for three weeks or longer in patients without neutropenia or immunosuppression. Of these patients, the statistical breakdown of cause is as follows:

- 25% have chronic, indolent infection.

- 25% have autoimmune disease.
- 10% have a malignancy.
- The remainder have miscellaneous or no known cause.

In cases of FUO, 5% to 35% go undiagnosed, with approximately 75% of these resolving without incident (the majority having an infectious etiology).<sup>5</sup> However, there are still concerns. As with a standard self-remitting fever, the most common cause of FUO is infection. The most common causes are tuberculosis and endocarditis. Other common infections that may not have obvious associated signs are sinus infections and urinary tract infections. The second most common cause of FUO is neoplasms, especially leukemias, lymphomas,

and solid tumors of the abdomen. Obviously, a patient with FUO must be referred for a medical evaluation to uncover these potentially life-threatening and often curable disorders.

## **General Strategy**

### **History**

Screen for patients at risk, including those with a history that might suggest an infectious, inflammatory, hemorrhagic, or cancerous process.

### **Evaluation**

- Determine the temperature using a mercury, electronic, or infrared device (rectal temperature readings are reserved for infants, or athletes suffering from hypo- or hyperthermia).
- Attempt to match other physical signs that localize to a specific organ system or process.

### **Management**

- Refer the patient if an underlying serious process is discovered, if the fever is persistent for more than 10 days, if the fever is greater than 104°F, or if the fever is present off and on over a period of three weeks (FUO).
- Minor fevers (101°F or less) associated with signs of gastroenteritis, flu, or other common infections can be managed with time and monitoring; if necessary, aspirin (not for children) or acetaminophen every four hours is effective.
- Fevers of 102°F to 104°F do not usually require treatment; however, cold sponges, ice packs, or cold baths may help in reducing body temperature.

### **Relevant Physiology**

Phagocytic leukocytes release endogenous pyrogens (proteins) into the bloodstream in response to a host of pyrogenic triggers. The

endogenous proteins reach the thermoregulatory center in the anterior hypothalamus, causing the production and release of prostaglandins. The result is a new set-point for the body requiring measures to raise body temperature, including shivering and vasoconstriction. Following is a general list of conditions that may cause fever:

- Infections
- Connective tissue disorders
- Thromboembolic hemorrhage
- Various metabolic conditions
- Neoplasms
- Vascular events

**Table 22-1** gives a more extensive list under each category. Generally, infection is the most common cause, resulting in a fever that is gone within one week. When fever persists beyond this time frame, the other categories of disorders should be considered. **Table 22-2** is a list of named fever disorders.

## Hyperthermia

### Heatstroke (Sunstroke)

With heatstroke, hyperthermia is due to a failure of the body's normal heat loss mechanisms. Usually sweating is markedly decreased, allowing for sustained body temperatures in the 40°C to 41°C (104°F–106°F) range for several hours, with associated circulatory collapse and death if untreated. The individual will often experience disorientation, headache, vertigo, and fatigue, leading to unconsciousness and convulsions. Pulse increases without a concomitant change in blood pressure. The skin is flushed, dry, and hot. If the patient survives, permanent brain damage and renal failure are possible. Emergency management (until hospital management) includes removing all clothes and wrapping the individual in wet blankets while fanning to increase loss of heat through evaporation. If the patient can be immersed in water, especially cold water, this should be done, watching for shivering. Shivering should be avoided because it increases core temperature. Temperature is monitored rectally every 10 minutes and not allowed to drop below 39.3°C (101°F).

## Heat Exhaustion

Unlike heatstroke, the body’s ability to dissipate heat is functional. Heat exhaustion is a loss of fluid and electrolytes through excessive sweating. Initially presenting as a fatigued, weak, and anxious individual, heat exhaustion will progress to circulatory collapse with the individual losing consciousness. With progressing circulatory collapse, the patient will have cold, clammy skin and a slow, difficult-to-palpate pulse. The core temperature is usually in the “fever” range of 38.3°C to 40.6°C (101°F-105°F). The primary concern is conserving fluid loss and assuring blood supply to the heart and brain. Placing the patient flat or with the head slightly down and replacing fluids slowly with an electrolyte solution such as a sports drink or slightly salted water should be initiated until the patient can be assessed medically.

## Heat Cramps

Heat cramps may occur when excessive sweating results in significant fluid and electrolyte loss. This is most common with individuals involved in outdoor occupations and with athletes. It is more common in dry environments where sweating is not as obvious. Cramping is usually in the extremities; however, it may start in the abdominal muscles and simulate an abdominal (visceral) presentation. Replacement of water and electrolytes is preventive and palliative.

Table 22-1 Causes of Fever		
Infection	Autoimmune disease	Neoplasms
Bacterial	Systemic lupus erythematosus	Primary neoplasms
Viral	Polyarteritis nodosa	• Colon
Rickettsial	Rheumatic fever	• Rectum
Fungal	Polymyalgia rheumatica	• Liver
Parasitic	Giant-cell arteritis	• Kidney
Mycobacterial	Still’s disease	Neuroblastoma
Hematologic	Relapsing polychondritis	Liver metastasis

	Dermatomyositis	
Lymphomas	Adult rheumatoid arthritis	
Leukemias		
Hemolytic anemias		
<b>Endocrine disease</b>	<b>Cardiovascular disease</b>	<b>Abdominal disease</b>
Hyperthyroidism	Myocardial infarction	Inflammatory bowel disease
Pheochromocytoma	Pulmonary embolism	Liver abscess
		Alcoholic hepatitis
		Granulomatous hepatitis
<b>Miscellaneous</b>	<b>Central nervous system disease</b>	<b>Chemical</b>
Sarcoidosis	Cerebral hemorrhage	Drug reactions
Familial Mediterranean fever	Head injuries	
Factitious fever	Brain and spinal cord tumors	
	Degenerative CNS disease	
	Spinal cord injury

**Table 22-2** Some Named Fever Conditions

<b>Type</b>	<b>Summary of Information</b>
Colorado tick	An infection transmitted by tick bites in the western United States and Canada, most often in the "tick season" of March through November. Acute onset of a high fever, often with chills, other flu-like symptoms, and a light rash. There are often two to three bouts of fever lasting 1-3 days. There is

	leucopenia with a shift to the left. A reverse transcriptase PCR assay is diagnostic.
Dengue	Spread by mosquitoes, this viral infection previously was limited to Thailand, the Philippines, India, the Caribbean, Central America, and the northern half of South America, but has now reached the southern United States. Infection may be asymptomatic or present as a wide range of severity, including severe hemorrhage and fatal shock. There is a biphasic fever, with the first phase lasting a few days longer. There is also a biphasic rash appearance during remission from the first fever or beginning of second phase. This may be the only distinguishing clinical sign differentiating it from malaria or yellow fever. Leukopenia and thrombocytopenia will be present in the hemorrhagic form. There are rapid serologic assays available to help diagnose the condition. There is no specific treatment other than to maintain volume and use acetaminophen.
Hemorrhagic	A very diverse group of infections may cause hemorrhagic diastasis. Transmission is also variable, including transmission from ticks, rodents, and mosquitoes. Examples include the following fevers: yellow, dengue, Chikungunya, Ebola, Omsk, and Forrest fever among many others. A high fever with leukopenia, hemorrhagic diastasis, and altered mental status are common in the presentation. There is no specific treatment for most.
Mediterranean (familial)	An autosomal recessive disorder affecting people of the Mediterranean with a specific appearance in Sephardic Jews, Armenians, Arabs, and Turks. The (familial) disease is due to a lack of a specific protease. Patients develop severe abdominal pain, peritonitis, and fever that resolves within one to two days. There is a genetic test to confirm the diagnosis. Colchicine is used if amyloidosis develops.
Rheumatic	A sequelae to a beta-hemolytic infection of the pharynx, this immune response is quite rare in the United States. Antibodies are developed against primarily the heart (heart valves), joints, and nervous tissue. The Jones criteria are used, which include two major and two minor criteria. In essence, mitral valve or other cardiac involvement, erythema marginatum (skin lesions), Sydenham's chorea, and arthritis are the areas evaluated. The laboratory diagnosis is with the finding of antistreptococcal antibodies, which includes antistreptolysin O and antiDNase B. A nonspecific finding is an increase in ESR. Treatment is with penicillin or, in those who are allergic, sulfonamides or erythromycin. Salicylates are used for the fever and joint pain. Prophylaxis for recurrent attacks may be necessary.
Scarlet	An uncommon disorder caused by group A streptococcal infection that produces an erythrogenic toxin causing an abdominal rash and lateral chest, a "strawberry" tongue, and symptoms similar to other streptococcal pharyngitis diseases. Group A beta-hemolytic streptococci are found in culture from the throat, and the antistreptolysin O titers rise. Treatment is with penicillin or, in those who are allergic, sulfonamides or erythromycin. Salicylates are used for the fever and joint pain. Prophylaxis for recurrent attacks may be necessary.
Typhoid (enteric)	A salmonella typhi infection that produces malaise, headache, cough, sore throat, abdominal pain and, initially, constipation. The patient may develop a rash (rose spots), abdominal distention, splenomegaly, and bradycardia. Diagnosis is preferentially from blood culture of the organism. The fever gradually increases over 10-14 days, at which time the patient is feeling the worst. If there are no complications, the patient will gradually improve over the following 7-10 days. Transmission is through consumption of contaminated food or drink. Incubation is 5-14 days. There is growing

	resistance to the traditional antibiotics. Most recently, ceftriaxone and fluoroquinolones are used.
Yellow	Yellow fever is a viral infection spread by mosquitoes primarily in Africa and South America. There is a mild and a severe form. The mild form presents simply as "flu" symptoms. The severe form (15%) first appears as the mild form, and after a few days progresses to fever, bradycardia, GI bleeding, nasal bleeding, jaundice, hypotension, and delirium. Diagnostically, there is proteinuria and is usually confirmed by a specific rapid test IgM capture enzyme immunoassay (EIA). There is no specific treatment. Those who do not survive often have signs of intractable hiccups, black vomitus, anuria, and melena.
Malaria	Malaria is a parasitic infection transmitted by mosquitoes in many parts of the world, including the tropics and subtropics, accounting for 300 million infected individuals per year and 1.5–2.7 million deaths. There are four species of plasmodium; some are more endemic to certain regions. Malaria is still evident in Mexico, Haiti, the Dominican Republic, Central and South America, Africa, Southeast Asia, China, the Middle East, and Indonesia. Cases have been "imported" to the United States. Malarial attacks occur over hours, with shaking chills and fever. Associated flu-like symptoms are present. Symptoms seem to alter on an every-other-day or every-three-days cycle. The organism is demonstrated on thick or thin blood film. Approximately 2% of the RBCs are affected. A large armamentarium of antimalarial drugs is available. Some strains have become resistant to some of the standard approaches. Chemoprophylaxis is available for those traveling to high-risk areas.

## Evaluation

## Examination

Although generally the history is the starting point in evaluation, the order has been switched to emphasize the need for an accurate, consistent measurement of body temperature. The armamentarium for body temperature evaluation has expanded beyond the simple mercury thermometer.<sup>6</sup> Now available are mercury-in-glass, electronic, infrared, and strip thermometers. Mercury thermometers can be used orally, rectally, and in the axillary region. (The least reliable and most susceptible to variation is the axillary reading; it has largely been avoided when possible.) Oral mercury thermometers are accurate when properly used; however, readings take between four and eight minutes depending on whether or not the patient is febrile. Electronic thermometers take only about 30 seconds in comparison. They also use disposable, unbreakable probe covers. The new infrared thermometers have recently become less expensive and provide an accurate

measurement in a few seconds. Paper strip thermometers are convenient, but they are not considered very reliable.

The standard for medical recording is in degrees Celsius (centigrade) (C). The conversion formulas are: • degrees C =  $(^{\circ}\text{F} - 32) \times \frac{5}{9}$

• degrees F =  $(\frac{9}{5}^{\circ}\text{C}) + 32$

Following is a suggested technique for taking an oral temperature with a mercury thermometer: • If the patient has just had hot or cold liquids, wait 15 minutes prior to evaluation.

- If the patient has just smoked, wait two minutes.
- Shake the thermometer down to a temperature of 35.5°C (96°F).
- Make sure the thermometer has been sterilized and/or has a disposable probe slip in place.
- Place the thermometer at the base of the tongue on either side of the posterior sublingual pockets (not in the middle of the tongue).
- Instruct the patient to keep his or her lips closed.
- Leave the thermometer in place for three to four minutes if the patient is afebrile.
- Leave the thermometer in place for up to eight minutes if the patient is febrile.

For an infrared thermometer:

- Gently place the covered probe tip in the patient's ear.
- Do not force the thermometer into the ear or fully block the canal.
- Activate and read the temperature in approximately two to three seconds.

Rectal temperature is considered to be a more accurate measure; however, it is less convenient in most cases. When other devices are not available or when measuring for hypo- or hyperthermia, rectal temperature is preferred.

- Wear gloves.
- Lubricate the probe end of the rectal thermometer (it has a more short, blunt probe compared with the oral thermometer).
- Insert the thermometer about 1 inch toward the umbilicus.
- Leave the thermometer in for two and a half minutes.
- Rectal readings are generally 0.5°C (1°F) higher than oral readings.

A factitious fever should be suspected in patients who are emotionally disturbed. These patients are often women working in

healthcare positions. Clues to a factitious fever include the following: • The fever is out of proportion to patient's general appearance—no loss of weight, no prostration, no sweating.

- The pulse rate does not increase proportionately with the degree of fever.
- The urine temperature does not match the rectal temperature (rectal temperature is significantly higher).

The remainder of the examination is a generalized approach looking first for clues such as the following: • Examination of the skin for patterns of lesions (and in the history a sequence of appearance) (found with common childhood diseases, venereal disease, and rheumatoid and connective tissue disorders) • Auscultation of the heart for murmurs

- Auscultation of the lungs for rales
  - Palpation of the calves for localized swelling (thrombophlebitis) • Examination for tophi at the big toe, knees, elbows, and ears • Examination of the abdomen with a complaint of associated abdominal pain
- This generalized approach should provide clues that narrow the possibilities. Further testing with laboratory, radiographs, or special studies should be justified by the history and physical exam findings. Researchers performing a literature review evaluated the value of signs, symptoms, and tests for adult patients with meningitis.<sup>7</sup> The researchers concluded that given the seriousness of meningitis, most physicians proceed to lumbar puncture based on a few positives. In adult patients, the absence of the classic triad of fever, neck stiffness, and altered mental status virtually eliminates a diagnosis of meningitis (i.e., rules out meningitis). Kernig's and Brudzinski's signs have low sensitivity but possibly high specificity (rule-out) value. Jolt accentuation of a patient's headache may be useful. Seventy-three percent of patients with meningitis have a petechial rash according to this study.

## History

Given the enormous numbers of pyrogenic stimulators, the diagnostic approach is a search for the above-listed categories. The approach is a broad-based evaluation looking for any clue that may suggest the underlying cause. It is highly unusual to have fever as the only indicator of a disease or disorder. Localizing findings by organ or system is

usually revealing. See the applicable chapters of this text based on these accompanying signs or symptoms.

General indicators of a viral infection in an adult are a low-grade fever and associated general aches and pains, a headache, malaise, or fatigue. An adult with a bacterial infection presents with a fever above 103° F and the general symptoms of a viral infection plus some localizing findings in the throat, abdomen, or chest. Children, on the other hand, may run high temperatures with almost any illness, including viral infections, otitis media, measles, and roseola. Very high readings (>105° F) are medical emergencies suggesting intracranial hemorrhage or tumor, pancreatitis, or a bad urinary tract infection. If the temperature remains at this elevation, significant brain damage or malignant cardiac arrhythmias may occur.

When the fever is not obviously tied to a flu or upper respiratory infection, a potential valuable avenue of questioning is recent travel within or outside the United States.<sup>8</sup> Certain fungal infections are endemic to specific regions of the United States. Following the same line of questioning, contact with certain animals such as birds, dogs, cats, rats or other rodents, or livestock suggests a specific infectious organism.

In the past, it was recommended to determine a time curve for fever presentation in an attempt to attach a specific diagnosis to a specific pattern of fever activity. This approach is now not considered useful as a match-type approach. The temporal sequence, however, may provide valuable clues to the underlying cause.

## Management

There are two overlapping goals of management: (1) control for excessive fever and ensure adequate hydration, and (2) treat the underlying cause if it poses a health risk to the patient. Control of fever is rarely necessary unless it reaches the range of 103° to 104° F. At this level of fever it may be necessary to use cold packs, alcohol or cold sponges, or cold baths. Generally, this level of fever is well tolerated. If medication is used it is important to give aspirin or acetaminophen every four hours without a break in routine. Giving it only at night may cause a reactionary occurrence of chills or sweats. It is important not to give aspirin to children, especially those with flu or chicken pox, because of the risk of Reye's syndrome (leads to brain and liver damage or death).

## **CHAPTER 23**

# **Sleep and Related Complaints**

### **Context**

If asked, most patients would have a complaint of disrupted sleep at some times in their lives. Often they can relate this to a specific event such as a stressful incident, alcohol ingestion, or pain. When it is a prolonged or chronic problem, the patient becomes concerned. The conscious effort to initiate sleep often may worsen the condition. It is interesting to note that underreporting is the standard for one of the most common sleep disorders: insomnia. A Gallup survey found that only 5% of insomniacs consulted a physician. Approximately 30% had mentioned it when presenting to a doctor for other complaints.

It is not always obvious what a person does or does not do during sleep. This is important when considering that the result of sleep dysfunction is excessive sleepiness often without a complaint of disrupted sleep. Instead, the primary complaint is tiredness or fatigue. With excessive tiredness or fatigue, there is the obvious disruption of functional ability with daily activities; however, the larger concern is the potential danger when driving a car or operating other potentially dangerous machinery.

Although many sleep problems are transient and/or benign, when a primary sleep disorder is detected, further

evaluation at a sleep laboratory is necessary to identify clearly the cause and plan for subsequent management.

## General Strategy

# History and Evaluation

- Determine whether the patient is able to describe the complaint, attempting to clarify whether the problem is in falling asleep, constant interruption of sleep, inability to fall back to sleep after early morning awakening, “light” sleep, or other difficulty.
- Determine associated problems such as excessive daytime sleepiness.
- Determine possible causes or contributing factors, including the following:
  - 1.** Diet related—alcohol, caffeine, food allergy
  - 2.** Smoking (more than one pack per day)
  - 3.** Drugs—cocaine, over-the-counter (OTC) stimulants such as nasal sprays, abuse of OTC sleep medications, prescription drugs
  - 4.** Underlying disorders such as asthma, hypo- or hyperthyroidism, chronic obstructive pulmonary disease, congestive heart failure
  - 5.** Painful conditions (headaches; hip, knee, shoulder, low back, and/or neck pain)
  - 6.** Restless legs or muscle cramps
  - 7.** Amount of sleep, jet lag, work habits
  - 8.** Stress and possible depression
  - 9.** Moderate exercise prior to sleep
  - 10.** Past diagnosis or treatment of a psychologic/psychiatric disorder
- If the patient is presenting with a complaint of fatigue or tiredness, it may be necessary to obtain an eyewitness account of his or her sleep pattern.

# Management

- If a primary sleep disorder is suspected, referral to a sleep laboratory is warranted.
- Make recommendations regarding sleep hygiene (**Exhibit 23-1**).
- Conservative management may be appropriate when sleep hygiene is the primary cause; however, specific sleep disorders should be referred to a specialist for management.
- For obstructive sleep apnea, use of a dental appliance and loss of weight may be effective. If not, referral for Continuous Positive Airway Pressure (CPAP) will likely be beneficial.

## **Exhibit 23-1 Sleep Hygiene**

- Go to bed at a consistent time.
- Sleep in a comfortable room that is cool and free of stimulation (noise, light, restless sleep partner).
- Sleep on a comfortable bed (more firm is suggested).
- Do not eat large amounts of food prior to sleeping.
- Avoid alcohol, smoking, and caffeine prior to sleeping.
- Do not exercise heavily before sleeping.
- Avoid daytime napping.
- If focused on a bothersome mental concern, write it down and deal with it in the morning if possible.
- If unable to sleep after 30 minutes, get up and have a light snack or listen to soothing music; then return to bed.
- Avoid the use of OTC sleep medications.
- Weight reduction may be helpful to those with central sleep apnea.

# Relevant Anatomy and Physiology

Sleep is a complex interactive function coordinated by many parts of the brain. The structures that facilitate sleep include the basal forebrain, the dorsal raphe nuclei, the midline thalamus, and the area around the solitary tract in the medulla. Waking is facilitated by the reticular activating system (pons and midbrain) and the posterior hypothalamus. This interaction is dependent on changing levels of serotonin, catecholamines, acetylcholine, and a host of other neurotransmitters. During sleep there are also fluctuations of hormonal levels that may play a role in the quality of sleep and wakefulness. One example is the decrease in epinephrine and cortisol coupled with elevated histamine and other mediator levels between midnight and 4 a.m. These changes correlate with worsening of asthma at night.<sup>1</sup>

Sleep is generally divided into two phases in relationship to changing eye movement and other electrophysiologic events: rapid eye movement (REM) sleep and nonrapid eye movement (NREM) sleep. These two distinct states cycle throughout the night at about 90- to 120-minute intervals. Most individuals pass through three to five cycles per night. They are not equal, however. NREM accounts for approximately 80% of total sleep.

Sleep is further divided based on EEG changes.<sup>2</sup> Normally, individuals pass through the following sequence based on these changes, waves, and rhythms: • Alpha rhythm is evident in primarily occipital leads with the eyes closed and the individual relaxed.

- NREM

- 1.** Stage 1 characterized by theta waves.
- 2.** Stage 2 characterized by theta waves interrupted by sleep spindles and K-complex spikes.
- 3.** Stage 3 characterized by delta (slow) waves.  
(Patients awakened during delta sleep recall more thought fragments than actual dreams. Only 5% of patients recall vivid dreams.<sup>3</sup>)
- 4.** After about one

hour, stage 2 patterns are repeated followed by a longer time spent in slow-wave sleep.

- 5.** Approximately a one-minute delay is followed by REM sleep, although generally this does not occur on the first pass-through cycle of sleep.
- REM
    - 1.** Characterized by beta waves (paradoxical sleep because more characteristic of wakefulness). Heart rate, respiration, blood pressure, and penile erections vary widely throughout REM sleep.
    - 2.** Characterized by vivid dreaming, rapid eye movements but paralysis of trunk and limb musculature. This accounts for the occasional phenomenon of sleep paralysis wherein, upon wakening, an individual is temporarily not able to move. Vivid dreaming during REM is purported to be due to visual cortex activation through a pathway connecting the pontine reticular formation and the lateral geniculate body to the occipital cortex (PGO pathway).
    - 3.** REM becomes more dominant throughout the last two sleep cycles prior to waking.

There is a maturation phenomenon associated with time spent in REM or NREM. Newborns spend 50% of their time in REM and enter REM soon after sleep initiation.<sup>4</sup> The time spent in REM decreases as the newborn matures to as little as 20% by six months of age. The corresponding switch to an adult pattern of NREM/REM cycling begins at around four months of age and is associated with a concomitant increase in the production of melatonin. This connection between melatonin and sleep has led to the recent use of melatonin in the elderly to help “normalize” sleep. In the elderly the amount of REM remains the same; however, there is a marked decrease in deep sleep.

## Classification System

The International Classification of Sleep Disorders is the standard used for categorizations of sleep-related problems.<sup>5</sup> (See **Table 23-1**.) The primary divisions are: **1.** Dyssomnias

**2.** Parasomnias

**3.** Sleep disorders associated with mental, neurologic, or other medical disorders **4.** Proposed sleep disorders

Dyssomnias usually result in excessive daytime sleepiness or are involved with difficulty starting or maintaining sleep, and are further divided into (selected examples given):

- Intrinsic sleep disorders—most insomnias, narcolepsy, and sleep apnea
- Extrinsic sleep disorders—categories of external factors such as eating, drinking, toxins, altitude, and any environmental disruption
- Sleep-wake transition disorders—jet lag, shift work, and circadian rhythm sleep disorders

**Table 23-1** Categorization of Sleep-Related Disorders: An Abbreviated List

Dyssomnias			
Intrinsic		Extrinsic	Circadian Rhythm
Insomnia		Inadequate sleep hygiene	Time zone change (jet lag)
Hypersomnia		Environmental	Shift work
Narcolepsy		Altitude insomnia	Irregular sleep-wake pattern
Sleep apnea (central)		Adjustment sleep disorder	Delayed sleep-phase syndrome
Sleep apnea (obstructive)		Insufficient sleep syndrome	Advanced sleep-phase syndrome
Central alveolar hypoventilation syndrome		Sleep onset association disorder	Non-24-sleep-wake disorder
Periodic limb movement		Food allergy insomnia	
Restless legs syndrome		Nocturnal eating/drinking syndrome	
		Hypnotic-dependent sleep disorder	
		Alcohol/stimulant/toxin-dependent sleep disorder	
Parasomnias			
Arousal Disorders	Sleep-Wake Transition	REM-Related	Other
Confusional	Rhythmic movement	Nightmares	Sleep bruxism
Sleep walking	Sleep starts	Sleep paralysis	Sleep enuresis
Sleep terrors	Sleep talking	Penile erection dysfunction	Abnormal swallowing
	Leg cramps	Painful erection	Paroxysmal dystonia
		REM sinus arrest	Sudden infant death
		REM sleep behavior disorder	Benign sleep myoclonus
Sleep Disorders Associated with Other Medical Conditions			
Mental	Neurologic	Other	
Psychosis	Cerebral degenerative disorders	Sleeping sickness	
Mood disorders	Dementia	Nocturnal cardiac ischemia	
Anxiety disorders	Parkinsonism	Chronic obstructive pulmonary disease	
Panic disorders	Fatal familial insomnia	Sleep-related asthma	
Alcoholism	Sleep-related epilepsy	Sleep-related gastroesophageal reflux	
	Sleep-related headaches	Peptic ulcer disease	
		Fibromyalgia	

Parasomnias are not necessarily abnormalities of sleep but deal primarily with external or internal elements that tend to disrupt sleep and include disorders such as sleep-walking, sleep-talking, movement disorders, nocturnal leg cramps, nightmares, and sleep apnea. See **Table 23-2** for a further breakdown.

## Evaluation

# History

- Obtain a detailed history of the patient's complaint with regard to length of the problem and any recognizable contributing lifestyle events.
- Obtain a detailed history from the sleep partner if available (personal videotaping may be feasible).

## Difficulty Falling Asleep

At some time in everyone's life, difficulty falling asleep has occurred. When this is chronic, it is important to ask questions regarding lifestyle and environment. The most productive avenue of investigation is to ask what occurs prior to going to bed, such as stimulation from exercise, caffeine, smoking, alcohol, stimulating reading, nasal sprays (active ingredient is often ephedrine), argument with family member, or paying bills. If this line of questioning is unproductive, a search for daily activities may yield a possibility. Does the patient take naps; smoke more than a pack of cigarettes during the day; or take steroids, dopaminergic agents, xanthine derivatives other than caffeine (e.g., theophylline for asthma),  $\beta$ -agonists, appetite suppressants, or decongestants?

**Table 23-2** Characteristic EEG Findings with Various Causes and Disorders of Sleep

<b>Disorder or Substance</b>	<b>Characteristic EEG Findings</b>
--------------------------------------	--

Depression	Decreased total sleep time Fragmented sleep Early onset of REM sleep Shift of REM sleep to first half of night Decreased slow-wave sleep
Bipolar disorder	Total sleep time decreased Shortened REM latency Increased REM activity
Sleep panic attacks	Occurs in transition from stage 2 to stage 3 (NREM) in patients with a longer REM latency
Acute alcohol intake	Decreased sleep latency Reduced REM sleep in first half of night Increased REM in second half of night (REM rebound) Increase in stage 3 sleep Vivid dreaming and frequent awakenings
Chronic alcohol intake	Increase in stage 1 Decreased REM sleep
Alcohol or sedative withdrawal	Delayed onset of sleep REM rebound
Smoking (other stimulants)	Decreased total sleep time (mainly NREM) Increased sleep latency
Sedatives/hypnotics	Increased total sleep time Decreased sleep latency Decreased awakenings Variable effects on NREM sleep Antidepressants decrease REM

A curious but distressing disorder is restless legs syndrome. The patient complains of a dysesthesia that is relieved only by moving the legs. In fact, the urge to move the legs is irresistible. The dysesthesia can occur as often as every 20 to 30 seconds and delay sleep well into the early morning. Because of the associated hereditary tendency, it

is important to ask whether relatives experience the disorder or have been diagnosed with a similar condition.

---

## **Early Morning Awakening with Difficulty Falling Back to Sleep**

Questioning directed at possible depression should be initiated with any patient who reports waking up early and not being able to get back to sleep. A quick screening question is, “Are there activities/hobbies/relationships that used to give you pleasure, events that you would look forward to, but no longer hold any interest?” If it seems that the patient has lost interest in past hobbies or activities and feels a lack of drive or energy, endogenous depression is a possible cause when associated with this pattern of sleep disturbance.

Other possibilities include drug-induced early-morning waking. This is more likely to occur with the use of some short-acting benzodiazepines. Alcohol may cause a rebound REM effect, which also will result in early-morning waking. Another condition that may manifest similarly is advanced sleep phase syndrome. This is frequently seen in the elderly.

---

## **Frequent Awakenings (Interrupted Sleep)**

Secondary effects of drugs, pain, an uncomfortable environment, alcohol, abuse, or stress could all result in frequent awakenings. If a screening for the causes of these complaints is unrewarding, however, it is likely that the patient has a primary sleep disorder. Those that cause frequent awakenings are divided into those that result in excessive daytime sleepiness and those that may not.

Does the patient notice repetitive, uncontrolled muscle jerks throughout the night? Some patients with sleep-related (nocturnal) myoclonus are aware of the jerks and partial awakenings throughout the night. Others are aware

of waking often but do not recall the muscle jerks. In these cases, it is extremely helpful to have the report of a sleep partner to corroborate your suspicion. Another possibility is restless legs syndrome. This is characterized by an irresistible urge to move the legs because of a “creeping” sensation inside the calves. Many of these patients also have nocturnal myoclonus. Patients with restless legs syndrome may have an underlying cause. Therefore, it is important to determine whether a deficiency of iron or folate exists or whether the patient is pregnant or has uremia or a peripheral neuropathy. A common misinterpretation is the presence of hypnic jerks, which occur in many people sporadically. This phenomenon is the sudden jerking that occurs as one is falling asleep and does not represent a sign of myoclonus. Persistent leg cramps may also be a cause of frequent awakenings and may be due to excessive exercise, inadequate hydration, or deficiencies in potassium or calcium.

## **Excessive Daytime Sleepiness**

Excessive daytime sleepiness (EDS) is caused by sleep apnea syndrome (43%), narcolepsy (25%), and insufficient sleep.<sup>6</sup> Sleep apnea that is central is not as likely as obstructive sleep apnea to result in EDS. Obstructive sleep apnea causes the patient to increase abdominal pressure as he or she recovers from an apneic episode. As a result the patient may have an apparently unrelated list of associated problems, including the following:

- Early-morning headache
- Urge to void early in the morning or often throughout the night
- Esophageal reflux
- Early-morning hypertension

## **Examination**

The primary evaluation tool for sleep disorders is an overnight polysomnogram.<sup>7,8</sup> This consists of a series of measurements that are superimposed to present a composite picture of various sleep activities. These measurements include the following:

- An EEG

- An electrooculogram (EOG)
- An electromyogram (EMG)
- Arterial oxygen saturation ( $\text{SaO}_2$ )
- Oral airflow (N/OT)
- Thoracic movement (TSG)
- Heart rate (by a cardiometer)
- An electrocardiogram (ECG)

REM and NREM sleep are distinguished by characteristic patterns, especially with the EEG and EOG. These are summarized in [Table 23-1](#).

The most common disorder discovered on polysomnography is obstructive sleep apnea (OSA) syndrome. It is characterized by excessive daytime sleepiness and breathing cessation (apnea) or a reduction of airflow (hypopnea) during sleep. The diagnosis is a combination of these. Following are the terms and criteria:<sup>9</sup>

- **Apnea:** breathing cessation for >10 seconds
  - **Hypopnea:** reduced respiratory airflow by 30% with a 4% decrease in oxygen saturation
  - **Apnea-hypopnea index (AHI):** number of apnea and hypopnea events recorded per hour of sleep
  - 1.** Mild OSA:  $\text{AHI} \geq 5\text{--}15/\text{h}$
  - 2.** Moderate OSA:  $\text{AHI} \geq 15\text{--}30/\text{h}$
  - 3.** Severe OSA:  $\text{AHI} \geq 30/\text{h}$
  - **OSA syndrome:**  $\text{AHI} \geq 5$  with evidence of daytime sleepiness
- The quality of sleep and the degree of excessive daytime sleepiness can be determined by a number of questionnaires or by using laboratory measures such as the multiple sleep latency test (MSLT), which measures how quickly an individual falls

asleep. However, the best combination of evaluation tools is still the Sleep Apnea Clinical Score (SACS). The items are easily determined by history and physical examination:

- Neck circumference

- Hypertension
- Habitual snoring
- Nocturnal gasping or choking

As a single indicator, neck circumference of 50 cm or higher is associated with a modestly increased risk. As neck circumference increases, fewer of the other three variables are required to increase the likelihood of OSA. Matching the value of this approach to a diagnostic threshold of AHI 10/h or higher (determined by polysomnography in a study population):

- SACS >15: increases the likelihood of OSA (LR, 5.2; 95% CI, 2.5–10).

- SACS ≤5: OSA is less likely (LR, 0.25; 95% CI, 0.15–0.42).

Although factors such as snoring and hypertension are important, the literature appears to indicate that although the absence of snoring makes a diagnosis of OSA less likely, neither snoring alone nor self-reported sleepiness and morning headaches discriminate between those with and without OSA.

## Management

- Alter aspects of the patient's lifestyle that might assist sleep, such as reducing smoking, alcohol, caffeine, or OTC stimulants; keeping regular sleeping hours; or decreasing stress (see Exhibit 23–1).
- Refer to a sleep disorder clinic for evaluation and management of primary disorders.

- Refer for psychologic evaluation when sleep disturbance is typical of depression, such as early-morning waking with difficulty falling back to sleep.
- Treat any coexisting musculoskeletal complaints.

Some general measures apply to most patients with sleep difficulties. These include keeping a regular sleep cycle, avoiding stimulation such as exercise, reducing stimulants (nasal sprays, caffeine, smoking, etc.), and decreasing stress. If the patient has a more severe problem or a clear-cut primary or secondary sleep disorder, referral for sleep analysis and treatment is needed. Most sleep medications cause dependence. Zolpidem tartrate (Ambien) is used for the short-term treatment of insomnia. It is a nonbenzodiazepine hypnotic. Eszopiclone (Lunesta) affects GABA receptor complexes, which may be coupled to benzodiazepine receptors. It shortens sleep latency and improves sleep maintenance and does not cause dependence. Below are some selected conditions and the options for management.

## **Sleep Apnea**

Sleep apnea may be central or obstructive. Central sleep apnea is associated with morbid obesity and appears to be associated with a central nervous system, primarily brainstem-related dysfunction that decreases sensitivity to  $\text{CO}_2$  levels and the reflex triggering of breathing to expel excess  $\text{CO}_2$ . Obstructive sleep apnea is far more common and is characterized by periods of apnea due to mechanical or functional blockage to airflow.

Several conservative measures are recommended specifically for those patients with obstructive sleep apnea disorders. It is realistic to state that many of these alterable factors are effective only in mild cases and when the patient

is or can be compliant. Given that two-thirds of patients with sleep apnea have moderate to severe obesity,<sup>10</sup> a loss of weight often will subjectively and objectively improve breathing.<sup>11,12</sup> This is due to increased lung volumes and decreased pharyngeal collapse. Maintaining the weight reduction, however, is notoriously elusive.

Sleep position change may help, with the caveat that it is difficult to avoid certain positions while asleep. It has been demonstrated that apnea occurs less often in the lateral decubitus (side-lying) position than the supine position.<sup>13</sup> Avoidance of alcohol may eliminate a compounded effect on sleep apnea. Alcohol has been shown to depress hypoglossal nerve activity with genioglossal and other support muscle decreases in tone, leading to increases in upper airway resistance even in nonapneic sleepers.<sup>14,15</sup> If sedatives (or narcotics) are used to assist sleep, they should be discontinued if the patient has obstructive problems.

The mainstays for management of OSA are either mandibular advancement devices (MAD), also known as oral appliances, and nasal continuous positive airway pressure (CPAP).<sup>16</sup> Although many oral appliances have been utilized, little information on criteria for the devices or the specific patient group that would benefit has been provided. A fairly comprehensive study suggests, however, that an oral appliance may be beneficial with some patients.<sup>17</sup> Both snoring severity and apnea are improved. In a 2013 study<sup>18</sup> evaluating both the categorization of patients and the results of mandibular advancement using oral appliances, there was again confirmation of the effectiveness; however, there was no real distinction among the types of obstruction. Oral appliance therapy was modestly effective for all types of obstruction including primary retropalatal, retroglossal, and retroepiglottic. The researchers concluded that the success or failure of the device is not based on an anatomical identification of the region of maximal upper airway collapse.

It has been found that although oral appliances can be effective, as many as 35% of patients still needed additional therapy. The compliance rate for patients using oral appliances is approximately 75%. Although side effects are minimal, long-term effects on the temporomandibular joint might occur. Devices generally caused the mandible to advance and rotate downward, thereby enlarging the posterior airway. This may have a secondary effect on the soft palate.

Nasal CPAP was introduced in 1981 as a potential treatment option for obstructive sleep apnea. The general principle is simple: maintain air pressure through a mask that delivers a continuous stream of room air under high pressure, thereby creating a “pneumatic splint.” Although the device appears to be extremely effective, there are several compliance issues that render it far less effective than had been hoped. The mere presence of the machine, the loudness of the blower, and the irritation to the mucosa from constant air have led to a poor compliance rate after several months. Patients complain of nasal problems, throat soreness, and headaches, among other side effects. Patients who remain on CPAP for a minimum of several weeks have improvement in NREM and REM sleep and particularly in daytime function, with much less daytime tiredness. CPAP also improves hypertension and quality of life and even reduces depression and motor vehicle crashes. Improvements in technology may allow adjustment of pressure and oxygen concentration, decreasing some side effects and increasing compliance.

For those patients who do not improve, various forms of surgery are an option. Removing nasal polyps; correcting a deviated nasal septum; or removing tonsils, adenoids, or the uvula is often a first attempt. More radical approaches involve mandibular restructuring. A new technique using a laser to remove or shrink the uvula has a dramatic effect on snoring; however, the effect on apnea is variable.

## **Narcolepsy and Narcolepsy/Cataplexy Syndrome**

Narcolepsy is characterized by sudden sleeping episodes during the day. This is a condition whereby the patient drops into REM sleep without warning. Usually this is for periods of about one hour, several times a day. In addition, the individual will experience sleep paralysis for a minute or two prior to or just after falling asleep. Also associated are hypnagogic hallucinations where the individual combines dreaming from his or her REM state with his or her waking environment. The narcoleptic syndrome involves brief attacks of cataplexy that involves muscle paralysis ranging from simply dropping the head or jaw, or dropping a held object, to full paralysis of the trunk and limbs without loss of consciousness.

It appears that narcolepsy has an autoimmune basis due to the strong association with human leukocyte antigens (HLA) DQw6 and DRw15.<sup>19</sup> There appears to be a decrease in cells in the walls of the hypothalamus and decreased production of an excitatory peptide orexin (hypocretin).<sup>20</sup> Symptoms tend to develop rather early, between ages 15 to 25 years, but it has been recorded as early as at age 2 years and as late as age 45 years. The ASDA criteria for narcolepsy state that no other known disorder is responsible. Symptoms and signs include: **1.** For at least three months, daily or almost daily, lapses into sleep or naps. Indications of cataplexy, including sudden loss of all postural muscle tone related to intense emotion.

- 2.** Excessive daytime sleepiness or sudden muscle weakness. Associated complaints would include sleep paralysis, hypnagogic hallucinations, and automatic behaviors.
- 3.** Polysomnography findings include one of the following: sleep latency of less than 10 minutes and REM latency less than 20 minutes, multiple sleep

latency test with latency of less than five minutes, and two or more sleep-onset REM periods.

Treatment includes central nervous system stimulants for the hypersomnolence (e.g., amphetamine or methylphenidate) and anticholinergics for the cataplexy (e.g., imipramine or protriptyline). Drugs such as modafinil may function by decreasing GABA-mediated neurotransmission while amphetamines (low-dose) and monoamine oxidase inhibitors (MAOIs) may maintain levels of norepinephrine released from the locus coeruleus.

## **Restless Legs Syndrome**

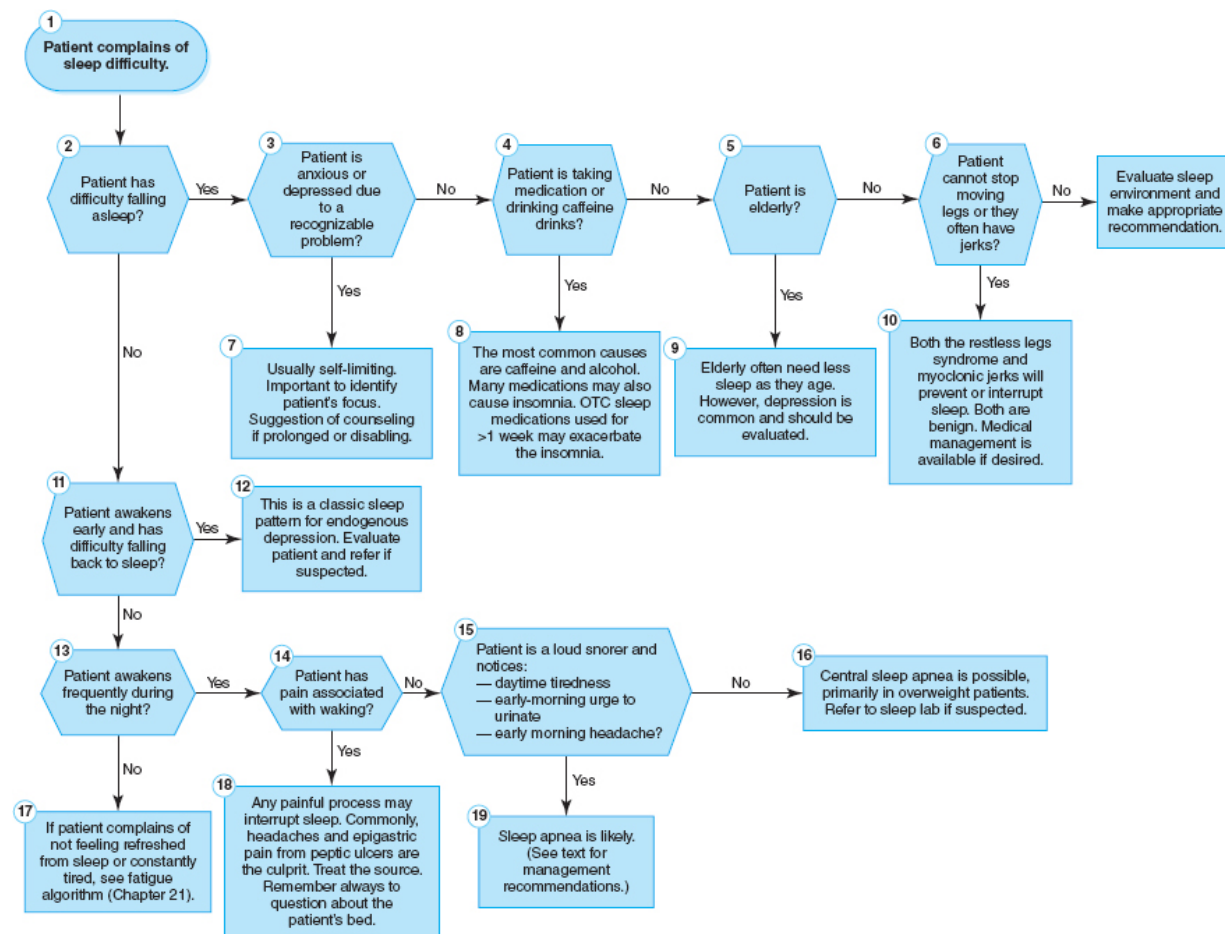

Although many cases are benign, some patients have severe dysesthesia and irresistible leg movements in an attempt at temporary relief. These abnormalities can lead to serious sleep deprivation in some patients because of a prolonged sleep latency until after 3 a.m. Iron supplementation may be beneficial with 65 mg of elemental iron given one to three times a day as needed. Other conservative options include magnesium, passion flower, and valerian root. Caution for those taking quinine. Many individuals are sensitive to quinine and there is no evidence for its use with RLS.

Medical approaches are similar to Parkinson's management. The newest is the use of Requip (ropinirole). The mechanism appears to be stimulation of postsynaptic dopamine D2-type receptors. Another treatment is a tablet containing 25 mg of carbidopa and 100 mg of levodopa (Sinemet) taken before bedtime, and occasionally a second dose during the night or during the day. Other drugs include Neurontin (gabapentin), Lyrica (pregabalin), and gabapentin enacarbil (Horizant). These are referred to as alpha-2 delta drugs, which affect calcium channels.

It is important to caution the doctor that these are not muscle cramps and will not respond to the usual recommendations. The disorder is quite distressing and requires medication in most serious cases.

## Algorithm

An algorithm for insomnia or other complaints of sleep is presented in **Figure 23-1**.

# CHAPTER 24

## Hypertension

### Context

The most common primary diagnosis in the United States is hypertension.<sup>1</sup> Because it is essentially a silent disorder, 30% of individuals are unaware of their hypertension. Cardiovascular disease has been estimated to total more than \$320 billion in healthcare costs in the United States alone.<sup>2</sup> Hypertension is a significant modifiable risk factor for cardiovascular disease.

As primary contact doctors, chiropractors are well positioned for detecting patients with high blood pressure/hypertension (HTN). Given that the majority of these patients will be asymptomatic for HTN, it is important to include screening on all new patients. Jamison et al.<sup>3</sup> have demonstrated that the chiropractor may serve an important role in screening for, and recommending, important lifestyle changes. HTN is found in as many as 50 million Americans; 18% of the adult white population, and 35% of the adult black population.<sup>4</sup> Sixty percent of these individuals have a blood pressure (BP) in the high-normal range. Patients with BP in the high-normal or mildly elevated range can be managed initially with diet and exercise prior to referral for drug management. These patients have been demonstrated to have a 40% increase in risk for cardiovascular disease; thus their management is not to be taken lightly.<sup>5</sup> A 2007 study by Hansen et al.<sup>6</sup> indicates that there is underdiagnosis of hypertension in children and adolescents. In a group of 507 children and adolescents, 3.6% had hypertension. Only 26% of those with HTN had an entry in their medical records and only 11% with prehypertension had an entry. Factors related to an increased associated risk were older age, increase in 1% height-for-age

percentile, obesity, and frequency of prior abnormal blood pressure readings.

The risk of HTN increases with age and is greater in African-Americans than in whites.<sup>4</sup> Although some cases of HTN are due to secondary causes (5%), primary (essential) hypertension accounts for 95% of cases, with no identifiable cause. Secondary causes include the following:

- Estrogen use (5% of women taking oral contraceptives chronically are hypertensive)
- Renal disease and renal vascular HTN (1% to 2% of hypertensive patients)
- Primary aldosteronism and Cushing's disease (or chronic corticosteroid use; 0.5% of hypertensive patients)
- Coarctation of the aorta (prevalence is 0.1 to 0.5 per 1,000 children)<sup>7</sup>
- Pheochromocytoma
- Pregnancy (preeclampsia/eclampsia)
- Disorders associated with hypercalcemia such as thyroid conditions
- Sleep apnea

Uncontrolled HTN puts an individual at risk for coronary heart disease (CHD), congestive heart failure, cerebrovascular events, aortic aneurysms, renal disease, and retinopathy. Many of these disorders are life-threatening. Fortunately, the death rate from CHD and stroke has been reduced 50% or more over the last two decades.<sup>8</sup> This decline has been attributed to public awareness leading to improvements in diet, exercise, and medical intervention.

## Relevant Physiology

Blood pressure is the result of cardiac output and peripheral vascular resistance (PVR). There are numerous factors that can influence either. Basically, the PVR can be increased by smooth muscle contraction or intrinsically elevated through blockages as seen with athero- and arteriosclerosis. Cardiac output increases as

a result of sympathetic discharge from stress or increased metabolic demand. Output also increases with an increased vascular volume; there is more fluid to pump.

PVR is predominantly determined by an interplay among the autonomic nervous system, renal system, and neuroendocrine/hormonal actions. Sympathetic activity increases BP through increases in both PVR and cardiac output. The renin-angiotensin system also plays a key feedback role. Decreases in renal perfusion, increased sympathetic activity, hypokalemia, and arteriolar stretch all may act as initiators of this sequence. Renin secreted by the juxtaglomerular cells causes angiotensinogen to form angiotensin I that is then converted to angiotensin II. Angiotensin II is a potent vasoconstrictor and also causes the release of aldosterone, another vasoconstrictor.

The underlying cause of essential hypertension is unknown; however, it appears to be multifactorial. There may be a genetic predisposition that is most evident when both parents are hypertensive. Other factors that influence HTN are those that influence the development of atherosclerosis, such as diet and exercise, diabetes mellitus, and smoking. Salt intake is a factor in some patients; however, it is usually only one component of an individual's BP increase.<sup>9</sup> Obesity influences HTN through several mechanisms, the most obvious being an increase in intravascular volume with a consequent higher cardiac output.<sup>10</sup> Alcohol consumption also influences BP. The increase in BP is thought to be due to increased levels of catecholamines.<sup>11</sup> Patients with HTN who drink excessively have HTN that is more difficult to control. Smoking has a similar effect, possibly due to increased levels of norepinephrine.<sup>12</sup>

Theories regarding underlying pathology with essential HTN patients include the following:<sup>13</sup>

- Sympathetic nervous system hyperactivity or decrease in sensitivity of baroreflexes
- Renin-angiotensin-aldosterone system (RAAS) dysfunction
- Intracellular increases in sodium

Obesity has been tied to HTN. There is the obvious contribution from increased sympathetic activity and RAAS activity but

additionally there have been some proposed mechanisms through an imbalance of bioactive molecules such as increases in leptin and resistin and decreases in adiponectin. Additionally, obese patients often have obstructive sleep apnea. The contributions of intermittent hypoxia coupled with increased endothelin-1 may also be factors.

One study found that the number of nephrons is reduced in patients with primary HTN and that this appears to be a cause versus a result of HTN.<sup>14</sup>

## General Strategy

- Screen all patients for HTN.
- Check for possible signs and symptoms suggestive of a secondary cause of hypertension: in young patients, renal insufficiency, renal artery stenosis, or coarctation of the aorta are possible causes; in adults, renal artery stenosis, Cushing's disease, hyperthyroidism, and pheochromocytoma should be considered.
- Screen for major risk factors for HTN including smoking, dyslipidemia, diabetes mellitus, age older than 60 years, being male or a postmenopausal female, or a family history of cardiovascular disease (affected relatives are women under age 65 years or men under age 55 years).
- Screen for target organ disease such as left ventricular hypertrophy, angina or prior myocardial infarction (MI), prior coronary revascularization or heart failure, past history of stroke or transient ischemic attack (TIA), nephropathy, peripheral vascular disease, or retinopathy.
- Be vigilant for signs of HTN in the pregnant patient. Its development in later trimesters may be the first sign of preeclampsia/eclampsia.
- Use proper cuff size and procedure; make sure the patient has avoided alcohol for 12 hours and smoking and caffeine at least 30 to 60 minutes prior to examination.
- Recheck high findings at least two other times over the next week to confirm original reading (**Exhibit 24-1**); if severely high on the initial reading, refer for medical evaluation.

- Categorize patients based on level of HTN and associated risk factors.
- Refer patients with mild HTN and existing CHD and patients with moderate to severe HTN.
- Manage or comanage patients with mild HTN with diet, exercise, and possibly stress relaxation approaches.

## Exhibit 24-1 Screening for Hypertension

**Patient's initial BP is out of normal range**

**Determine whether the patient is truly hypertensive:**

Consider, transient influences:

1. Patient
  - caffeine, smoking, or exercise within 30 minutes of BP reading
  - medications
  - stress (white-coat syndrome)
2. Doctor
  - poor technique
  - using too small a cuff
  - wrong arm position

**Measure the BP:**  
BP should be taken 3 times, preferably over 3 days, twice daily. Initial concerns may be decreased by taking 3 BP readings, 20 to 30 minutes apart. If BP reduced to acceptable level, stress is often the cause. Be careful not to take the BP repeatedly on the same arm without adequate rest periods.

**Prehypertensive**  
DBP 80–89 mm Hg  
SBP 120–139 mm Hg

Prescribe lifestyle modifications, monitor, and recheck in 3–6 months.

**Stage 1**  
DBP 90–99 mm Hg  
SBP 140–159 mm Hg  
(70% of all hypertensives)

Half of these individuals have a DBP between 90 and 94 mm Hg. These patients may do well with diet modification and moderate aerobic exercise. Refer if ineffective.

**Stage 2**  
DBP > 100 mm Hg  
SBP ≥ 160 mm Hg

Patients in this range need medical evaluation with appropriate medication. Diet and exercise are important adjuncts to management.

**BP is severely elevated (> 200 SBP or 120 DBP).**

Immediate referral

Always consider a secondary cause in individuals who are younger than age 20 or older than age 55, and/or when the onset is abrupt. Look for endocrine imbalances such as hyperthyroidism or adrenal disease, and in the older individual look for renal artery stenosis.

## Evaluation

### History

Historical clues are important in determining underlying causes of HTN and any end-organ dysfunction as a result of HTN. A significant finding in younger patients is a family history, especially if both parents have HTN. Other familial findings that are significant include stroke, diabetes, cardiovascular disease, and hyperlipidemia. Important personal history information to be elicited include the following:

- Note any symptoms suggestive of end-organ problems (congestive heart failure, stroke, kidney dysfunction, peripheral vascular problems).
- Determine whether there are indicators of a secondary cause (mainly renal, cardiac, or endocrine factors); a history of oral contraceptive use; alcohol abuse; use of antihypertensive medication; or use of possible hypertension-inducing herbs or drugs such as licorice root, corticosteroids, nonsteroid anti-inflammatory drugs, or monoamine oxidase (MAO) inhibitors.
- Ask about any past levels of high BP, cholesterol, and other lipids. Ask about a previous diagnosis of cardiovascular, cerebrovascular, or renal disease.
- Obtain a dietary history; if feasible, ask the patient to keep a diary indicating intake of sodium, potassium, folic acid, fat, and alcohol.
- Determine other lifestyle factors such as intake of caffeine, amount of exercise, work and family environment, and general response to stress.

### Examination

Key to the diagnosis of HTN is an accurate BP measurement. Many factors can influence this reading, thus sequential measurements are required for confirmation. These variables can be classified as

extrinsic or intrinsic to the patient. If the patient has smoked, taken alcohol or caffeine, exercised, or is nervous, BP may be increased transiently. It is generally recommended to wait 30 to 60 minutes after the patient has smoked or ingested alcohol or caffeine (some authors recommend 12-hour abstinence from alcohol). Otherwise the patient should rest at least five minutes prior to examination. Equipment errors may occur if the sphygmomanometer is not calibrated, the pressure leaks, the stethoscope has defects, or the wrong size cuff is used. Although controversial, one study indicated no differences between using the bell or the diaphragm of the stethoscope.<sup>15</sup> However, adding too much pressure from the stethoscope head may decrease the diastolic reading by as much as 10 mm Hg.<sup>16</sup> To accommodate different arm sizes, pediatric, adult, and oversized cuffs should be available. The bladder portion should cover four-fifths (80%) of the patient's arm circumference. Using too small a cuff will increase the BP reading, often substantially. Preferably, measurements should be taken with a mercury sphygmomanometer. Second choices include a recently calibrated aneroid manometer or a validated electronic device. Ambulatory readings performed by patients may be appropriate if there is a high level of suspicion regarding the "white coat" elevation seen in the office with some patients. For in-office measurement, it is important to do the following:

- Seat patient in a chair with his or her back supported.
- Make sure the patient's arm is bare and at heart level.
- Wait at least two minutes between readings on the same arm.
- Measure the BP twice on one arm when the patient is seated or supine; take the BP twice again after the patient has stood for two to three minutes (two minutes between each reading).
- Follow the same procedure on the opposite arm.
- Recheck high readings on the following three days (same time of day).

Ambulatory blood pressure monitoring (ABPM) is an alternative used by medical doctors that provides information throughout

daily activities and sleep.<sup>17</sup> Blood pressure is automatically taken every 15 to 30 minutes. It is used to obtain a more accurate profile for patients in the following scenarios:

- A suspicion of “white-coat” HTN in the absence of target organ damage
  - Patients with apparent drug resistance; patients who have apparent hypotensive symptoms related to antihypertensive medications
  - Fluctuating hypertension
  - Individuals with suspected autonomic dysfunction
- Ambulatory measurements are generally lower than in the clinic setting and correlate better as an indicator of target organ injury. Sleep ABPM is usually 10% to 20% lower than daytime readings. When these reductions do not occur, there is an increased risk for cardiovascular disease and events such as stroke.<sup>17, 18</sup>

The Eighth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure has again redefined the classifications and recommendations for high blood pressure based on new evidence.<sup>19-21</sup> The previous committee felt the need to establish a new prehypertension category based on data that suggest those with a blood pressure between 120–139 mm Hg systolic and 80–89 mm Hg diastolic are at twice the risk of developing HTN compared to those below these levels.<sup>22</sup> Additionally, data from the Framingham Heart Study indicate that even those individuals who are normotensive at age 55 still have a 90% lifetime risk for developing HTN.<sup>23</sup> However, this was not compared to a control group of individuals who lived a healthy lifestyle or changed to a healthy lifestyle. For patients older than age 50 years, systolic blood pressure is a more important CVD risk factor than diastolic blood pressure and is more difficult to control.<sup>24</sup>

Two-thirds of individuals over age 65 years have hypertension, and they also have the poorest success rates for blood pressure control.<sup>25</sup> The JNC guidelines are based on recommendations from the National High Blood Pressure Education Program (NHBPEP), a coalition of 39 professional, public, and voluntary organizations

coordinated by the National Heart, Lung, and Blood Institute (NHLBI). The JNC 7 guidelines categorize blood pressure into the following classifications with recommendations for those without compelling indications (comorbid conditions or risks):

- Normal: <120 mm Hg systolic and <80 mm Hg diastolic: medication not needed, lifestyle recommendations are encouraged
- Prehypertensive: 120–139 mm Hg systolic or 80–89 mm Hg diastolic: medication not needed, lifestyle modification given
- Stage 1 hypertension: 140–159 mm Hg systolic or 90–99 mm Hg diastolic: lifestyle modifications given, medications recommended starting with thiazide-type diuretics (consider others if ineffective)
- Stage 2 hypertension: >160 mm Hg systolic or >100 mm Hg diastolic; lifestyle modifications given; two-drug combination therapy recommended

To be consistent with the literature and recommendations of the JNC, systolic blood pressure is considered the point at which the first of two or more sounds is heard (phase 1) and diastolic blood pressure at the point before the disappearance of sounds (phase 5). Using the visual gauge is not accurate. The JNC also recommends giving patients their specific blood pressure readings and recommendations both verbally and in writing.

In addition to BP measurement, a search should be made for physical signs due to secondary causes or contributors to HTN. Measurement of height and weight is important to determine any level of obesity. Atherosclerosis may diminish pulses. Atherosclerosis and/or high volume or turbulent flow may cause bruits. Auscultation for thyroid, subclavian, aortic, and renal bruits should be performed. Auscultation of the heart may indicate murmurs, S3 or S4 sounds, and arrhythmias. Indication of congestive heart involvement is found with distended neck veins, bilateral lower leg edema, and ascites. Fundoscopic evaluation includes a search for arteriovenous nicking, cotton-wool patches, or papilledema. The thyroid should be palpated and the patient examined for possible hyperthyroidism if indicated.

Laboratory evaluation may be helpful if an underlying cardiac or renal problem is suspected. Indications of kidney dysfunction include creatinine or the corresponding glomerular filtration rate (GFR) (<60 mL/min. is a cardiovascular risk factor). Diabetes is an important cause of HTN and high-risk individuals should be screened for this disease. In addition, a serum cholesterol and lipid panel are helpful in determining hyperlipidemia.

## Management

The 2014 JNC guidelines have made some substantial changes in their recommendations. These changes are really simply establishing thresholds for drug management and seem to ignore lifestyle recommendations. They largely focus on two things; the level of HTN in need of management for those 60 years old and older, and the types of drugs utilized. Following is a summary of those recommendations that reflect the changes:

- For persons aged 60 years or older use a BP goal of less than 150 mm Hg and a diastolic goal of less than 90 mm Hg.
- Keep the threshold of 140/90 mm Hg for all other groups including adults with diabetes or nondiabetic chronic kidney disease (CKD).
- For HTN, initiate drug treatment with either an angiotensin-converting enzyme inhibitor, angiotensin receptor blocker, calcium channel blocker, or thiazide-type diuretic in the nonblack hypertensive population, including those with diabetes.
- As initial therapy in the black hypertensive population, including those with diabetes, a calcium channel blocker or thiazide-type diuretic is recommended.
- There is evidence to support initial or add-on antihypertensive therapy with an angiotensin-converting enzyme inhibitor or angiotensin receptor blocker in persons with CKD to improve kidney outcomes.

Although there are many contributing factors to the development of coronary heart disease (CHD), a recent study

emphasized that 80% to 90% of individuals with CHD have the four “conventional” risk factors.<sup>26</sup> These are cigarette smoking, hypertension, diabetes, and hyperlipidemia. The focus must be on lifestyle changes, including smoking cessation and control of the other three factors that are interrelated.

The conservative management options for the chiropractor hinge mainly on lifestyle modification, including diet and exercise. This approach may be successful if these patients do not have cardiovascular disease or signs of organ damage; however, failure to reduce BP after a reasonable trial of perhaps 6 to 12 months should warrant referral for comanagement. Although there have been several isolated studies reporting reduction in HTN following adjustments of the spine, the current evidence<sup>27</sup> suggests that these effects do not appear to be consistent or permanent. There are only about six publications related to manipulation and its effect on blood pressure (see **Table 24-1**).<sup>28-33</sup> Three utilize a single treatment. Two of these utilized a pre- and posttreatment measurement of blood pressure without any further follow-up. The other four studies had a follow-up of between four to eight weeks. Only two studies demonstrated any significance in blood pressure reduction; however, one was posttreatment only. In the Goertz et al. study,<sup>31</sup> groups were divided into a dietary intervention group only and a combined dietary intervention group plus manipulation. The manipulation was administered three times per week for four weeks for a total of 12 treatments. There was no difference between the dietary intervention only and dietary intervention plus manipulation groups. The other study by Bakis<sup>32</sup> demonstrated a decrease, on average, of 17 points in the systolic blood pressure and 10 points in the diastolic blood pressure after eight weeks. This specific upper-cervical technique approach is currently being expanded to a larger study to determine the effect on a larger patient population with different doctors applying treatment rather than one doctor. In the Plaughter et al. study,<sup>33</sup> the control group actually had a slightly lower average blood pressure than the manipulated group. Clearly more research is needed.

There is an increasing body of literature that supports the use of lifestyle modification for blood pressure control. A recent study reporting the results of the PREMIER Clinical Trial indicated that

even recommending lifestyle changes can have an effect of lowering systolic blood pressure.<sup>34</sup> A supervised program can have even more effect.

Although lifestyle modifications have been undersold with regard to degree of effect, it has been shown that the effects of a 1,600-mg sodium DASH diet is equal or similar to single-medication treatment.<sup>35</sup> Making two or more modifications can result in even greater effects. **Table 24-2** is a summary of the effects of various lifestyle modifications, showing that even small changes can have a dramatic effect.

Physical inactivity is a major risk factor for CVD. Those individuals who are less active have a 30% to 50% higher risk for high blood pressure.<sup>34</sup> Specifically, aerobic exercise has been shown in a recent meta-analysis to decrease blood pressure in both normotensive and hypertensive individuals.<sup>36</sup> Interestingly, a decrease in blood pressure was not always associated with a decrease in weight, indicating that the effects of aerobic exercise on blood pressure may be independent of weight loss. For young adults, it is important to consider psychosocial factors for the risk of HTN. Researchers in one study demonstrated a dose-response increase in the long-term risk for HTN in those young adults with indications of time/urgency/impatience and hostility.<sup>37</sup> The relationship did not exist for achievement/striving/competitiveness, hostility, or depression in this study.

Specific lifestyle modifications include the following:

- Recommend a weight reduction program if the patient is overweight.

**Table 24-1** Manipulation and Hypertension

Study	Technique	# Points	Follow-Up	# Treatments	Results
(2007) Bakris	NUCCA	50	8 weeks	1 (85%)	-17/-10
(2002) Goertz	Diversified	140	4 weeks	12	Not significant
(2002) Plaugher	Gonstead	23	8 weeks	20	Not significant
(2001) Knutson	Upper cervical	110	Post Tx	1	Not significant
(1998) Yates	Activator	21	Post Tx	1	-14/-13
(1985) Morgan	Osteopathic	29	6 weeks	6	Not significant

**Table 24-2** Lifestyle Modifications to Manage Hypertension\*†

<b>Modification</b>	<b>Recommendation</b>	<b>Approximate SBP Reduction (Range)</b>
Weight reduction	Maintain normal body weight (body mass index 18.5–24.9 kg/m <sup>2</sup> ).	5–20 mm Hg/10 kg weight loss
Adopt DASH eating plan	Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat.	8–14 mm Hg
Dietary sodium reduction	Reduce dietary sodium intake to no more than 100 mmol per day (2.4 g sodium or 6 g sodium chloride).	2–8 mm Hg
Physical activity	Engage in regular aerobic physical activity such as brisk walking (at least 30 min per day, most days of the week).	4–9 mm Hg
Moderation of alcohol consumption	Limit consumption to no more than 2 drinks (1 oz or 30 mL ethanol; e.g., 24 oz beer, 10 oz wine, or 3 oz 80-proof whiskey) per day in most men and to no more than 1 drink per day in women and lighter-weight persons.	2–4 mm Hg

DASH, Dietary Approaches to Stop Hypertension.

\*For overall cardiovascular risk reduction, stop smoking.

† The effects of implementing these modifications are dose- and time-dependent, and could be greater for some individuals.

- Emphasize a diet of vegetables, fruits, low-fat dairy products, and foods low in saturated and total fat.
- Reduce daily sodium intake to no more than 1 teaspoon of salt/day (2.4 g of sodium or 6 g of sodium chloride); one suggested approach is to cut down on processed foods (details provided in the National Institutes of Health DASH (Dietary Approaches to Stop Hypertension) Diet (see **Appendix 24-1**).
- Use food sources to increase potassium intake to at least 3.5 g/day by eating foods such as bananas, orange juice, yogurt, potatoes, prunes, or winter squash.

- Perform aerobic physical activity for 30 to 45 minutes per day most days of the week.
- Limit alcohol use to no more than 1 oz of ethanol alcohol per day for men (24 oz of beer, 10 oz of wine, or 2 oz of hard liquor) and half that amount for women or lighter-weight individuals.

The interrelationship among hypertension, atherosclerosis, obesity, diabetes, diet, and exercise should be considered when making recommendations for nutritional support. Specific recommendations for each disorder should be considered if found in an individual patient's profile of risk. Refer to the appropriate chapter for recommendations. Specific recommendations for HTN have included increases in calcium, potassium, magnesium, vitamin E, and folic acid.<sup>38</sup>

The role of potassium in the management of HTN has been underappreciated. It is clear from many population studies that societies with a high intake of dietary potassium have a dramatically low prevalence of HTN. For example, less than 1% of individuals in an isolated society have HTN versus one-third of adults in more industrialized countries.<sup>39</sup> One factor is the amount of naturally acquired dietary potassium. It is known that potassium restriction is the trigger for cells to take in sodium in order to maintain their volume and tone. The difficulty in detecting low levels is that serum potassium may be normal, however, skeletal/muscle potassium is low. Low potassium inhibits insulin secretion and is associated with glucose intolerance. The Institute of Medicine recommends 4.7 grams of potassium per day, which is twice the U.S. average. The forms of potassium that have the greatest antihypertensive effect are fruits, vegetables, and other foods rather than supplementation. However, it has been shown that potassium supplements can dramatically reduce the need for antihypertension medication. In one study, 82% of individuals needed less than half of their medication dosage and 38% required no medication after a one-year follow-up.<sup>40</sup>

There has been a concern regarding sodium restriction, suggesting that it may activate the renin-angiotensin system and adversely affect both the lipid profile and insulin sensitivity. The literature indicates that these concerns have no support. The role

of dietary magnesium and calcium is still debated. Generally, recommendations are that supplementation of magnesium or calcium is not preventive or effective in treating HTN; however, there is still some debate with some subgroups of patients who might benefit.<sup>41,42</sup> Recent evidence suggests that folic acid may be helpful in reducing HTN. The foods highest in folic acid are broccoli, asparagus, and spinach. It has also been suggested that calcium supplementation may lead to a small reduction in systolic BP.<sup>43</sup> A study by Siani et al.<sup>44</sup> indicates that a diet with foods containing L-arginine versus L-arginine supplements had a more beneficial effect on hyperlipidemia and HTN. Arginine is a precursor to nitric oxide, which is a vasodilator. It is found in brown rice, chocolate, caffeine, nuts (e.g., walnuts, filberts, pecans, Brazil nuts), oatmeal, raisins, seeds, and whole wheat bread. The one concern is the balance between L-lysine and L-arginine, especially with patients who have a viral infection (e.g., herpes).

Pregnant women appear to be at increased risk of preeclampsia/eclampsia with calcium deficiency. Either supplementation at 2 g of calcium per day or drinking one or two glasses of milk per day has been shown to decrease the risk of HTN during pregnancy.<sup>45</sup> Interestingly, one study<sup>46</sup> demonstrated an increased risk when women drank three or more glasses of milk per day.

In 2007, the American College of Sports Medicine and the American Heart Association published their updated recommendations for physical activity and public health.<sup>47</sup> All healthy adults age 18–65 years need at least:

- Moderate-intensity aerobic physical activity (e.g., jogging) for a minimum of 30 minutes five days each week.
- Vigorous, intense aerobic exercise for a minimum of 20 minutes three days each week.
- Combinations of moderate and vigorous activity can be used to meet the minimum such as walking briskly for 30 minutes twice per week and jogging for 20 minutes two times during the same week, or moderate-intensity exercise in bouts of 10 minutes or more.

- To perform exercise to maintain strength and endurance two days a week.

They also recommend exceeding the minimum requirement for those individuals wishing to further improve their physical fitness, avoid gaining weight, or decrease their risk for chronic disease and associated disability. Moderate exercise in the range of 50% to 65% of MHR may decrease DBP 15 to 20 mm Hg in patients with mild HTN. Exercise at levels of 70% or above demonstrated an abrupt increase in DBP. One study<sup>48</sup> indicated that patients with mild HTN (DBP, 90 to 105 mm Hg; SBP, 140 to 180 mm Hg) showed no difference between those on an aerobic program and those on a waiting list with regard to blood pressure reduction. However, these patients were exercising at 70% or above the maximum oxygen consumption (VO<sub>2</sub> max). Recent studies<sup>49-51</sup> indicate a benefit to using a routine of aerobic exercise, independent of other factors, in lowering blood pressure. This effect may diminish in magnitude with age.<sup>52</sup> With regard to mortality rates, a study<sup>53</sup> published in 2013 indicated that there was no advantage for running over walking as a choice of exercise for hypertensives.

The use of breathing exercises has been demonstrated in a number of small studies to lower blood pressure.<sup>54-57</sup> From these studies, it appears that reducing the respiratory rate to less than 10 per minute with prolonged expiration has cardiovascular benefits. Reduction rates vary among the studies but seem to be around 10 to 15 mm Hg for systolic blood pressure. There also appears to be an advantage to using a device designed to give feedback for the patient to guide their breathing. The studies indicate that performing breathing exercises at least 15 minutes daily for two months is most beneficial. The effect seems to be more dramatic in seniors and in those with higher baseline blood pressure measurements.

There is still some debate as to the benefit of stress reduction; however, the recommendations of the Canadian Medical Association suggest a role in individualized cognitive behavioral interventions.<sup>58</sup> One recent study<sup>59</sup> suggests that patients who spent time with a personal pet had half the increase in blood pressure compared to those who did not own a pet.

# Medication Summary

Medications reduce the pressure in the cardiovascular system by reducing the force of contraction of the heart, reducing the amount of fluid in the system, or reducing the tension in the arteries/veins. **Table 24-3** is a list of medications commonly used for the control of hypertension. The following general classes of medications accomplish these actions:

**Table 24-3** Antihypertensives

Drug Class	Examples	General Mechanism	Interactions/Side Effects
Angiotensin converting enzyme (ACE) inhibitors	Captopril	ACE inhibitor used in the management of hypertension, congestive heart failure, diabetic nephropathy, left ventricular dysfunction, and post MI	Hypersensitivity reactions, angioedema, persistent cough, orthostatic hypotension, altered taste sensation, positive ANA titers
	Capoten		
	Enalapril	An ACE inhibitor. Blocks the conversion of rennin to angiotensin II, thereby decreasing the release of aldosterone. This blocks the potent vasoconstriction effects of these substances, resulting in a decrease in blood pressure without a compensation of increased heart rate or cardiac output.	May cause headache, dizziness, fatigue, postural hypotension, chronic cough, hoarseness, and rash. May increase potassium levels, BUN, or creatinine.
	Vasotec		
	Lisinopril	An ACE inhibitor. Blocks the conversion of rennin to angiotensin II thereby decreasing the release of aldosterone. This blocks the potent vasoconstriction effects of these substances resulting in a decrease in blood pressure without a compensation of increased heart rate or cardiac output.	May cause headache, dizziness, fatigue, postural hypotension, chronic cough, hoarseness, and rash. May increase potassium levels, BUN, or creatinine.
	Zestril		
Alpha and beta blockers	Atenolol	Beta blocker: A $\beta$ -adrenergic antagonist blocking primarily $\beta_1$ receptors (less bronchoconstriction effect than $\beta_2$ blockers); decreases heart rate and rennin release used in the treatment of hypertension.	CNS depressive effects with concerns for those with diabetes, heart block and heart failure, asthma, and emphysema.
	Tenormin		
	Labetalol	An antihypertensive that acts as an alpha-adrenergic blocker and nonselective beta blocker. Results are decreased peripheral resistance, decreased conduction at sinus node, AV node, and ventricular muscle. Often used with thiazide diuretics.	May cause postural hypotension, bronchospasm, dizziness, fatigue, malaise, tremors, and GI disturbance. May cause positive results on ANA or testing and SLE-like syndrome.
	Trandate		
	Normodyne		
	Metoprolol	Beta blocker: A $\beta$ -adrenergic antagonist blocking primarily $\beta_1$ receptors (less bronchoconstriction effect than $\beta_2$ blockers) decreases heart rate and rennin release used in the treatment of hypertension.	CNS depressive effects with concerns for those with diabetes, heart block and heart failure, asthma, and emphysema.
	Lopressor		
	Toprol XL		
	Nadolol	Beta blocker: Blocks both $\beta_1$ and $\beta_2$ adrenergic receptors, decreases heart rate and rennin release used in the treatment of hypertension. Also has bronchoconstriction effect due to $\beta_2$ blockade.	May cause CNS depressive effects with concerns for those with diabetes, heart block and heart failure, asthma, and emphysema. Transient hypertension due to blockage of $\beta_2$ receptors (which normally dilate large arteries).
	Corgard		
	Prazosin	Alpha blocker: $\alpha$ -adrenergic antagonist causing dilation of arteries and veins used for the treatment of hypertension.	Postural hypotension, dry mouth, edema, congestion, headache, sexual dysfunction, and lethargy.
	Minipress		
	Propranolol	Beta blocker: Blocks both $\beta_1$ and $\beta_2$ adrenergic receptors, decreases heart rate and rennin release used in the treatment of hypertension. Also has bronchoconstriction effect due to $\beta_2$ blockade.	CNS depressive effects with concerns for those with diabetes, heart block and heart failure, asthma, and emphysema. Transient hypertension due to blockage of $\beta_2$ receptors (which normally dilate large arteries).
	Inderal		

	Terazosin	An $\alpha_1$ -adrenergic blocker used in the management of hypertension in combination with a $\beta$ -adrenergic blocker and thiazide diuretic. Also used in the management of benign prostatic hypertrophy.	May cause weakness, dizziness, headache, weight gain, or syncope.
	Hydrin		
	Timolol	Beta blocker: Blocks both $\beta_1$ and $\beta_2$ adrenergic receptors, decreases heart rate and rennin release used in the treatment of hypertension. Also has bronchoconstriction effect due to $\beta_2$ blockade.	CNS depressive effects with concerns for those with diabetes, heart block and heart failure, asthma, and emphysema. Transient hypertension due to blockage of $\beta_2$ receptors (which normally dilate large arteries).
	Blocadren		
<b><math>\alpha_2</math> adrenergic agonists</b>	Clonidine	An $\alpha_2$ adrenergic agonist used as an antihypertensive. It decreases cardiac output, heart rate, and blood pressure.	Rash, drowsiness, headache, impaired ejaculation, dry mouth, and if stopped suddenly, rebound hypertension.
	Methyldopa	An $\alpha_2$ -adrenergic agonist used as an antihypertensive. It decreases cardiac output, heart rate, and blood pressure.	May cause dry mouth, possible postural hypotension, and sedation. May experience nightmares or psychic disturbances.
	Aldomet		
<b>Diuretics</b>	Furosemide	A sulfonamide "loop" diuretic that inhibits resorption of sodium and chloride at the loop of Henle and proximal and distal renal tubules. Used in the management of hypertension, fluid reduction for CHF, hepatic cirrhosis, and renal dysfunction.	May cause hypokalemia (supplement with potassium), GI complaints, circulatory collapse, or aplastic types of anemia.
	Lasix		
	Fumide		
	Lauramide		
	Furomide		
	Vasopressin	An extracted animal hormone from the posterior pituitary that has primarily an antidiuretic effect (no oxytocin effect). Effect is primarily due to increasing tubular resorption of water creating a concentrated urine. Used in the management of diabetes insipidus, for dissipation of gas shadows on abdominal films, or for reducing abdominal distention postsurgically. Has also been used as intranasal spray for maintenance treatment of diabetes insipidus and sometimes for enuresis.	Small doses may cause angina or MI and aggravate other pre-existing heart conditions. May cause headache, water intoxication, and anaphylaxis among other common drug side effects.
	Pitressin		
<b>Calcium channel blocker</b>	Nifedipine	A calcium channel blocker that causes smooth muscle relaxation of coronary and peripheral blood vessels, decreasing peripheral resistance without affecting serum calcium levels. Used in the management of hypertension usually in combination with a diuretic and also vasospastic (Prinzmetal or variant) angina.	May cause dizziness, lightheadedness, postural hypotension, facial flushing, palpitations, peripheral edema, hepatotoxicity, sore throat, and various GH symptoms.
	Adalat		
	Procardia		

- Diuretics (decrease fluid in system)
- Drugs that affect the sympathetic nervous system such as  $\beta$ -blockers and  $\alpha$ -adrenergic blockers (reduce force of contraction of the heart and/or tension in the vascular system)
- General vasodilators
- Calcium channel blockers (similar effect on heart and vasculature as sympathetic drugs)
- Angiotensin-converting enzyme (ACE) inhibitors (inhibit the renin-angiotensin-aldosterone cycle)
- Angiotensin receptor blockers

Common and popular examples are: Lisinopril (ACE inhibitor), hydrochlorothiazide and furosemide (diuretics), and Norvasc (calcium channel blocker). Each drug has its potential side effects. The most characteristic side effects are as follows:

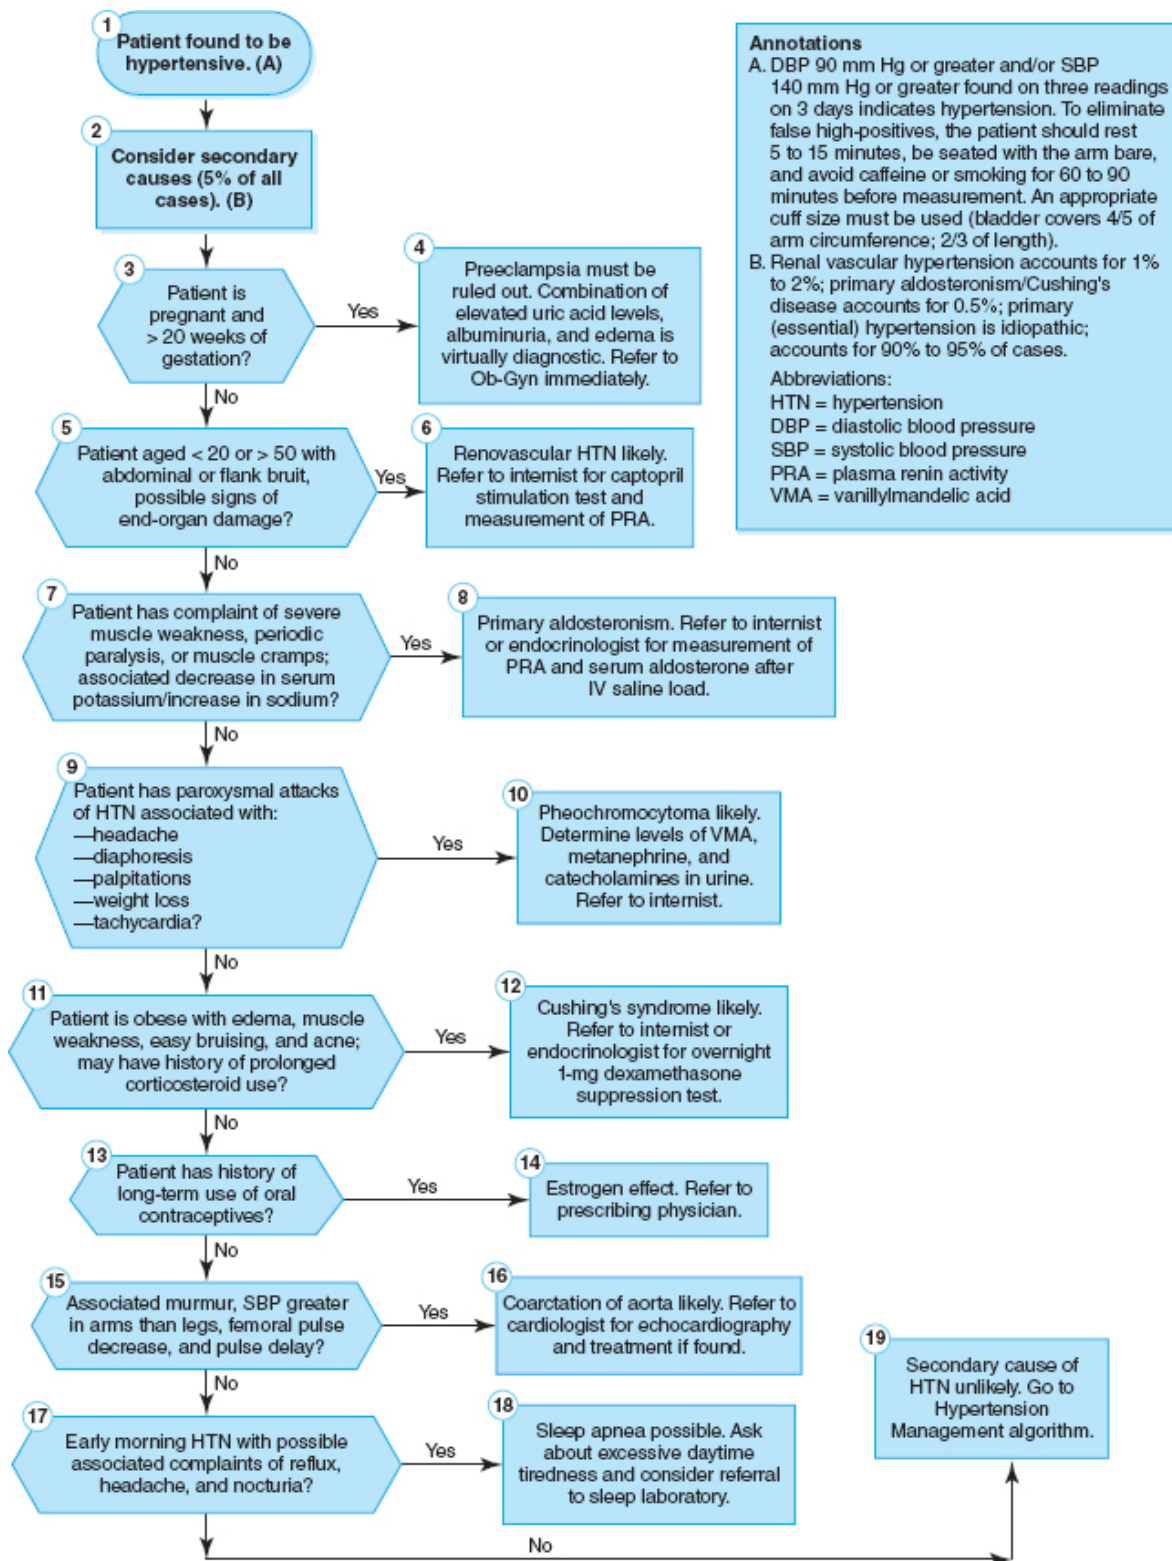

- Diuretics—Some diuretics will cause loss of potassium or magnesium and lead to some increase in low-density lipoprotein cholesterol.
- $\beta$ -Blockers— $\beta$ -blockers often have an effect of causing a decrease in energy or inducing general malaise.
- Calcium channel blockers—Some of the older types of calcium channel blockers have been associated with an increased risk for certain cancers.
- ACE inhibitors—Facial edema and a nonproductive cough may occur. The dry cough associated with ACE inhibitors may be alleviated with iron supplementation but not at the same time due to potential interference with the drug's absorption.

It is important that the patient consult his or her physician prior to decreasing or increasing the dose of medication. Older patients may forget to take their medication (or with diuretics, potassium supplementation) or decide to stop taking medication because of the cost. It is important to ask questions regarding any change in medication, in particular with those patients who appeared to be under control, yet now have a high BP.

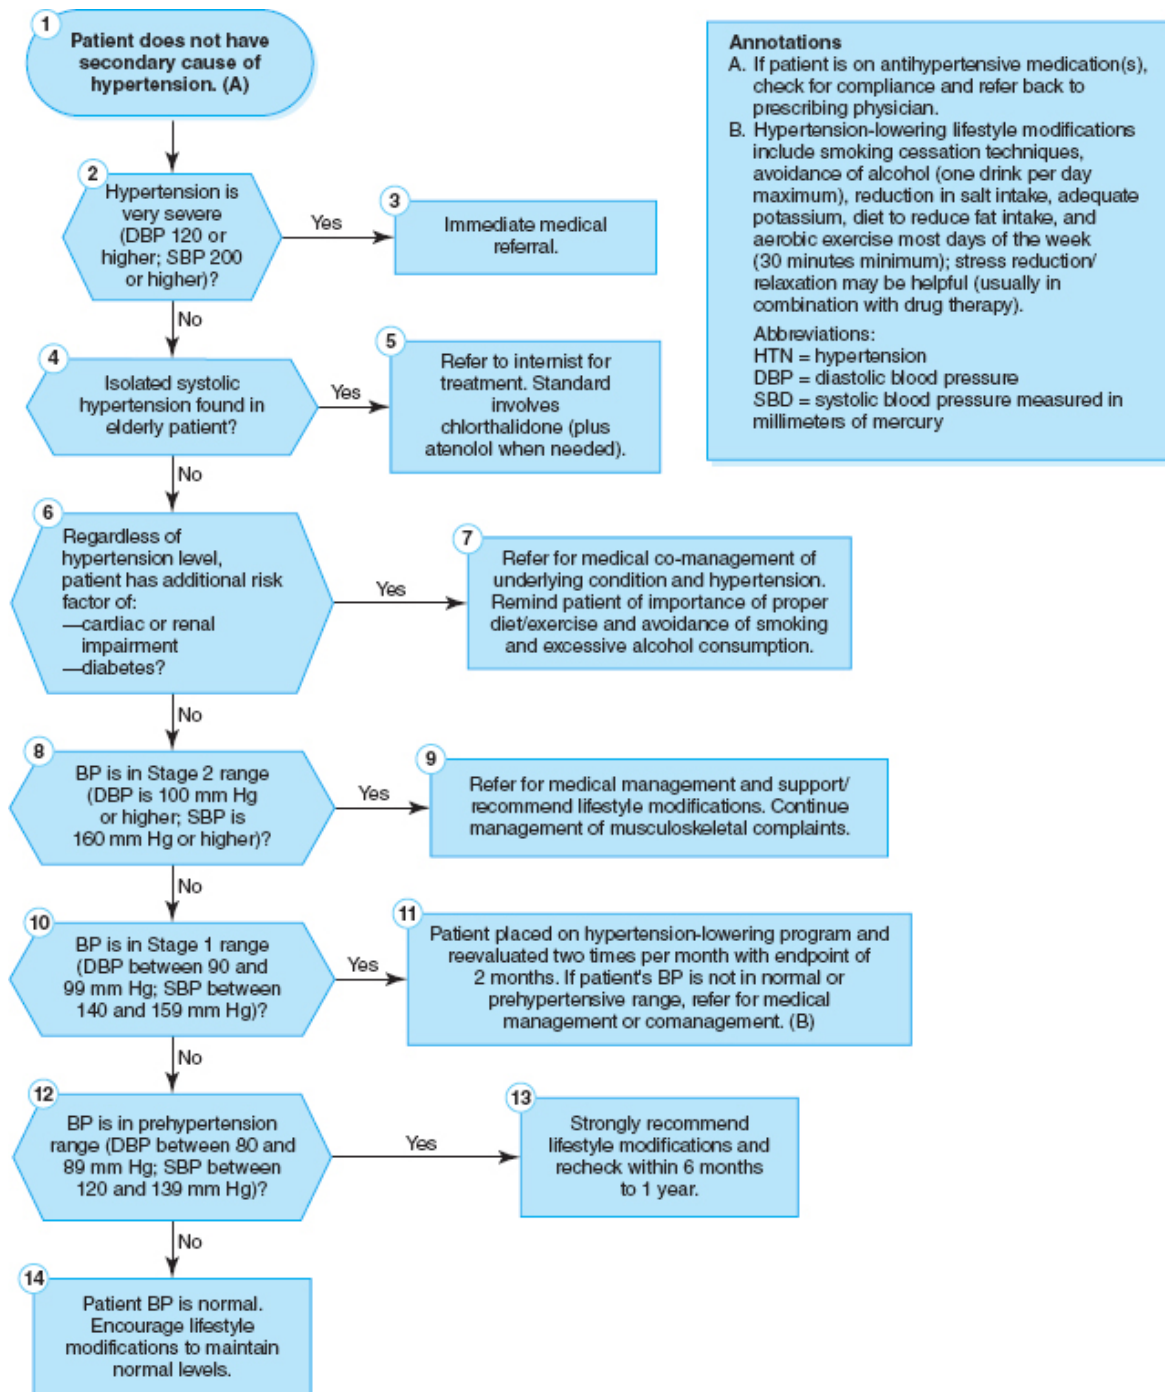

## Algorithms

Algorithms for evaluation and management of HTN are presented in **Figures 24-1** and **24-2**.

# CHAPTER 25

## Lower Leg Swelling

### Context

Lower leg swelling may be the result of a variety of causes via a variety of mechanisms. In general, swelling is usually vascular, muscular, fatty, myxedematous, or tumorous. Bilateral leg swelling is suggestive of a systemic process and is often the result of fluid retention and stagnation due to congestive heart failure, salt-retaining drugs, liver or kidney disorders (hypoproteinemia), primary lymphedema, and dependency. Unilateral leg swelling is usually secondary to trauma, requiring a differentiation between thrombosis and a muscular tear, a task not always as simple as it may seem.

### General Strategy

## Unilateral Acute Leg Swelling

- Determine whether trauma was involved.
- Determine whether there is a history of contraceptive use or immobilization.
- Determine whether there was a sudden or gradual onset of pain with exercise.

# Bilateral Chronic Leg Swelling

- Determine whether the onset was at an early age.
- Determine the patient's cardiopulmonary status.
- Determine whether the patient is taking drugs that cause salt retention or has a high-salt diet.
- Determine whether the patient stands for many hours at a time.
- Determine whether the patient has varicosities and, if so, test to determine which part of the venous system is involved.

## Relevant Physiology and Anatomy

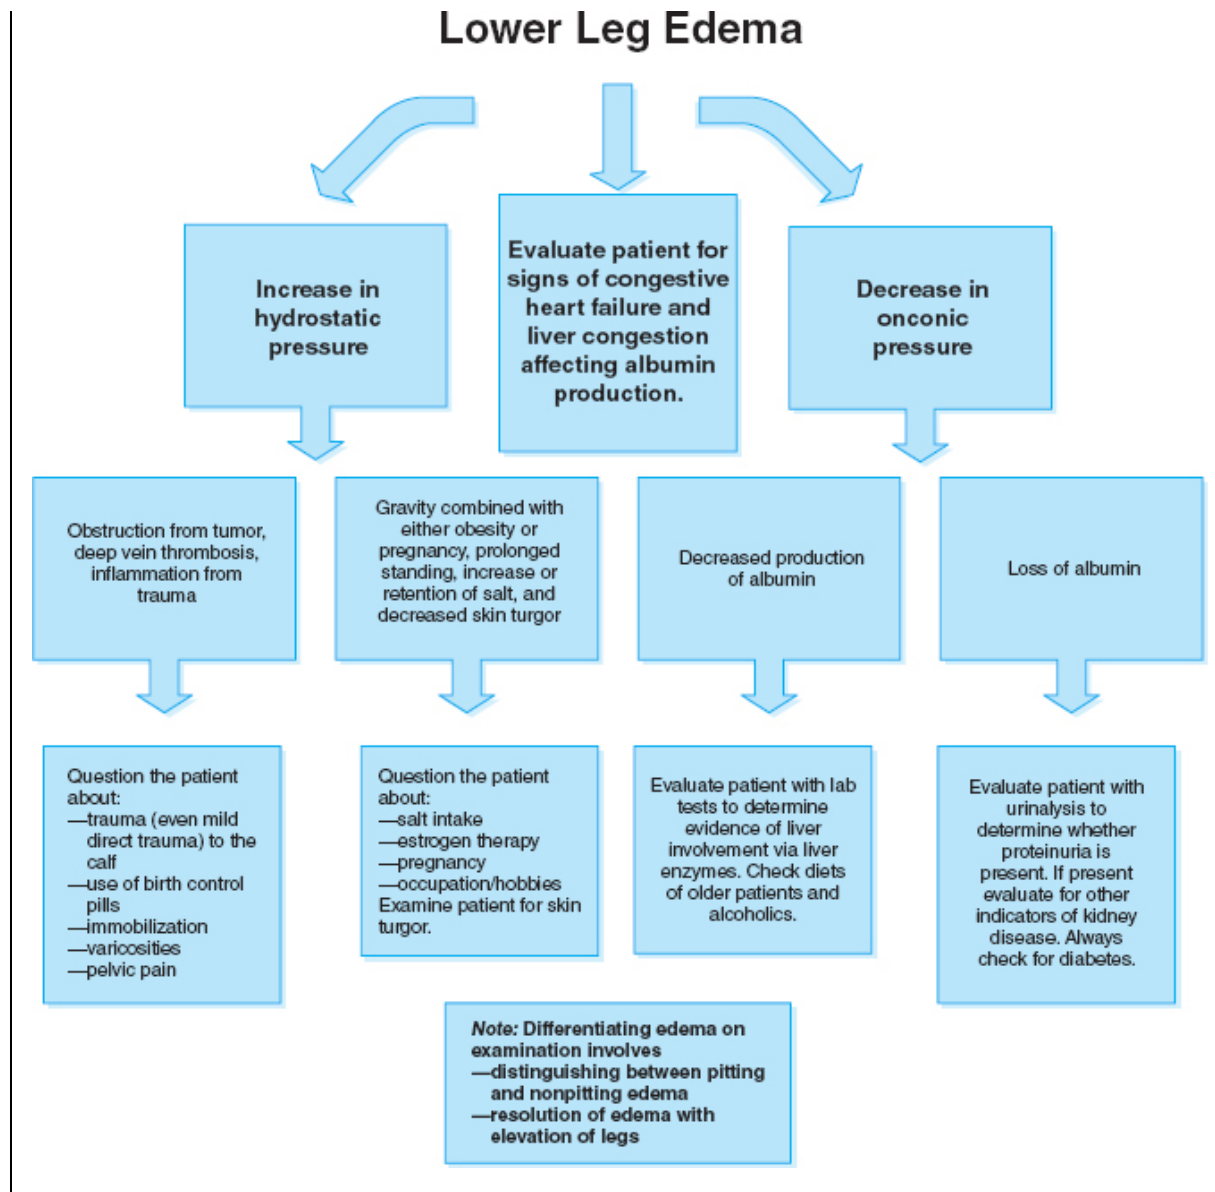

Review of simple physiologic principles reveals most of the common causes of edema (**Exhibit 25-1**). Fluid within the vascular system remains in the system unless drawn or forced outward by two processes. One process is simply pressure within the system. Hypertension, gravity, venous valvular incompetence, and venous or lymph blockage will increase hydrostatic pressure, forcing fluid into the interstitium. The second mechanism involves oncotic pressure. Key to the retention of fluid is the osmotic influence of protein, specifically albumin. Low albumin states are usually due to loss or decreased production. Production of albumin occurs in the liver. Albumin is usually retained by the kidney, yet in some pathologic states, such as long-term diabetes or chronic renal failure, albumin is lost in the urine.

Veins allow unidirectional (toward the heart) movement of blood. This is dependent on one-way valves. When these valves are incompetent or pressure and dilation exceed

their restraining ability, blood flows retrograde and can be forced into the interstitium. The venous system has two levels of veins that connect via communicating veins. Blood in the deep system is pumped toward the heart through muscular contraction. Lack of muscular contraction or blockage in the deep system forces blood to flow retrograde through the communicating system to the superficial veins. The superficial system does not have the advantage of muscular contraction to aid in transport and as a result is more likely to demonstrate superficial signs of incompetence—varicosities.

Salt either in the diet or due to drugs or hormones such as estrogen, which cause the retention of salt, can increase vascular fluid and cause lower leg edema. Localized “edema” may be found over the tibia with myxedema. This is not true edema, but a deposition of mucoid material.

### **Exhibit 25-1 Common Causes of Edema**

## Evaluation

## History

Timing and position are helpful discriminators. Acute, unilateral swelling of the calf is most often due to deep vein thrombosis (DVT) or muscle tear. Associated indicators of DVT are a history of immobilization, use of birth control pills,

or minor trauma to the area (especially in an older patient). It is more likely that a muscle strain occurred when the patient can identify a sudden onset with activity, especially with plantarflexion of the ankle. Slow onset of swelling that is relieved by elevation of the legs is suggestive of venous insufficiency or congestive heart failure. Diffuse swelling that is unrelieved by elevation suggests lymph blockage. Calf pain and swelling that appear with exercise are more likely due to a compartment syndrome in a younger person and DVT in an older person. Cancer such as pancreatic cancer should be considered in the differential for lower leg swelling when multiple swellings represent a superficial thrombophlebitis process.

A review of medications and diet may indicate a salt-retaining mechanism for swelling. Substances such as estrogen promote salt retention (this occurs as a natural consequence of estrogen production during a regular menstrual cycle).

## **Examination**

Observation for the degree of swelling and whether it is localized may be extremely helpful, for example, in the following cases:

- In obese women, swelling that spares the ankles is often due to fat deposition (lipedema), especially if bilateral.
- Localized swelling that appears rather hard and sometimes tender may indicate an underlying bone or soft tissue tumor.
- Swelling localized behind the knee may indicate bursal swelling, a Baker's cyst, or a medial gastrocnemius rupture.

- Swelling localized to the tibial crest probably represents myxedema, which is found in some patients with hyperthyroidism.
- A unilateral swelling in the calf may represent thrombophlebitis.

Skin texture and appearance may be characteristic for some causes of leg swelling.

- Lymphedema—The skin becomes dry and scaly with progressive thickening.
- Chronic venous insufficiency—The skin may become golden brown (hemosiderin deposition) at the medial ankle or more diffusely.
- Cellulitis—Diffuse redness and warm skin or red streaks appear on the leg.
- Erythema nodosum—Discrete, nummular areas that are warm appear on the anterior leg.
- Reflex sympathetic dystrophy—In the early stage, the skin is hypersensitive and cool; later, the skin is taut, shiny, and thin.
- Gastrocnemius tear—Bluish purple discoloration appears at the medial malleolus.
- Congenital venous malformations—Flat, purplish red angiomas or dark purple verrucous lesions appear.
- Lymphatic obstruction—Eventually the skin is indurated with a texture like an orange peel (peau d'orange).

Another distinguishing factor is whether the swelling is pitting or nonpitting. Pitting edema is often found in conditions that produce a less viscous fluid; for example, the edema found with congestive heart failure. Swelling that is nonpitting is more often associated with lymph blockage as may occur with tumors. The excess proteinaceous fluid that is normally cleared from the interstitium by the lymphatics is allowed to accumulate.

Improvement of swelling with leg elevation may also help distinguish between lymphedema and edema due to venous involvement. There is a marked improvement with elevation when venous engorgement is the main problem. There is little improvement when the lymphatics are involved. Additionally, venous insufficiency is evaluated with several tests. Trendelenburg's test is used to determine whether varicosities are due to incompetence of the superficial, communicating, or deep veins. The patient's leg is elevated to drain the venous system. A tourniquet is tied tightly enough to occlude the superficial veins at the proximal thigh. The patient stands. If the varicosities fill, the deep and communicating systems are responsible (usually deep vein obstruction). If the varicosities do not appear, but do develop with removal of the tourniquet, the incompetency is in the superficial system.

A running debate as to how long to maintain anticoagulant medication has led to a search for predictors of future risk while not on anticoagulants. Recently, one study noted that D-dimer is a global indicator of coagulation activation and fibrinolysis.<sup>1</sup> A high D-dimer level has been associated with increased risk for a first venous thrombosis. This study found that patients with a D-dimer level less than 250 ng/mL after withdrawal from oral anticoagulants has a low risk for recurrence of venous thrombosis.

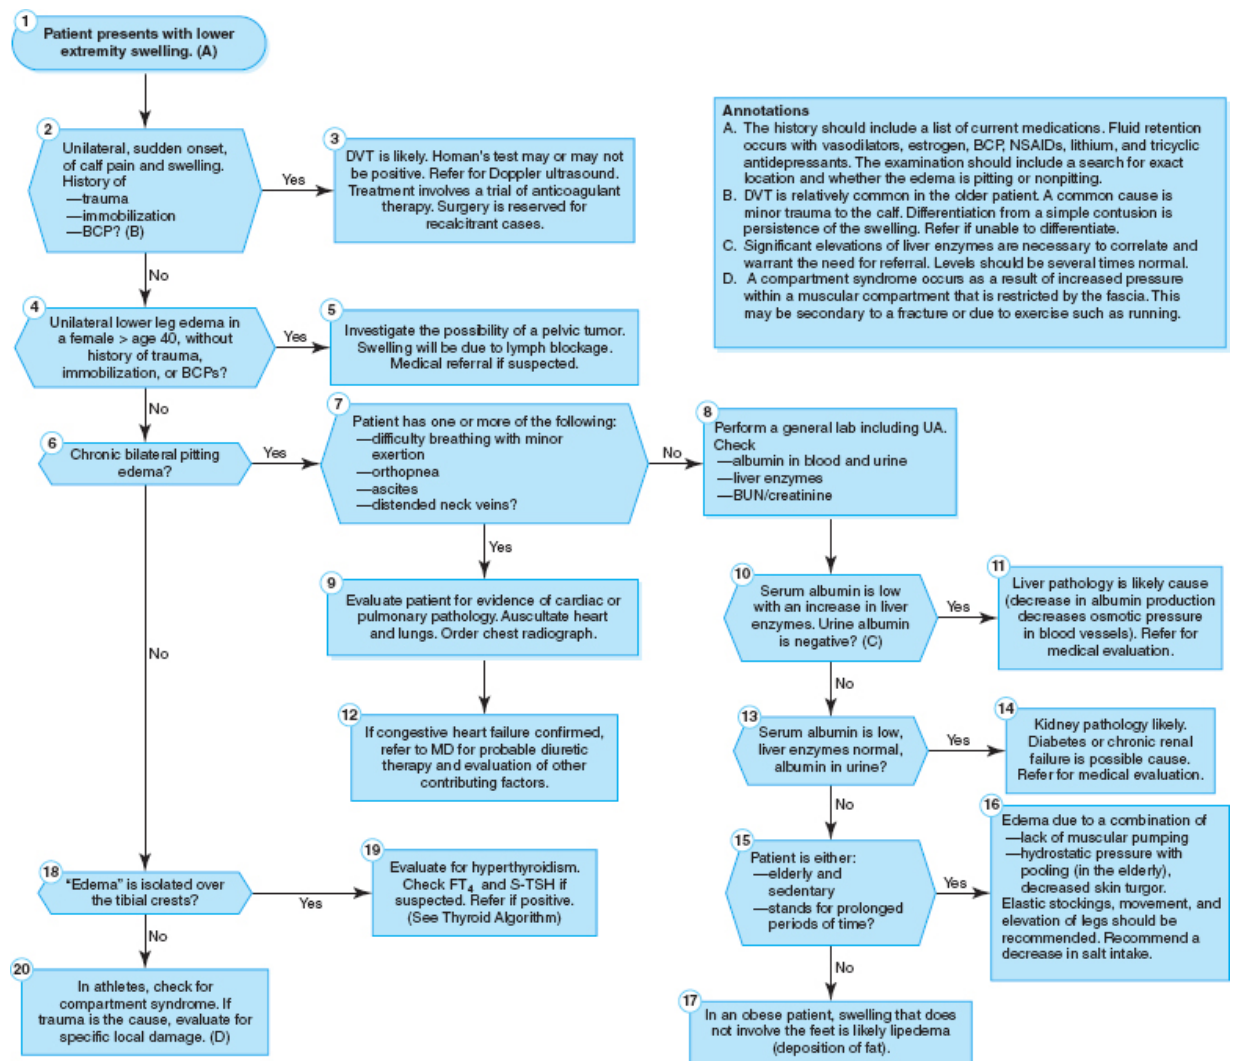

If the patient has history and examination results suggestive of DVT, referral for noninvasive Doppler ultrasound is needed to confirm the suspicion. Doppler ultrasound is replacing the gold standard of venography in most cases. A positive finding is identification of an area of noncompressibility along the suspected vein.

## Management

- Acute unilateral swelling that is suggestive of DVT should be referred immediately for evaluation with Doppler ultrasound or a venogram; if positive, medical management would include immobilization with elevation for approximately one week and anticoagulant therapy for three months or longer.
- Congestive heart failure should be referred for comanagement. Long-term management should include the use of natural diuretics when possible, reduction of salt, and a graduated, supervised diet and exercise program.
- Varicose veins may be treated conservatively through advice, including advice on the use of elastic stockings, use of frequent breaks with leg elevation, weight loss, and avoidance of prolonged standing. If these measures are unsuccessful or unacceptable by the patient, referral for a discussion of surgical options should be made.

## Algorithm

An algorithm for evaluation and management of lower extremity edema is presented in **Figure 25-1**.

### **Deep Vein Thrombosis**

## **Classic Presentation**

The patient may complain of calf pain or tightness that is worse with walking. There may be a history of a minor trauma to the calf or a prolonged period of rest due to a chronic illness (or a long airline flight).

## **Cause**

Eighty percent of thrombosis occurs in the deep veins of the calf, although other sites may include the femoral and iliac veins. Predispositions include prolonged rest, surgery (especially hip surgery), use of oral contraceptives in women, and cancer.

## **Evaluation**

The clinical examination is often unrevealing. In fact, 50% of patients are not even symptomatic. When symptomatic, there may be mild swelling and tenderness in the calf. Other findings that are relatively nonspecific include a slight fever and tachycardia. The standard Homan's test, which involves passive dorsiflexion of the ankle in an attempt to increase pain, is nonspecific in an ambulatory population. When the suspicion is high, plethysmography or Doppler ultrasound is an acceptable noninvasive screening tool.<sup>2</sup> A D-dimer test should also be included. The definitive diagnosis may require the gold standard of ascending contrast venography.

## **Management**

The medical approach is to prevent the lethal consequence of pulmonary embolism through the use of anticoagulant therapy (i.e., heparin) for several

months. **Table 25-1** is a list of some medications used in the management of DVT. In addition, elevation of the legs for approximately one week is needed with the knees slightly flexed. Return to weight-bearing is gradual. Recent evidence suggests that for patients requiring more than three months of anticoagulant therapy, low-intensity warfarin therapy is warranted and is effective in preventing recurrence.<sup>3</sup>

## **Cellulitis**

### **Classic Presentation**

The patient complains of a diffuse, hot, swollen area on the leg. There may be a history of a break in the skin.

### **Cause**

Cellulitis is due primarily to gram-positive organisms; however, *Escherichia coli* may also be a cause. Cellulitis may be seen as a complication of chronic venous stasis.

### **Evaluation**

Finding an area that is red and swollen, with either a history or evidence of a break in the skin, is a classic presentation. If the patient has a history of venous stasis, finding a new area of tenderness is also suggestive. Attempts at isolating the organism are usually unsuccessful.

## **Management**

Refer for antibiotic treatment in suspected cases.

## **SUBACUTE OR CHRONIC**

### **Venous Insufficiency**

### **Classic Presentation**

The patient complains of chronic lower leg swelling. There are itching and a dull ache in the area that is worse with prolonged standing. There may be a

history of phlebitis or leg trauma.

## Cause

Damage to the deep vein valves is usually secondary to DVT or trauma.

**Table 25-1** Medications Used for DVT

Drug Class	Examples	General Mechanism	Interactions/Side Effects
Heparin Dalteparin	Hepalean Heparin Hep-Lock Lipo-Hepin Liquaemin	Prepared from bovine lung tissue and porcine intestinal mucosa, this potent mucopolysaccharide anticoagulant enhances the inhibitory actions of antithrombin III. Used for the treatment of venous thrombosis and pulmonary embolism, prevention of thrombi/emboli following surgeries, and also used for the treatment of disseminated intravascular coagulation (DIC).	May cause spontaneous bleeding, transient thrombocytopenia, bronchospasm, anaphylaxis, osteoporosis, and hypoaldosteronism.
Warfarin	Coumadin Panwarfin Warfilone	An anticoagulant that decreases the synthesis of vitamin K-dependent coagulation factors. Similar to heparin but actions are accumulative and prolonged. Used prophylactically for embolic and thromboembolic conditions such as deep vein thrombosis, transient ischemic attacks, prosthetic valves, pulmonary embolism, and atrial fibrillation with embolization.	May cause bleeding at any site. Caution when adjusting patients on warfarin due to subarachnoid bleeds, bruising of skin, and other potential bleeding sites. May also cause anorexia, abdominal cramps, diarrhea, and may increase liver enzymes.
Clopidogrel	Plavix	An inhibitor of platelet aggregation acting by inhibition of ADP binding to its receptor. Used to prevent atherothrombotic events after recent MI (especially ST-segment elevation-related), stroke, or with peripheral artery disease, acute coronary syndrome.	Bleeding major and minor, abnormal liver function tests, hepatitis, confusion, hallucinations, taste disorders, angioedema, bronchospasm, hypotension and other autonomic nervous system events.
Streptokinase (tissue plasminogen activator: TPA is similar)	Kabikinase Streptase	Produced from beta-hemolytic streptococcus, this potent thrombolytic enzyme promotes conversion of plasminogen to plasmin. This process breaks apart clotting materials into a soluble form clearing blocked areas in acute thrombotic or embolic situations. Used for acute treatment of deep vein thrombosis, pulmonary embolism, coronary artery thrombosis, etc.	Given this is an antithrombotic agent, hypocoagulation exists which may lead to bleeding at any body site. May also cause an allergic reaction, anaphylaxis, unstable blood pressure, ventricular arrhythmias, musculoskeletal pain, and flushing.

## Evaluation

The patient will have edema that is reduced by elevation of the leg. Associated findings include varicosities and leg lesions. When the valves are incompetent, resulting venous stasis will eventually lead to the development of skin lesions around the medial ankle and anterior lower leg. These may include nonhealing ulcers.

## Management

Like primary varicosities, the long-term management involves avoiding prolonged standing, elevating the legs as often as possible, wearing

supportive elastic stockings, and reducing weight and salt intake. When acute stasis dermatitis is present, compresses using isotonic saline, Burow's solution (buffered aluminum), or boric acid may be applied for one hour four times daily. Over-the-counter corticosteroid creams may be helpful. Ulcerations require a medical consultation to determine the need for grafting.

## **Primary Varicosities**

# **Classic Presentation**

The patient may complain of cosmetic and/or painful discrete swellings on the inside of the leg. The pain is a dull, aching heaviness in the lower extremity that is worse with prolonged standing. Cramping may also occur; it is relieved by leg elevation.

## **Cause**

Varicosities are abnormally dilated, tortuous superficial veins. Primary varicosities occur due to incompetence of the valves in superficial veins, and communicating veins (veins that connect the deep and superficial venous system), occurring most often in the long saphenous vein (inside of leg) and its tributaries. Patients who are overweight or pregnant or who stand for prolonged periods of time are more often affected. There does appear to be a genetic predisposition.

## **Evaluation**

The diagnosis is primarily through visual inspection. The Trendelenburg test is an attempt to differentiate between deep vein occlusion and superficial vein valve incompetence. The patient's leg is elevated for 20 to 30 seconds. A tourniquet is tied around the upper thigh (enough to occlude the superficial venous system). The patient is then asked to stand. If the varicosities become apparent with the tourniquet still applied, deep vein occlusion or communicating vein incompetence is the cause. If varicosities appear only after removal of the tourniquet, superficial vein valve incompetence is the cause. Doppler ultrasound or duplex scanning may identify the sites of valve incompetence and help in planning surgery (if performed).

# **Management**

Conservative management includes taking frequent breaks to elevate the legs, the use of elastic stockings, losing weight, and avoidance of prolonged standing. If conservative management is ineffective or cosmetically

unacceptable by the patient, surgery involves ligation or removal of involved segments, preserving uninvolved segments for the potential need of vein grafting with cardiac bypass surgery. Sclerotherapy is reserved for small varicosities. The vein is injected with a sclerosing agent and compressed, obliterating the vein.

## **Congestive Heart Failure**

### **Classic Presentation**

The patient complains of bilateral leg edema. He or she has associated complaints of difficulty breathing with exertion or lying fully supine at night (orthopnea).

### **Cause**

Right-sided heart failure is often secondary to left-sided failure. Pressure increases into the venous system, delaying return to the heart from the lower extremities.

### **Evaluation**

The edema is reduced by elevation of the legs. Rales are often apparent on auscultation. The chest radiograph provides important confirmation of cardiac failure with a demonstration of cardiomegaly, dilation of the upper-lobe veins, haziness of vessel outlines, and interstitial edema. Electrocardiography may reveal associated arrhythmias or hypertrophy.

## **Management**

Comanagement is recommended. The standard approach is the use of diuretics for early-stage failure. However, long-term management should include a change to a strict, low-fat diet, with gradual supervised exercise.

### **Reflex Sympathetic Dystrophy (Complex Regional Pain Syndrome: Type 1)**

### **Classic Presentation**

The patient will report having persistent pain and swelling following an episode of trauma.

## Cause

There are many theories regarding reflex sympathetic dystrophy (RSD). Some investigators question the existence of this disorder. It is believed that sympathetic nervous system (SNS) dysfunction is at the core of this syndrome. Theories include hyperactivity of the SNS, abnormal connection between the sympathetic and sensory neurons, an autoimmune reaction, nerve sprouting following injury, or abnormal activation of receptors.<sup>4</sup>

## Evaluation

RSD may progress through stages. In the early stage, the patient may complain more of a burning, sharp pain in the area. In the “moderate” stage, sympathetic signs may appear, including atrophic skin changes with cold, moist, or mottled skin. The generalized area becomes hypersensitive to stimuli and the pain becomes continuous. In more severe stages, the pain becomes throbbing and aching. Dystrophic changes become visible in the skin and nails. Muscular atrophy and contracture may become evident. Radiographically, localized osteoporosis (i.e., Sudeck’s atrophy) occurs in the later stages of RSD. Bone scans will demonstrate an increased uptake on the involved side. Thermography will usually demonstrate a temperature differential between the two sides, but it is nonspecific.

## Management

Conservative management would include manipulation of spine-related segments, physical therapy, and elevation to decrease swelling. Two reports suggest that chiropractic manipulation may increase distal blood flow; however, the reports are not specific to RSD.<sup>5, 6</sup> Stress reduction may be helpful for some patients. Medically, sympathetic blockades through injectable blocks (e.g., bretylium and lidocaine),<sup>7</sup> ganglion blocks, implanted neuro-stimulators, and  $\alpha$ - and  $\beta$ -adrenergic blocker drugs are all approaches that are employed.<sup>8</sup>

# CHAPTER 26

## Lymphadenopathy

### Context

Patients present with a concern of either an enlarged or a tender lymph node, or upon examination the examiner discovers a suspicious enlargement. The patients' common concern is whether this is an indication of cancer.

Statistically, their concern may be justified if they are over age 50 years, when approximately 60% of lymphadenopathy represents a malignancy. However, if they are under age 30 years, there is an approximately 80% chance that the cause is benign.<sup>1</sup>

The chiropractor's role is to determine whether an enlarged lymph node is simply an inadvertent discovery. For the patient this represents a "new" or enlarged nodule; however, in reality it represents a chronic, benign node or group of nodes unnoticed by the patient in the past. Additionally, it is important to attempt to differentiate among other causes of "nodules" (especially in the head and neck area in thin individuals), including the following:

- Sebaceous or dermoid cysts
- A cervical transverse process or cervical rib
- The carotid body (high cervical area)
- Nodularity in the brachial plexus

The next two important steps in the process of evaluation are, first, to distinguish among generalized, regional, and localized involvement. Second, it is important to determine whether there are associated signs of infection or indicators of malignancy. In general, follow-up with specific laboratory procedures should be reserved for specific suspicions or when there is little evidence to indicate a specific cause.

## **General Strategy**

### **History**

#### **Determine whether the following apply:**

- The patient's onset was acute? or chronic?
- The patient has associated signs of infection
- The complaint is generalized? more regional? localized?
- The patient has been exposed to others with similar signs
- The patient has been exposed to birds, cats, or dogs or their excrement
- The patient is taking medications that may cause a hypersensitivity reaction
- The degree of exercise is associated with the degree of inguinal enlargement

### **Evaluation**

- Palpate the lymph nodes in an effort to distinguish the texture and whether or not the nodes are fixed.

- Determine the degree of involvement: a single node, all regional nodes, or generalized.
- Consider laboratory investigation when a specific disorder is suspected such as mononucleosis, hyperthyroidism, tuberculosis (TB), human immunodeficiency virus (HIV), connective tissue disorder, or fungal infection.
- Consider radiographs when TB, sarcoidosis, lung disease, or fungal infection is suspected.
- Refer for biopsy if the patient has indicators of high risk (e.g., solitary supraclavicular node).

## **Management**

- Many causes are benign and self-resolve.
- When lymphadenopathy is an indicator of an underlying serious or medically responsive condition, referral for consultation is suggested.
- When lymphadenopathy is persistent beyond three weeks with no identifiable cause, refer for medical evaluation.

## **Relevant Anatomy and Physiology**

The lymphatic system includes the lymph nodes, the lymphatic channels, and the spleen. The function of the lymphatic system is to remove excess protein-rich fluid and return it to the vascular system. The lymph nodes are sites of immune response. There are more than 500 lymph nodes in the body. Certainly, not all are peripherally located and therefore are not accessible. Hilar lymph nodes, for example, require radiographic or invasive investigation to

determine involvement. Children have as much as twice the amount of lymphoid tissue as adults and are more likely to respond to an infectious, inflammatory, or other inciting reaction than adults, and in a more dramatic way.

Node involvement is found with a variety of processes including infectious, inflammatory, and neoplastic diseases; metastatic carcinomas; connective tissue disorders; endocrine/metabolic disorders; hypersensitivity reactions; and infiltrative disorders. It would seem impossible to narrow down this large list; however, there are some anatomic predispositions and some classic presentations that may help. Generalized lymphadenopathy usually represents a systemic process involving infection, connective tissue disease, or hematologic neoplastic disease. Lymphomas and leukemias are two general categories to consider. Lymphocytic leukemia is more likely to produce a generalized response. Carcinomas are more likely to cause a regional lymphadenopathy; however, carcinomas are more likely than sarcomas to produce general involvement. Sarcomas are much more likely to disseminate hematogenously and are therefore less likely to cause lymph node involvement.

When investigating enlargement of lymph nodes, it is important to understand the watershed area of the node(s). Draining for common involved areas is listed below:

- Occipital, postauricular, and posterior cervical nodes—the scalp
- Preauricular—the face and eye
- High superficial and deep cervical nodes, submaxillary, and submental—the pharynx and mouth
- Supraclavicular and scalene—the head and neck, arms, mediastinum, and abdomen
- Axillary nodes—arm and breast
- Epitrochlear—arm and hand

- Inguinal-femoral nodes—most of the lower extremity and buttocks, lower anus, genitalia, perineum, and the lower anterior abdominal wall (ovarian and testicular cancer do not usually enlarge the inguinal nodes)

Additionally, certain regional presentations represent systemic processes:

- Posterior cervical and postauricular—viral infections, intra-articular pathology, mononucleosis
- Preauricular—eyelids and conjunctivae
- High cervical nodes—carcinoma of the oral cavity (often submaxillary)
- Supraclavicular and scalene—often represents a neoplastic process (i.e., Virchow's node)
- Axillary—metastatic breast carcinoma, catscratch disease, streptococcal and staphylococcal infections of the arm, brucellosis, tularemia
- Epitrochlear—infections of the hand and forearm; occasionally mononucleosis and non-Hodgkin's lymphoma
- Inguinal—lymphogranuloma venereum, venereal disease, excessive exercise (i.e., marathon running or heavy lower extremity workouts)

## Evaluation

## History

Timing may be an important discriminator. Nodes that appear abruptly and are tender more often will represent an infectious or inflammatory process. Chronic or recurrent node enlargement often represents a neoplastic or connective tissue disorder. Associated signs of infection

such as cough, sore throat, and fever are common in children with cervical lymph node enlargement.

Associated signs and symptoms often will help narrow down the possibilities:

- night sweats, fever, and weight loss suggest either lymphoma or tuberculosis
- joint pains, skin rash, and muscle weakness suggest a connective tissue disorder (e.g., lupus erythematosus)
- fever, sore throat, and cervical lymphadenopathy suggest mononucleosis

Determining the patient's exposure to particular environments or with others having similar signs and symptoms may be helpful in the following cases:

- HIV—homosexual contact among gay or bisexual men (although heterosexual contact is also a possibility), sharing needles (use of contaminated needles) with drug abuse (also consider syphilis)
- mononucleosis—saliva transmission
- cat-scratch fever or toxoplasmosis—contact with cats or cat litter, respectively
- fungal infection—travel to specific areas or contact with soil or bird excrement (e.g., coccidioidomycosis in the San Joaquin Valley of California)

## **Examination**

It is recommended that the chiropractor palpate as many “normal” individuals as possible to gain a sense of the variations in lymph node presentation. Palpation of the area of enlargement is performed with a focus on the area of drainage and the most common causes of regional involvement. These are listed above. Additionally, it may be

important to determine whether the lymph nodes are tender. This is more indicative of an inflammatory or infectious cause. Hard and matted lymphadenopathy that is fixed to underlying muscle is suggestive of cancer. If the nodes are more rubbery in consistency, lymphoma is more likely. The distinction between the two is not always easily made.

A prediction rule has been devised, called the “lymph node score.” Its scoring involves adding certain risk factors with assigned risk points such as age >40 years old, the size of the lymph node, nontenderness, and supraclavicular location and subtracting items such as lymph node tenderness and a correction factor to arrive at a final lymph node score. Scores less than 3 virtually rule out serious disorders while scores of greater than 5 or 6 warrant further evaluation for a serious cause (**Table 26-1**). The value of the physical exam expressed as likelihood ratios is graphically represented in **Exhibit 26-1**.

Evaluation of the throat, skin, and joints is essential in differentiating common upper respiratory infection from generalized connective tissue disease or fungal infections. The spleen and liver must be palpated for enlargement. These may be enlarged in several conditions, such as mononucleosis (cervical lymph node enlargement), lymphomas, and leukemias. Axillary lymph node involvement in a woman warrants a breast examination and follow-up mammography or biopsy if suspicious.

Some lymph node involvement is not palpable but is visible radiographically. Sarcoidosis is more often characterized by hilar lymphadenopathy visible on a chest radiograph. This is also true of bronchogenic carcinoma of the lungs. A chest radiograph may add evidence to a suspicion of fungal infection such as coccidioidomycosis or histoplasmosis if it demonstrates diffuse granulomatous involvement.

**Table 26-1** Lymph Node Score

Finding	Points
Age > 40 years	+ 5
Lymph node tenderness	-5
<b>Lymph node size</b>	
< 1 cm <sup>2</sup>	0
1-3.99 cm <sup>2</sup>	+ 4
4-8.99 cm <sup>2</sup>	+ 8
≥ 9 cm <sup>2</sup>	+ 12
Generalized pruritus	+ 4
Supraclavicular nodes present	+ 3
Lymph node is hard	+ 2
Correction factor	-6*

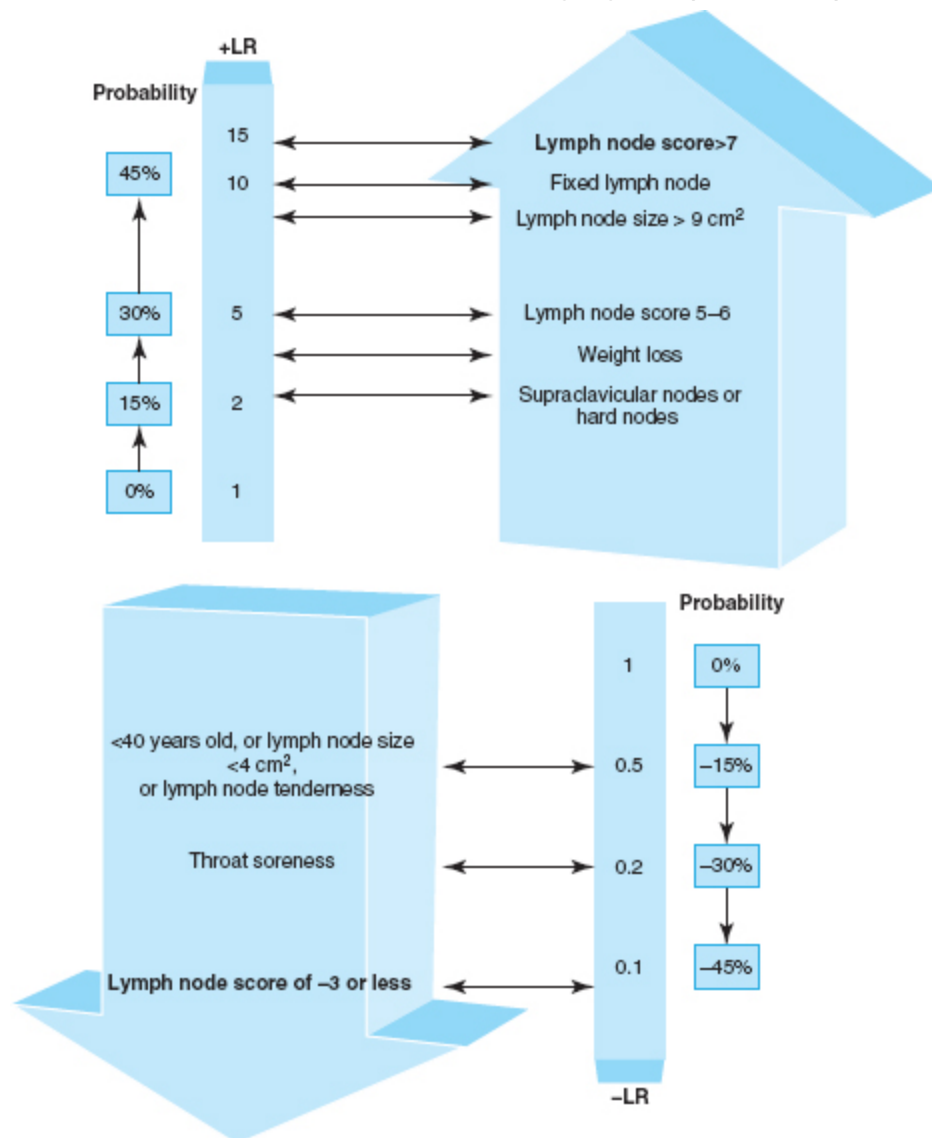

\*Included in every patient's score. For example, a 55-year-old asymptomatic patient with nontender but hard supraclavicular adenopathy measuring 6 cm<sup>2</sup> has a score of 12 (i.e., 5 + 8 + 3 + 2 - 6).

Reproduced from Vassilakopoulos TP, Pangalis GA. Application of a prediction rule to select which patients presenting with lymphadenopathy should undergo a lymph node biopsy. *Medicine* (Baltimore). 2000;79(5):338-347.

### **Exhibit 26-1 Likelihood Patient Has a Serious Cause of Lymphadenopathy Approximating Probability**

The likelihood ratios (LRs) in this graphical representation represent estimates of probability based on the aggregate of multiple reviews of each

test finding. They are only approximations and only reliable indicators of a change in the context of a patient having an intermediate pre-test probability of between 20% to 80%. If the pre-test probability is very high or very low, the LR has little effect on changing the probability.

Determining which laboratory evaluations to perform is important given the large number of disease processes possible and the separate laboratory evaluation for each. Following are some examples:<sup>3</sup>

- mononucleosis—heterophile antibody or monospot test

- HIV—enzyme-linked immunosorbent assay (ELISA) test confirmed by Western blot test (testing may be performed by the patient through a mail service if desired)
- lupus erythematosus and mixed connective tissue disease—antinuclear antibody (ANA)
- TB—purified protein derivative (PPD) skin test and if positive, culture and smear
- coccidioidomycosis, histoplasmosis, lymphogranuloma venereum—complement fixation test

Biopsy of lymph nodes is often needed to determine the cause in persistent lymphadenopathy. Therefore, patients without an identifiable cause after two to four weeks or with a suspicious single node involvement in the supraclavicular area or axilla should be referred for biopsy. Lymph node biopsy is not entirely sensitive; however, a second attempt will often raise the positive yield. Biopsy is important in diagnosing neoplastic and fungal causes. Reactive hyperplasia is a nonspecific finding with viral and connective tissue disease causes. It must be remembered that lymph node biopsy of the neck in an elderly patient has been shown to increase the incidence of distant metastasis.

Sometimes it is necessary to biopsy other areas of the body when a specific disease is suspected, including the following:

- transbronchial lung biopsy for sarcoidosis
- renal biopsy for systemic lupus erythematosus
- bone aspiration and biopsy for leukemia

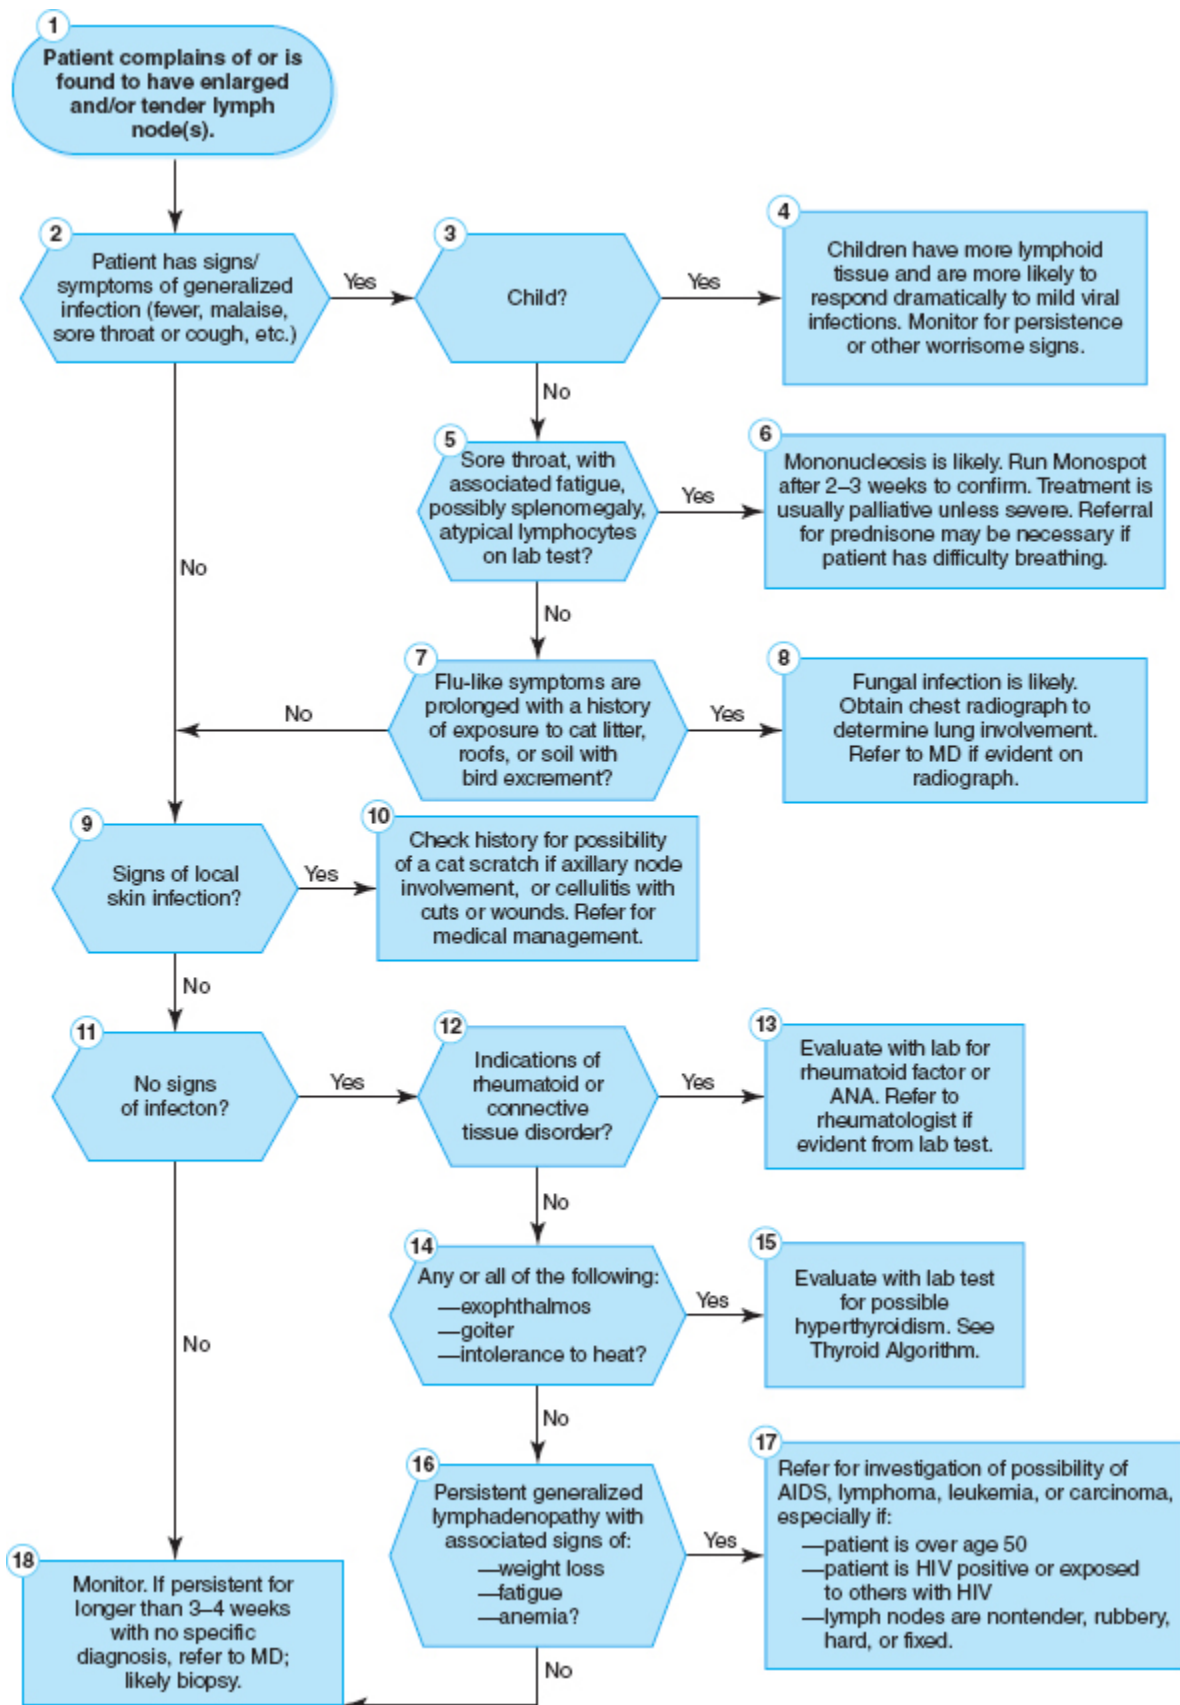

## Management

Because of the large list of lymphadenopathy causes, there is no common management approach. Treatment is specific

to the underlying cause. Chiropractically, it is important to act as a watchdog for lymphadenopathy, pursue a rational diagnostic approach, and consider referral when evidence suggests a serious disorder requiring further evaluation or amenable to medical management. Persistence of lymphadenopathy beyond three weeks with no identifiable cause is reason for medical consultation.

## Algorithm

An algorithm for evaluation and management of lymphadenopathy is presented in **Figure 26-1**.

**Figure 26-1** Lymphadenopathy—Algorithm

# Selected Causes of Lymphadenopathy

## Acquired Immunodeficiency Syndrome

### Classic Presentation

The presentation of acquired immunodeficiency syndrome (AIDS) varies, dependent on the staging of the disease. Following is the earliest presentation. The patient is often a homosexual male (this is not always true; see below) who complains of generalized symptoms such as fever, sore throat, lymphadenopathy, and headache. The symptoms are resolved, but there is persistent lymph node swelling.

### Cause

The HIV is a retrovirus that infects mainly T cells and cells related to monocytes. The major factor for immune dysfunction is the progressive depletion of T lymphocytes (primarily CD4+ lymphocytes), leading to decreased ability to fight disease. Lymphocyte functions such as cytotoxic and natural killer cell function are impaired. The antibody response to antigens is reduced.<sup>4</sup> There are several groups at risk, including sexually active, unprotected individuals, particularly homosexual males; drug users who share needles; hemophiliacs and others who received blood transfusions from 1978 through 1985; sexual partners of high-risk individuals; and children born to HIV-infected mothers.

### Evaluation

Physical examination may reveal few signs in the early stages. Persistent generalized lymphadenopathy (PGL) is one of the few indicators. Later in the course of disease progression, acquisition of minor opportunistic infection is common, followed by progressive susceptibility to more life-threatening infections. Oral manifestations include thrush and leukoplakia. HIV may be tested by a screening for antibodies to viral protein using an ELISA. A positive test is then confirmed with a Western blot test. Home kits are now available, allowing the person to send a sample to a lab. An indicator of progression is

the CD4+ cell numbers. These numbers correlate well with the acquisition of common opportunistic infections. The correlations are TB in patients with a count of 300; *Pneumocystis carinii* pneumonia with counts less than 200; cytomegalovirus and mycobacterium avium complex (MAC) when counts are less than 50.<sup>5</sup> HIV-related malignancies are common causes of death, including Kaposi's sarcoma and non-Hodgkin's lymphoma.

## Management

AIDS is managed medically with zidovudine (AZT) (antiviral drug).<sup>6</sup> Alternative drugs include didanosine, zalcitabine, protease inhibitors, stavudine, or a combination of these drugs. Treatment of an acquired disease is specific to the disease, but is more difficult in these immunosuppressed individuals. Prevention is crucial to eliminate further spread. This includes condom protection and the use of sterilized needles.

## Non-Hodgkin's Lymphoma

### Classic Presentation

The patient may present with lymphadenopathy alone or complain of constitutional symptoms such as night sweats, fever, or weight loss.

### Cause

Non-Hodgkin's lymphoma represents a broad array of lymphocytic cancers. The classification is based on the degree of aggressiveness, including low-grade, intermediate-grade, and high-grade classifications. Patients with HIV disease are particularly prone to non-Hodgkin's lymphoma.

### Evaluation

Finding regional or disseminated lymph node involvement warrants referral for biopsy if persistent. Laboratory results vary and may include increased levels of serum lactate dehydrogenase and occasionally a leukemic response.

## Management

Indolent lymphomas are not usually curable, but high-grade lymphomas may respond to chemotherapy. The survival period for indolent lymphoma is between six and eight years. The disseminated large-cell lymphomas can be cured in about half of patients.<sup>7</sup>

## **Hodgkin's Disease**

### **Classic Presentation**

Because of the bimodal age distribution, the patient may be in the 20s or over age 50 years. The patient complains of constitutional symptoms such as fever, weight loss, night sweats, or generalized pruritus. He or she may have noticed a painless mass in the neck and is concerned.

### **Cause**

Hodgkin's disease is characterized by lymphoreticular proliferation of unknown cause. One study indicated a possible relationship between infectious mononucleosis and Hodgkin's lymphoma. The relationship was based on the finding that 55% of biopsied tumors from patients who had Hodgkin's lymphoma and infectious mononucleosis in the past were positive for Epstein-Barr virus.<sup>8</sup>

### **Evaluation**

The patient presentation is nonspecific. Suspicion requires referral to a hematopathologist who can determine whether there is the presence of Reed-Sternberg cells on lymph node biopsy. Additionally, it is important to stage the disease. This is done with two approaches: (1) degree of involvement, and (2) whether or not symptomatic (A = asymptomatic; B = symptomatic). Stage I indicates one lymph node region involved, stage II indicates involvement of two lymph node regions, stage III indicates lymph nodes involved on both sides of the diaphragm, and stage IV is disseminated involvement of bone and liver.

### **Management**

Treatment is often based on staging. Stage IA and stage IIA diseases are treated with radiotherapy, with a 10-year survival rate of 80%. Chemotherapy is used in patients with stages IIIB and IV (five-year survival rate of 50% to 60%).<sup>9</sup>

## Chronic Lymphocytic Leukemia

### Classic Presentation

The patient is older than age 50 years and complains of fatigue and lymph node swelling.

### Cause

The cause is mainly a malignancy of B lymphocytes. The cells are immunoincompetent, leading to a predisposition to infection. Additionally, there is bone marrow failure and organ infiltration. Ninety percent of cases occur over the age of 50 years. The disease is slowly progressive.

### Evaluation

About half of patients have splenomegaly or hepatomegaly. Patients with fatigue and lymphadenopathy should be screened with a laboratory evaluation. The white blood cell count is usually more than 20,000 with the majority of cells being lymphocytes.

### Management

No treatment is used initially. Advanced stages are treated with chemotherapy and prednisone. The five-year survival rate is about 50%; the 10-year survival rate is 25%. Patients discovered with advanced disease usually survive less than two years.<sup>10</sup>

## **CHAPTER 27**

# **Skin Problems**

## **Context**

Dermatologic problems can be very difficult to diagnose because of the enormous number of causes and the variety of presentations. Chiropractors may serve a role as either a referral source or source of assurance to patients with many of the common, benign skin conditions. A discussion of skin problems is hampered without an atlas of color plate examples. The reader is encouraged to compare the following verbal descriptions with an atlas to compare better with specific patient presentations. The intention of the following discussion is to focus on several common scenarios in a chiropractic setting without a comprehensive discussion of all dermatologic possibilities.

It is important for the chiropractor to recognize the following skin presentations:

- Generalized skin changes such as pallor, cyanosis, jaundice, brown-tannish discoloration
- Danger signs with pigmented lesions
- The rashes associated with “childhood” diseases such as measles, chickenpox, and rubella
- Common causes of pruritus (itching)
- Lesions associated with venereal disease
- Lesions associated with rheumatoid/arthritic disorders

It is also important for the chiropractor to have a working knowledge of the vocabulary used to describe skin lesions to facilitate an intelligent discussion with a dermatologist in the course of consultation or referral. Following is a list of these terms (see **Figures 27-1** and **27-2** for illustrations).

## Primary Lesions

Primary lesions develop on previously normal skin due to a specific causative factor. *Note:* Primary lesions often evolve from flat, nonpalpable lesions to fluid-filled palpable lesions or may coexist, leading to combined descriptions such as maculopapular or vesiculopustular.

## Flat and Nonpalpable

- Macule—small (up to 1 cm) and circumscribed. Examples: freckles, flat nevi, petechiae, hypopigmentation
- Patch—larger than 1 cm. Examples: Mongolian spot, café au lait spot, vitiligo, chloasma

<b>Palpable (Raised) and Solid</b>
------------------------------------

- Papule—small (up to 0.5 cm). Examples: mole, wart, lichen planus
- Nodule—large (0.5 to 2 cm) and deeper than a papule. Examples: fibroma, xanthoma
- Tumor—larger (>2 cm) benign or malignant, hard or soft. Examples: lipoma, hemangioma
- Plaque—papules coalesce, forming a flat, elevated lesion larger than 0.5 cm. Examples: lichen planus, psoriasis
- Wheal—local, transient, skin erythema due to an allergic reaction, mosquito bite, dermatographism

- Urticaria (hives)—wheals coalesce to form a large reaction that is pruritic

### **Palpable, Fluid-Filled Lesions (Rupture Releases Pus or a Clear Fluid)**

- Vesicle—small, elevated lesion full of clear serum.  
Examples: chickenpox, shingles (herpes zoster)
- Bulla—larger lesions that are usually single-chambered.  
Examples: burns, friction blisters, pemphigus, a contact dermatitis
- Pustule—circumscribed lesion filled with pus.  
Examples: acne, impetigo
- Cyst—encapsulated, fluid-filled lesion that may be in the dermis or subcutaneous. Example: sebaceous cyst

## **Other**

Lesions involving hair include furuncle and carbuncle or comedo (blackhead).

## **Secondary Lesions**

Secondary lesions are due to evolutionary changes in primary lesions.

### **Below-the-Skin Lesions**

- Erosion—a superficial lesion involving only the epidermis, therefore no bleeding; heals without a scar; a scooped-out depression. Example: the appearance of skin after a vesicle has ruptured
- Ulcer—a deeper depression involving the dermis, therefore may bleed and heals with a scar; lesion is

irregular. Examples: pressure sore, stasis ulcer, chancre

- Fissure—a linear crack extending into dermis; may be dry or moist. Examples: cheilosis (corners of mouth) or athlete's foot
- Excoriation—an abrasion that is self-inflicted, usually due to scratching from intense itching. Examples: insect bites, scabies, varicella, dermatitis
- Atrophic scar—thinning of epidermis with associated depression. Examples: striae or injection site for insulin
- Scar—when normal tissue is replaced with connective tissue (collagen) the area is fibrotic. Examples: healed wound from surgery, injury, or acne; a hypertrophic scar (common in African Americans) is called a keloid

### **Above-the-Skin Lesions**

- Scaling—flakes of skin from dead epidermis that may be dry or greasy, silvery or white. Examples: psoriasis (silver), seborrheic dermatitis (yellow, greasy), eczema, or simply dry skin
- Crusting—when pustules or vesicles erupt they leave a thickened, dried-up exudate. Examples: impetigo, scab formation following abrasion, weeping eczematous dermatitis
- Lichenification (lichen = moss-like appearance)—an intermediate skin lesion due to prolonged, intense scratching leading to a thickened area of skin characterized by tightly packed papules

## General Strategy

If the patient has a skin complaint, determine whether it is a lesion, pruritus, or skin color change. For skin lesions, do the following:

- Determine whether there is a single lesion or multiple lesions (always check for sites that may not be visible to the patient).
- Determine whether the onset was associated with other signs such as fever, malaise, or joint pains.

- Determine whether the initial lesions appeared in one area and spread or moved to another.
- Determine whether there is associated pruritus.
- Determine whether there are other contact individuals with similar presentations.
- Elicit a medication history, including topical skin applications.
- Determine whether a rash occurred after sun exposure (miliaria [heat rash]).
- Determine whether the patient was exposed to dyes or color film developers (lichen planus).
- With single pigmented lesions, determine any “danger signs,” such as enlargement, change in color, ulceration, or change in sensation (melanoma).

With pruritus as the chief complaint (no obvious skin lesions):

- Determine whether the patient lives or works in an environment that is dry or whether central heating is used.
- Determine whether the patient may have been exposed to fiberglass.
- Determine whether the patient has signs or past diagnosis of renal failure.
- Determine whether the patient has signs of hypo- or hyperthyroidism.
- If the patient complains of specific itching of face, scalp, and genitalia without skin lesions, consider depression.

With skin color changes (not a color change of a lesion; see above):

- Determine whether the patient has had signs of flu and the skin color is yellow (jaundice).

- Determine whether the patient has associated signs of fatigue and has a brown-tan appearance without exposure to the sun (Addison's disease).
- Determine whether the color change is localized to an area of skin and whether this occurred at birth or was acquired (Mongolian spots, café au lait spots, vitiligo, some vascular nevi).

## Evaluation

# Contact and Allergic Dermatitis

One should first attempt to identify a contact allergen, especially when skin lesions appear to be regional ([Table 27-1](#)). Any environmental contact is a potential source. The most common are soaps, lotions, clothing, and poison oak or poison ivy. The onset and relationship to the potential contact allergen are usually clear.

Drug reactions are rare; however, they do occur in 2% to 3% of hospitalized patients. The onset is usually abrupt, resulting in a maculopapular rash involving the entire body or symmetrically the extremities. This may be accompanied by severe itching. The most common drugs are amoxicillin, trimethoprim-sulfamethoxazole, penicillin, or ampicillin. Fixed, single, or multiple lesions that become hyperpigmented are seen with reactions to barbiturates and tetracycline.

## Childhood Diseases

With children, maculopapular rashes are caused by common childhood diseases, including chickenpox (varicella), measles (rubeola), German measles (rubella), and roseola.

One helpful clue is a history of exposure to a patient with known disease (incubation period for most is two to three weeks). Second, the initial location of the rash and its evolution will usually make the diagnosis clear. A brief description of each follows:

**Table 27-1 Contact Dermatitis**

<b>Body Area</b>	<b>Cause</b>
Face and neck	Hairsprays, shampoos, conditioners, hair dyes
Scalp	Perfumes, hair sprays, insect sprays
Sides of neck	Hatband
Forehead	Lipstick, mouthwashes, toothpaste
Around the mouth	Metal earrings
Earlobes	Soaps or cosmetics
Face	
Hands and forearms	
Fingers/hands	Soaps, soap under rings, rings, fingernail polish
Forearms	Soaps, insect spray, wrist bands or tennis elbow brace, tape
Axillae	Deodorants, dress shields, dry cleaning solutions
Trunk	Any new clothing (especially wool or clothing with a dye) or clothing with attached metal or rubber
Anogenital	Douches, contraceptive creams, dusting powder, colored toilet paper, medications used to treat pruritus ani or fungal infections in infants
Feet	Shoe or foot powders, treatment for athlete's foot

- Varicella—Mild, generalized symptoms of malaise, fever, or headache are followed by lesions that first appear on the trunk and then spread to the face and extremities; the sequence of evolution is important, starting as maculopapules, changing in hours to vesicles, pustules, and crusting (new lesions may appear over three to five days).
- Rubeola—The rash is preceded usually by a high fever 40–40.5 °C (104° F to 105° F); two days before the rash, Koplik spots (resembling table-salt crystals) appear on the mucous membranes of the mouth (these are pathognomonic for measles); the rash appears on the face and behind the ears about four days after the onset of symptoms and spreads to the trunk and extremities (including soles of feet and palms).
- Rubella—Preceded by mild symptoms, the rash first appears on the face as a fine, pink rash that spreads to the trunk and extremities quickly over two to three days; the rash disappears over one day in each area (some patients do not have a rash).
- Roseola—Roseola is most common in infants between ages 6 and 18 months; it is heralded by a high fever 39.4 °C to 40.5 °C (103° F to 105° F) for four to five days followed by a faint macular rash on the trunk that lasts a few days.

When erythematous lesions follow an upper respiratory infection or flu (especially in children), two possibilities should be investigated: (1) erythema multiforme, and (2) erythema nodosum. Erythema multiforme lesions are symmetric and may be bullous lesions involving the distal extremities or mucous membranes. They are referred to as target or iris lesions forming a concentric ring with a central

purpura (grayish discoloration). Erythema nodosum commonly involves the pretibial area or arms. Red, tender nodules are found. There are numerous other causes in adults. Treatment of the above is mainly for the underlying disease; antibiotics are often used.

## Scaling

When scaling is prominent there are a few common disorders to consider. Their distribution and characteristic presentation are often helpful. Following is a list with a brief description of each:

- Eczema (atopic dermatitis)—There is often a personal or family history of allergies or asthma; itching may be a prominent symptom with dermal inflammation occurring on the face, neck, upper trunk, hands and wrists, popliteal area of the knees, and antecubital area of the elbows. Constant itching may lead to lichenification. Eczema is chronic and recurrent.
- Psoriasis—Silvery scaling or red plaquing that is usually not itchy appears on the scalp and extensor surfaces of the extremities, particularly the knees and elbows (although some patients may have inverse psoriasis in body folds that is itchy); associated findings include pitting of fingernails or onycholysis (nail separation); some patients may have an associated arthritis of the fingers or sacroiliac joint. Psoriasis is chronic and recurrent.
- Seborrheic dermatitis—This disorder presents as either a dry or oily scaling with a predilection for the scalp, eyebrows, body folds, and presternal or interscapular areas; it is possibly yeast-related. Factors such as stress, nutrition, and seasonal effects (drier humidity in winter due to heated homes) play a role. Patients who

are more prone include those with Parkinson's disease, those who are chronically hospitalized, and those with human immunodeficiency virus (HIV). Seborrheic dermatitis is chronic and recurrent.

- Pityriasis rosea—This disorder appears as ovalshaped, fawn-colored, scaly eruptions. A single patch, called a herald patch, appears one to two weeks prior to more extensive involvement of the cleavage lines of the trunk; the center of the lesions has a cigarette-paper appearance. Pityriasis rosea is more common in women and in the spring or fall (may be due to a virus); it is self-resolving over one to two months.
- Tinea capitis—A presentation similar to that of seborrheic dermatitis occurring in children is tinea capitis due to head lice. There are often small areas of hair loss (alopecia), with broken off or short stubs of hair visible. Accompanying cervical lymphadenopathy is often present. Tinea capitis is more common in African Americans.

## Pruritus

Many skin disorders have itching as an accompanying complaint; however, when the main complaint is itching, a search may be narrowed by location or associated findings. Following are some common presentations:

- Dry skin—Dry skin from environmental causes is more common in the winter, with low-humidity environments in heated homes. Skin may also become dry from frequent bathing or use of soaps with some individuals. Dry skin is also part of the presentation of hypothyroidism.
- Metabolic disease—Uremia occurring with kidney failure (or with hemodialysis), obstructive liver disease,

or malignant disorders (leukemia, lymphoma, or other cancers) may cause itching.

- Psychiatric disorder—Patients who complain of burning and itching that involve primarily the face, scalp, and genitalia with no obvious skin lesions may have an underlying depression.
- Genital/anal itching—In addition to the above-mentioned depression, anal itching may be due to irritation from toilet paper, contact dermatitis, extension of psoriasis or seborrheic dermatitis, irritation from fecal content or diarrhea, or pinworm in children. Localized vaginal itching suggests yeast infection in women (frequent occurrence in diabetics); in athletes and in the obese, “jock itch” (tinea cruris) is a common cause of groin pruritus (sparing the scrotum in men).
- Scabies—When the itching is primarily at night, scabies should be considered. Scabies is caused by mite infestation acquired through bedding or an infested individual. The most common location of lesions is on the sides of fingers and on the palms, appearing as vesicles and pustules occurring as “runs” or “burrows.”
- Urticaria—A hypersensitivity reaction mediated by immunoglobulin E, with quickly changing wheals or hives. The common causes are drugs, insect bites, heat (including hot showers) or cold, exercise or excitement, or reactions to vaccines or food (shellfish or strawberries). The response may be mild or lead to difficulty breathing; severe responses require epinephrine.
- Ringworm (tinea corporis or circinata)—Ring-shaped lesions appear on the face or arms after exposure to an infected cat. (Some patients have only scaly patches.)
- Lichen planus—Violet lesions along scratch marks with a symmetric distribution in a patient exposed to color

dyes or in color film developers is suggestive.

## Acne Vulgaris

Acne vulgaris is probably the most common skin condition; it is caused by sebaceous overactivity with subsequent plugging of follicles, leading to infection with the acne bacillus (*Propionibacterium acnes*, *Staphylococcus albus*, or *Pityrosporum ovale*). Overspill of sebum and fatty acids causes local irritation. Acne vulgaris often begins at puberty and is much more common and severe in males. A similar problem, rosacea, may occur in middle-aged patients and is associated with a higher incidence of migraine headaches. These patients may complain of burning or stinging of the face associated with flushing. It should be kept in mind that large, muscular, young men with acne may be abusing steroids.

The lesions with acne vulgaris are commonly found on the face and upper trunk area. The most common lesion is a comedone (blackhead). Papules, pustules, and cysts may also be seen. The general approach to treatment involves avoidance of touching the lesions, using an over-the-counter benzoyl peroxide cleanser, and avoidance of foods that seem to increase the occurrence. With moderate acne, antibiotic creams or oral antibiotics may be used. With severe acne, isotretinoin (Accutane) is often used.

## Warts

Warts are a common complaint representing single or multiple papules often on the hands or feet. Anogenital warts are not uncommon in homosexual men. Warts are due to a viral infection and often heal spontaneously. Large, chronic warts in older individuals may represent squamous

cell carcinoma and should be biopsied. Treatment for warts is usually with over-the-counter salicylic acid products or liquid nitrogen, or surgical or laser removal.

## Venereal Disease

Venereal disease does not always present with skin lesions; however, those that do should be recognized and referred. Chancroid is caused by *Haemophilus ducreyi*, beginning with a vesicopustule that breaks down and forms a soft, painful ulcer with a necrotic base. The chancre of syphilis, in contrast, is clean, painless, and characterized by a hard base. Granuloma inguinale produces painless nodules with a bright-red friable base. Lesions tend to spread out and can become infected secondarily. Lymphogranuloma venereum is caused by *Chlamydia trachomatis*, producing a quickly vanishing ulcerative lesion on the external genitalia. The characteristic associated finding is inguinal lymphadenopathy producing soft, matted nodes. A patient with herpes simplex virus type 2 will usually present with burning and stinging in a patch of skin in the genital or buttocks area that evolves into a lesion made up of small, grouped vesicles that eventually crust and fall off. Inguinal lymph nodes are often enlarged. Although only a brief introduction, any of the above descriptions or any genital lesions in a sexually active person should be considered suspicious, and referral for laboratory confirmation should be achieved through medical referral. Antibiotics are used for the bacterial causes, and acyclovir is used for herpes simplex virus type 2.

<b>Skin Lesions Associated with Polyarthrititis/Rheumatic Conditions</b>
--

Skin lesions are sometimes associated with conditions that cause joint pain, and therefore may present to a chiropractic office. The most common conditions are rheumatoid arthritis, seronegative arthritides, and connective tissue disorders. Most conditions have characteristic regional joint involvement and radiographic findings that support the diagnosis. However, skin involvement may assist in the diagnosis, or in a patient already diagnosed may represent an indicator of disease activity. Following is a brief list of these lesions:

- Reiter's syndrome—keratogenous lesions on the feet, oral ulcers (also uveitis and conjunctivitis)
- ankylosis spondylitis (although not specifically skin)—uveitis and conjunctivitis
- psoriatic arthritis—psoriatic lesions (usually extensor surfaces), pitting of nails
- rheumatoid arthritis—subcutaneous nodules (often extensor surfaces)
- systemic lupus erythematosus (SLE)—malar erythema, rash, hair loss, oral ulcers
- scleroderma—atrophic, edematous thickening of the skin
- sarcoidosis—erythema nodosum (tender nodules over pretibial area)
- dermatomyositis—discoloration of upper eyelids

## **Skin Cancer**

Patients and chiropractors should be aware of the relative risks of developing skin cancer. They are:<sup>1</sup>

- a history of childhood sunburns
- excessive exposure to sunlight as a child

- excessive exposure through occupational and recreational activities
- fair skin, light hair, and light-colored eyes, especially Irish or Scottish descent
- the presence of more than 50 moles
- a poor ability to tan or tendency toward sunburn
- a family history of skin cancers
- exposure to therapeutic radiography (acne, cancer) or ultraviolet light (psoriasis)
- immunosuppression such as in acquired immunodeficiency syndrome or organ transplantation

Probably the single most important role the chiropractor may play in the evaluation of a patient's skin is the detection of suspicious lesions in need of dermatologic referral. The most important is malignant melanoma. The distinction between a benign lesion and a malignant lesion is summarized by the American Cancer Society mnemonic ABCD (Asymmetry, Border irregularity, Color variation, and Diameter > 6 mm). Therefore, a mole that is burning, stinging, itching, changing shape or color, or growing or bleeding requires a dermatologic evaluation. The original ABCD checklist has been revised to a United Kingdom seven-point checklist. This revised checklist has a very high sensitivity but low specificity.<sup>2</sup> The checklist is a stratified list of seven items divided into three major and four minor criteria. The major criteria are historical and the minor are primarily physical examination findings. The major criteria are changes in size, shape, and color; the minor criteria are inflammation, crusting or bleeding, sensory change, and a diameter greater than or equal to 7 mm. In the elderly and the diabetic, these lesions are often ignored by physicians who assume that they are the consequence of poor healing. Basal cell carcinoma is more common in fair-skinned, young adults with chronic sun exposure. The lesions are found on areas of skin exposed to sun and appear as papules or

nodules with a characteristic “pearly” or translucent appearance. Squamous cell carcinoma, although occurring in a similar group of patients, is not as easily detected. The lesions are usually small, red, hard nodules that ulcerate.

The incidence rate for malignant melanoma has risen 4% per year since 1975, so that the rate of melanoma has gone from 1/1,500 persons in 1935 to a predicted risk of 1/75 in the year 2000 for those living in the United States.<sup>3</sup>

However, the five-year survival rate has gone from 40% in the 1940s to a current rate of 87%. The smaller the lesion the higher the predicted rate of survival. If the lesion is less than 1 mm thick, the survival rate approaches 95%; however, if the lesion is greater than 4 mm thick, the survival rate drops to 50% over five years.<sup>4</sup>

The ability of nondermatologists to detect skin cancer is not impressive. By testing with color pictures, one study indicated that malignant melanoma was correctly identified by only 12% of nondermatologists; an atypical mole by 42% (98% of dermatologists correctly identified).<sup>5</sup> Another limiting factor is that malignant melanoma occurs in exposed areas only 20% of the time, requiring a full body examination. Many patients are embarrassed by full body examination. Even if the examination is performed (with a patient same-sex “chaperone”), a lesion may still be missed. More education in detection of skin cancer is needed in the education of nondermatologist healthcare providers.

Self-examination may be helpful in detecting some of the “danger” signs. One study indicated that patients instructed on self-examination for palpable arm nevi and larger (> 5 mm) nevi scored specificities of 63% and 68%, respectively.<sup>6</sup> The recommendation for self-examination, coupled with an annual examination in patients over age 40 years and every three years in younger patients, is important in detecting skin cancer.

# Management

- If the underlying cause is obviously a contact dermatitis—unless complicated by infection—time and the use of over-the-counter medications such as corticosteroid creams, diphenhydramine hydrochloride (Benadryl), or calamine lotion for poison ivy are usually sufficient.
- For drug-reaction dermatitis, refer back to the prescribing physician or, if over-the-counter, have the patient discontinue use.
- Common childhood diseases (measles, rubella, chickenpox) usually resolve with minimal palliative care; all common childhood diseases should be monitored, and exposed individuals or institutions such as schools should be contacted. Each state has a list of reportable diseases; check individual state for reporting criteria. Monitor for complications.
- Seborrheic dermatitis and acne, if mild, may be helped minimally with over-the-counter medication; however, dermatologic referral is necessary in more involved cases.
- Refer all cases of venereal-related skin disease.
- Comanagement of collagen-vascular cases or referral is suggested.
- Refer all cases of suspected skin cancer to a dermatologist.
- Refer all cases that are not identifiable and worrisome to the patient to a dermatologist.

# CHAPTER 28

## Weight Loss

### Context

Rapid or excessive weight loss is often viewed as an ominous sign indicating life-threatening cancer. It is true that 25% of patients die within the first year of significant weight-loss detection. However, studies indicate that although a significant percentage of patients (7% to 36%) have cancer, very few are occult malignancies.<sup>1-4</sup> Another significant percentage of patients (9% to 18%) are diagnosed as depressed. Fourteen percent to 17% of patients have a gastrointestinal disorder such as inflammatory bowel disease, malabsorption, or peptic ulcer. Twenty-three percent to 35% of patients have no identifiable cause for their weight loss.

Weight loss is a comparative measurement. Past documentation as a base reference is necessary to establish true weight loss. When this information is not available, the next reliable source is family members. The severity of weight loss with regard to significance is not clearly defined. An accepted standard is loss of more than 5% of total body weight within six months or 10% within one year. It is interesting to note that as many as 50% of patients who complain of significant weight loss are unsupported by past medical records or family members.<sup>2</sup> Only about one-third of patients with significant weight loss report it as the chief complaint. The remainder have systemic complaints that

are elevated to a higher level of concern because of an associated weight loss.

The significance of weight loss increases with age. Either low body weight or unintentional loss of weight factors into increased morbidity and mortality.<sup>5</sup> Obviously, this is a multifactorial occurrence given that the elderly have a naturally higher morbidity and mortality rate. Compared with risk to seniors who are at ideal or high body weight, the risk of death is significantly higher with very low body weight. In a sense, those with higher body mass are protected because of an available “reserve” that buffers them from reaching the critical threshold beneath which skeletal and cardiac muscle wasting occur.

## **General Strategy**

### **History**

- Attempt to document a significant loss of weight from past medical records or corroborate the patient’s report with family member support or at the very least a change in clothing or belt size.
- Determine whether weight loss is intentional. If it is, determine whether the patient is educated in proper dieting.
- If weight loss is intentional, determine whether the patient feels that although he or she appears thin, the patient’s perception is that he or she is overweight.
- If weight loss is unintentional, determine whether the patient’s food intake is normal or decreased.
- If food intake is normal, determine whether there is associated diarrhea.
- If food intake is decreased, determine whether the patient has pain or discomfort associated with eating.

- Obtain a full medication, drug, and alcohol history.
- Screen the patient for depression or other psychologic problems.
- Determine if there are any symptoms that might suggest cancer, hyperthyroidism, diabetes, or gastrointestinal pathology, including peptic ulcer disease or inflammatory bowel disease.
- Determine the patient's ability to feed himself or herself (financially, functionally, environmentally).

## **Evaluation**

- Attempt to document true weight loss greater than 5% over six months or 10% over one year, comparing with any available past medical records.
- Look for indications of "occult" disease through examination of the mouth, skin, and lymph nodes.
- Look for any indications of hyperthyroidism, including a fine tremor, exophthalmos or lid lag, increased pulse, and respiratory rate.
- Evaluate the patient for chronic obstructive pulmonary disease (COPD) if suggested from history (chronic cough in a smoker for three consecutive months for two years).
- Evaluate the patient with laboratory testing for any suspected underlying metabolic problems such as anemia, diabetes, hyperthyroidism, cancer, liver, and kidney disease.
- Evaluate the patient with a chest radiograph (especially in smokers) and stool Hemoccult tests.
- Radiography of painful joints may reveal a metastatic or primary process. If negative yet the suspicion is high, a bone scan is warranted (especially in a patient with a past history of cancer).
- Refer for upper gastrointestinal studies, endoscopy, or colonoscopy in patients with suspected upper and

lower gastrointestinal disease.

## Management

- If occult processes are discovered or still suspected after evaluation, refer to an internist.
- Refer to a psychiatrist for depression and other psychologic problems.
- Refer to an eating disorders clinic if anorexia nervosa is suspected.
- Refer to a medical physician for evaluation of medication-induced weight loss or possible medical control of anorexia or cachexia if needed.

## Relevant Physiology

Weight loss occurs because of a decrease in caloric intake, increase in utilization, or loss in the stool or urine. A number of factors may contribute to weight loss when caloric intake is the cause, including anorexia, nausea, altered sense of taste or smell, and altered perception of satiety. High on the list of causes are cancer, depression, and medications. Following are some proposed mechanisms in these patients:

- Humoral substances (bombesin and somatostatin) may cause early satiety or anorexia in patients with cancer, possibly due to a distention effect.<sup>6</sup>
- Cytokines (tumor necrosis factor, methyl N-methylnipeotate [adipsin], and interleukin 1) are causes of anorexia in patients with cancer, acquired immunodeficiency syndrome (AIDS), and infection.<sup>7</sup>
- Decreased norepinephrine and increased corticotropin-releasing factor levels may play a role in an early satiety effect or food aversion with depression.<sup>8</sup>

- In the elderly, the satiety effect of cholecystokinin is increased; zinc deficiency may cause anorexia.

Of course, a decrease in caloric intake may be voluntary, as is the case with anorexia nervosa, or involuntary because of isolation or economic hardship. Increased utilization may be due to demands of increased physical exertion as is seen in marathon runners and triathletes. Internal metabolic demands may come from hypermetabolic states such as hyperthyroidism (more rarely pheochromocytoma) or cancer. Weight loss may be the most common presenting complaint of the elderly with hyperthyroidism. Patients with either congestive heart failure or chronic pulmonary disease may lose weight due to an increased workload of breathing.

Medications may lead to significant weight loss through a variety of mechanisms. Following are some common examples:

- Nonsteroid anti-inflammatory drugs (NSAIDs), theophylline, quinidine, procainamide, and other drugs may cause nausea.
- Digoxin toxicity causes stimulation of the “vomit” center in the medulla, leading to anorexia, nausea, and vomiting.
- Angiotensin-converting enzyme (ACE) inhibitors may alter taste or smell.
- Tricyclic antidepressants, diuretics, and clonidine may cause dry mouth, which adversely affects swallowing.
- Amphetamines and other stimulants inhibit the appetite center in the hypothalamus, as does smoking.
- Alcohol may be used as a substitute for food.
- Loss of calories may occur through several processes, as follows:
  - maldigestion and malabsorption
  - diarrhea
  - renal excretion of glucose and protein

Significant loss of weight may carry with it the following consequences:

- increased rate of infection
- cardiac and muscle wasting
- decreased sensitivity to chemotherapy in patients with cancer

## Evaluation

### History

Careful questioning of the patient during the history taking can point to the diagnosis ([Table 28-1](#)).

Intentional weight loss is due to a limited number of causes. Questioning first determines the patient's knowledge of proper dieting. Second, if the patient is thin, it is important to determine whether he or she has a distorted image of self. If patients feel that they are overweight and yet their weight is 15% below normal, anorexia nervosa is likely. Another subgroup of patients may be wrestlers. To meet certain weight classifications, wrestlers often resort to short-term approaches to weight loss through water loss.

Unintentional weight loss is often accompanied by other signs or symptoms that help lead to the diagnosis. The most logical line of questioning begins with a discrimination between those patients who have a normal or increased appetite and those who do not. Patients who have a normal or increased appetite may be further subdivided into those with chronic diarrhea and those without. Patients with diarrhea are likely to have inflammatory bowel disease, malabsorption, parasitic infection, or pancreatic disease. These patients often will have other abdominal symptoms that help differentiate further (see [Chapter 33](#)). Patients

with or without diarrhea should be screened for common symptoms related to the following:

**Table 28-1** History Questions for Weight Loss

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Are you intending to lose weight?	Dieting, anorexia nervosa	(With a thin patient) Do you feel you are overweight and need to restrict your diet? (With an overweight patient) What kind of diet are you on?	Possible anorexia nervosa, especially with a young female  Determine whether the patient understands the nutritional requirements and the yo-yo effect of many diet fads
Is your appetite normal or increased?	Conscious decision not to eat due to pain, poverty, or endocrine or hypermetabolic states if increased food intake	Is it painful to eat?  Do you have diarrhea?  Do you have any back pain unrelieved by rest, or past history of cancer?	Temporomandibular joint (TMJ) or dental problems are most common; ask about ill-fitting dentures and painful oral lesions  Increased loss; determine underlying cause (inflammatory bowel disease likely)  Cancer
Is your appetite decreased?	Side effect of medications, depression, cancer	What medications are you currently taking? Do you feel sad or depressed, not enjoying life's activities as you used to? Do you have a chronic history of smoking? Blood in stools?	Check drug handbook to determine effect on appetite Depression  Possible lung cancer  Possible colorectal cancer

- diabetes—polyphagia, polydipsia, polyuria, numbness and tingling in the hands or feet, or visual changes
- hyperthyroidism—nervousness, weakness, tremor, menstrual dysfunction, heat intolerance, etc.
- excessive exercise
- decreased eating—check for painful conditions associated with eating, including peptic ulcer, oral or anal conditions, and dysphagia; also check for limited diet and alcoholism

Patients who do not have a normal appetite should be questioned regarding medications, COPD, congestive heart failure, depression, liver disease, and kidney disease.

Certainly, the combination of weight loss and spinal pain that has been unresponsive to conservative care for one month in a patient over age 50 years with a history of prior cancer is highly suggestive of metastasis.

## **Examination**

The physical examination is less revealing than the history. Documentation of weight loss is the initial task. If convinced that there is significant weight loss, examination for signs of hyperthyroidism, congestive heart failure, COPD, and other lung pathology is warranted. Patients suspected of having anorexia nervosa may have coexisting signs of bulimia. These are usually the result of the erosive action of gastric juices or the loss of protein. Swollen parotid glands, hoarseness unrelated to respiratory symptoms, calluses on the backs of fingers, tooth erosions, or swollen hands or feet may be clues.

Given the broad list of possibilities, a general screening lab testing, including urinalysis, may indicate the underlying problem if anemia, kidney, liver, or diabetic disorders are the cause. Chest radiographs are often very revealing. One study indicated that 41% of weight loss cases had a significant abnormality on chest films, including a lung mass or infiltrate, congestive heart failure, or adenopathy.<sup>2</sup>

## **Management**

The chiropractor may serve in a primary care role by referring cases to appropriate specialists, and comanaging other cases. Comanagement involves a supportive and an educational role. Instruction on proper diet, assistance with access to financial assistance programs, and food programs such as Meals on Wheels are among the many adjunctive

tools that can be used. Patients who are depressed or suffering from prolonged bereavement due to the loss of a loved one will benefit from referral to a psychologist or psychiatrist. Patients with dental problems should be referred to a dentist. Those with motor skill or memory deficits should be referred to a therapist who specializes in these areas. Patients suspected of having anorexia nervosa must be referred to an eating disorders clinic. It is far beyond the scope of most healthcare professionals to manage this disorder. Simple advice or counseling is useless.

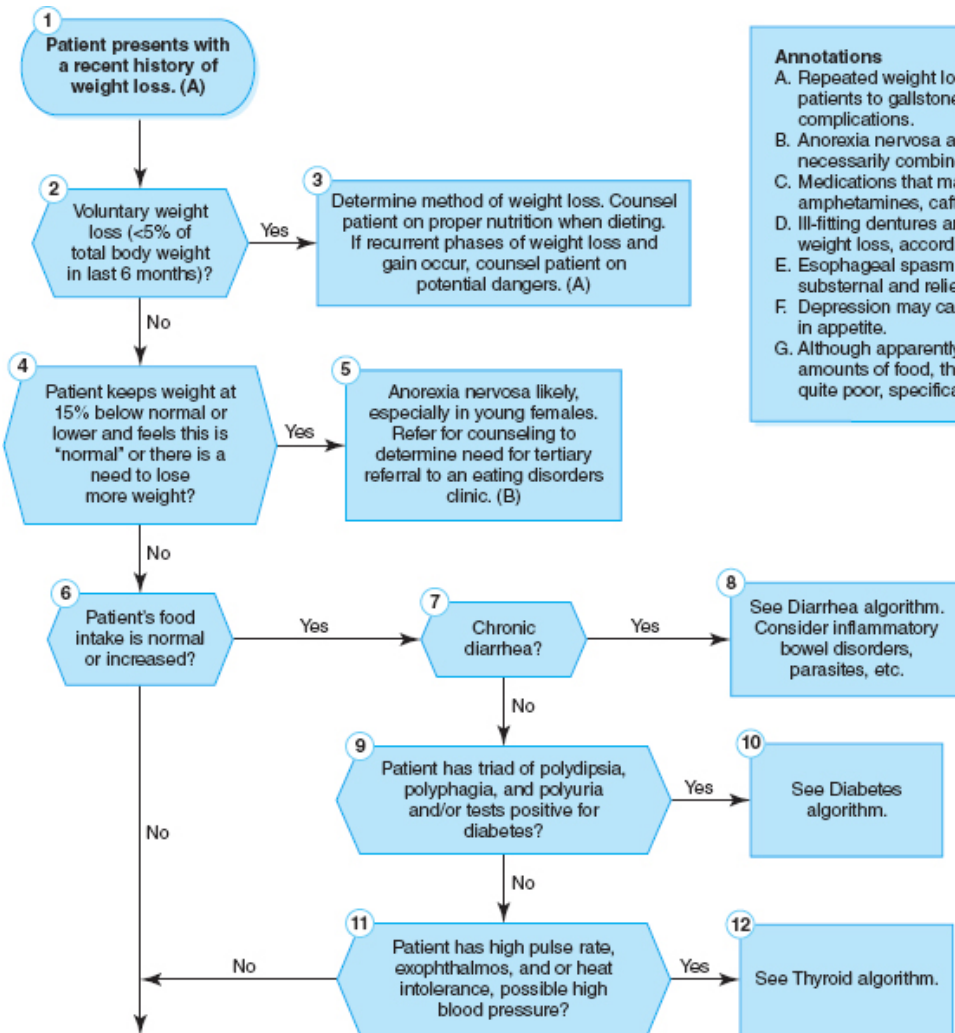

Neuropsychological disorders need a minimum of comanagement. Conditions such as Parkinson's disease, various causes of dementia, stroke, depression, and alcoholism require specialized care.

One option for some patients is referral to a medical physician for prescription of medication that increases appetite. There are several drugs available, as follows:

- Cyproheptadine (antiserotonergic drug), although generally effective, has not been shown to affect weight gain in patients with advanced cancer.
- Corticosteroids are used in patients with advanced cancer; however, it has yet to be demonstrated that the weight gain is not primarily fluid; in addition, side effects, including oral candidiasis and Cushing's-like effects, occur often.
- Megestrol acetate (progestational agent) is an expensive but effective medication with few side effects for patients with cancer.

## Algorithm

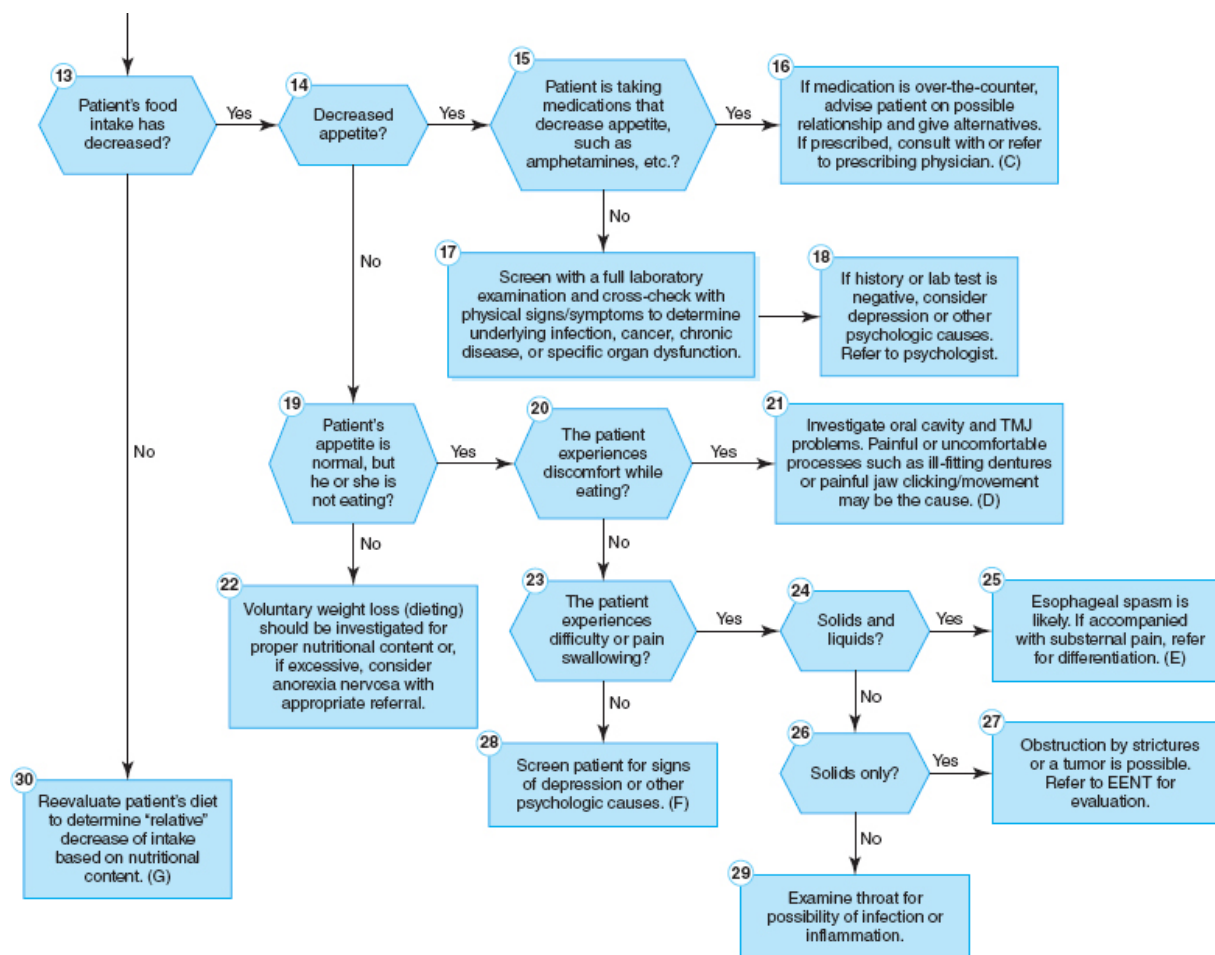

An algorithm for evaluation and management of weight loss is presented in **Figure 28-1**.

#### Annotations

- A. Repeated weight loss and gain may predispose patients to gallstones or cardiac and renal complications.
- B. Anorexia nervosa and bulimia are not necessarily combined disorders.
- C. Medications that may decrease appetite include amphetamines, caffeine, chemotherapy, etc.
- D. Ill-fitting dentures are not usually a cause of weight loss, according to one study.
- E. Esophageal spasm simulates angina in that it is substernal and relieved by nitroglycerin.
- F. Depression may cause an increase or decrease in appetite.
- G. Although apparently eating large or adequate amounts of food, the nutritional content may be quite poor, specifically in seniors and teenagers.

## CHAPTER 29

# Weight Gain/Obesity

### Context

Simply put, the most common cause of weight gain is an increase in caloric intake or a decrease in energy expenditure. Fluctuations in weight are common within a few pounds and generally reflect fluid retention and loss. Cyclic fluctuations are common in women in relation to menstruation. Substances that cause salt retention such as estrogen and steroids and appetite-stimulating drugs such as some antidepressants are less common causes. Familial obesity and low resting metabolic rates are uncommon. Only about 10% of obese patients have an underlying neurologic, endocrine, or genetic cause. Hypothyroidism may account for small increases in weight due to a slowed metabolic rate; however, significant weight gain is found in only 60% of patients and usually when the disease is advanced. Eighty percent of patients with adult-onset diabetes are obese.<sup>1</sup>

Obesity, to some extent, is a relative term. In the past a patient's weight was compared with actuarial tables that reflected averages based on height, weight, and gender. This simple approach was found to be misleading, not accounting for body build and the amount of muscle mass and body fat. A newer approach is to combine two methods. A determination of the body mass index (BMI) coupled with a body fat measurement accounts for some of these

variables. Some studies use a BMI greater than or equal to 25 kg/m<sup>2</sup> whereas others use greater than or equal to 30 kg/m<sup>2</sup> to indicate overweight or obesity. Obviously, the percentage of overweight individuals increases when using the lower threshold.

Obesity has been categorized into the following classes:

Class 1: BMI of 30–34.9

Class 2: BMI 35–39.9

Class 3: BMI  $\geq$  40 (morbid or extremely obese)

When using 25 kg/m<sup>2</sup> as the threshold BMI indicator of overweight or obesity, the prevalence of overweight or obesity in the United States increased more than 25% over the last three decades.<sup>2</sup> Sixty-three percent of men and 55% of women fall into the category of a BMI of 25 kg/m<sup>2</sup> or greater, meaning being either overweight or obese.

Averaged, this equals more than half of the adult population over the age of 17 years. Using 30 kg/m<sup>2</sup> as the threshold, the prevalence of overweight or obesity in the United States increased from 12% in 1991 to 17.9% in 1998.<sup>3</sup> These increases were independent of smoking status. It is alarming that the greatest magnitude of change was seen in younger individuals (18- to 29-year-olds) and those with higher education levels. Regionally, the greatest increases were seen in the mid- and south Atlantic states. Obesity prevalence increases were seen in all sociodemographic groups; however, the prevalence of obesity increased dramatically in the Hispanic population. More than one-third of U.S. adults (35.7%) are obese.<sup>4</sup>

More recent literature over the last several years appears to support earlier findings and emphasizes the growing concern regarding obesity, especially in the United States. Below is a summary of the findings from some of these studies:

- The prevalence of overweight has increased from release of the 1988–1994 NHAMES III report to release

of the 1999–2000 report and then again in the 2009–2010 report. For obesity, there was an increase of 8% between these two time points in men with no significant change in women, holding at around 35.8%. The prevalence of obesity increased from 14.0% in 1999–2000 to 18.6% in 2009–2010 among boys; among girls the prevalence was 13.8% in 1999–2000 and 15.0% in 2009–2010. There seems to be leveling off currently with no significant change in obesity prevalence from 2007–2008 to 2009–2010. Yet there are more than 5 million girls and approximately 7 million boys who were obese during this same time period.<sup>5,6</sup>

- The prevalence of class 3 obesity is increased rapidly in the years 1990–2000 from 0.78% in 1990 to 2.2% in 2000, with the highest increase among African American women, individuals who have not completed high school, and short persons.<sup>7</sup> However, between 1988–1994 and 2007–2008 the prevalence of obesity increased in adults regardless of income or education levels.
- The age-adjusted prevalence of obesity was 30.5% in 1999–2000 compared to 22.9% in 1994.<sup>8</sup> The prevalence of overweight increased from 55.9% to 64.5%. Extreme obesity increased from 2.9% to 4.7%.
- Sadly, in 2009–2010, over 78 million U.S. adults and about 12.5 million U.S. children and adolescents were obese.<sup>6</sup>

These statistics become important in the context of one study that found that white men aged 20 years with BMIs greater than 45 are predicted to have 13 years of life lost (YLL), with eight years of life lost for women in the same age and range.<sup>9</sup>

Another issue regarding obesity is cultural perception. It may be acceptable, and sometimes desirable, to be

overweight as one ages. This is often perceived as a sign of prosperity. It is important to recognize this cultural variation and be sensitive to different perspectives. However, morbid obesity carries with it enough risk that some degree of weight loss would need to be suggested.

Being obese carries some increased risk in several areas.<sup>10</sup> Individuals with the greatest weight had an increased prevalence of having two or more health disorders.

- Mortality rates are higher for patients with a BMI of 25 or higher compared with normal-weight individuals. The risk of death was from all causes including cardiovascular disease, cancer, and other diseases. African Americans were at lower risk than Caucasians when comparing rates of death with high-BMI individuals.<sup>11</sup> Rates for a condition known as non-alcoholic fatty liver disease has risen dramatically due to obesity. It is becoming a major reason for the need of a liver transplant.
- The obese are 3 to 10 times more likely to develop adult-onset diabetes (insulin resistance increases with weight gain).
- The obese have a higher incidence of cardiovascular disease, hypertension, dyslipidemia, and stroke.
- The obese are more likely to have sleep apnea or hypersomnolence syndrome, which carries with it the risk of arrhythmias, hypoxemia, cor pulmonale, and pulmonary hypertension. Specifically, there is a rising trend of atrial fibrillation found in the U.S. population with the highest risk factor being obese.
- The obese are more likely to have degenerative joint disease, especially in the hips and knees; it is also probably a risk factor for low back pain.
- The obese have an increased risk for cholelithiasis, thromboembolism, varicose veins, and blunted growth

hormone response.

- A recent study<sup>12</sup> estimates that obesity-related morbidity accounts for approximately 6.8% of U.S. healthcare expenses. The estimated annual medical cost of obesity in the U.S. was \$147 billion in 2008 U.S. dollars.
- Medical expenses for people who are obese were \$1,429 higher than those individuals of normal weight.

A new observation may be important to understanding fat accumulation. Findings from several studies suggest that parasympathetic activity increases insulin sensitivity and fat synthesis.<sup>13</sup> Supporting this theory is the observation that there appears to be an association between reduced parasympathetic nervous system function and increased plasma-free fatty acid levels, and also an association between insulin resistance in patients with a combination of obesity and type-2 diabetes mellitus. An increase in parasympathetic tone occurs at night, promoting nocturnal deposition of fat and possibly explaining why fat deposits in some areas and not others. For example, visceral white adipose tissue (intra-abdominal fat) is more heavily innervated than subcutaneous fat. Systemic effects may be that elevated plasma levels of free fatty acids may lead to a pro-inflammatory and pro-atherogenic state. A low-grade systemic inflammation may factor into some of the morbidity associated with obesity. A laboratory test, C-reactive protein (CRP), is an indicator of systemic inflammation and is more commonly used with rheumatoid and other overtly inflammatory-based conditions. CRP has been shown to estimate future risk of coronary artery disease. There appears to be a correlation between a high BMI and acute-phase CRP in middle-aged and elderly individuals. However, these studies did not account for confounding causes such as other disorders. A recent study<sup>14</sup> demonstrated that a higher BMI is associated with

higher CRP in adults aged 17 to 39 years. This association was independent of any coexisting disorders that might also influence CRP. This study also indicated that the distribution of fat was correlated with an increased CRP independent of BMI. A high waist-to-hip ratio was associated with an increase in CRP. This distribution indicates larger amounts of visceral fat. Elevated levels of CRP at 0.22 mg/dL were found in 27.6% of individuals.

## **General Strategy**

### **History**

- Determine the amount of weight gain and specify over what period of time.
- Determine what constitutes the patient's diet; follow with a diet diary.
- Determine whether the patient is taking any medications that may increase fluid retention or appetite.
- Determine the patient's family history with regard to obesity and diabetes.
- Determine whether the patient has recently stopped smoking.
- Determine any changes in exercise levels.
- Determine whether the patient is under stress and uses food for relaxation or reward.
- Determine whether the patient has any symptoms of hypoglycemia (insulinoma; rare).

### **Examination**

- Weigh and measure height of the patient.

- Determine the BMI.
- Determine the patient's percentage of body fat with skin calipers or an impedance device (referral for water immersion method is less practical, but most accurate).
- Examine the patient for signs of fluid retention in abdomen and legs.
- Examine the patient for congestive heart failure if suspected from history (difficulty breathing while lying recumbent) and obtain a chest radiograph.
- Perform laboratory evaluation if the patient has historical and/or physical signs of diabetes, Cushing's disease, or hypothyroidism.

## Management

- The majority of obese patients can be managed with a healthful diet and a graduated exercise program.
- It may be necessary to work with a team including a specialist in weight loss to better guarantee compliance with suggestions and provide a support network for those making substantial lifestyle changes.

## Evaluation

## History

It is extremely important to approach the obese patient from a health risk perspective and not be perceived as being judgmental or addressing the more cosmetic aspects of excess weight. As mentioned above, weight gain over a day or two is most often due to fluid retention. Therefore minor gain in weight over a number of days or during a

woman's menstrual period is of little concern. The patient who is dieting, however, may feel discouraged. Also, when patients are exercising they must keep in mind that muscle weighs more than fat.

## Examination

Estimation of a patient's relative body weight is best accomplished with a formula to determine the BMI. In addition, an estimate or measurement of body fat content is crucial to determining the degree to which weight is due to fat and muscle. The BMI is calculated by dividing kilograms of weight by meters of height. The conversion for pounds and inches is  $750 \times \text{lb/sq in.}$  A BMI over 27 is equal to being about 20% overweight and warrants further investigation and management.

## Management

Given that the most common cause of weight gain is overeating or eating an unbalanced diet, the chiropractor must decide how much time, investment, and interest can be donated to patient management. There are many centers that specialize in weight loss. **Table 30-1** is a summary of many popular diet plans with a general description of the plan's focus and the pros and cons of each. These centers do not focus on diet alone but address issues of mental attitude, motivation, and exercise. Quick fixes with diet drinks or fad diets are to be avoided. Statistically, most patients who diet eventually gain back weight over a period of a year or two. According to one study,<sup>15</sup> approximately one-third of adults who attempt to lose weight or maintain weight loss focus more on less fat than fewer calories. Less than one-fifth of individuals

combine a regimen of decreased caloric intake with a couple of hours of physical activity each week. Regular exercise such as brisk walking reduces body weight and body fat in overweight and obese postmenopausal women.<sup>16</sup> In a study of over 73,000 women ages 50 to 79 years, subjects who walked or were engaged in vigorous exercise 2.5 hours a week reduced the risk for cardiovascular events by about 30%.<sup>17</sup> Researchers in the Health Professionals Follow-Up Study assessed 44,000 men over 12 years for exercise and levels of daily activity. Men with the greatest activity had a 30% decreased risk over sedentary males for cardiovascular risk. Specific activities and risk reduction included weight training—33% reduction, rowing—18% reduction, and running—42% reduction.<sup>18</sup> Weight gain in women has been associated with a decrease in physical activity and increased levels of pain.<sup>19</sup> Pain may act as a deterrent to exercise, yet weight loss has been shown to decrease body pain.

**Table 29-1** Summary of Some Popular Diets

<b>Diet</b>	<b>Summary of Focus, Advantages, and Disadvantages</b>
Atkins	Focuses on restricting carbohydrate calories and emphasizes fat and protein. Examples of foods allowed include red meat, chicken, turkey, seafood, eggs, high-fat dairy, oil, nuts, and vegetables that do not contain high amounts of starch (i.e., potatoes). Three phases of diet include induction, weight loss, and maintenance. High degree of initial satisfaction due to “desirable” foods allowed plus initial rapid weight loss (water). Concerns include risk of cardiovascular disease and kidney stones. Any diet that restricts calories will, in the initial phases, likely decrease blood pressure and reduce blood sugar, cholesterol, and triglycerides.
Eat Right for Your Type	Not really a weight loss diet, but a diet that is based on blood type, founded on the belief that a patient’s blood type determines digestion and immune response. Diet has a list of

	<p>foods to avoid and foods to emphasize based on blood type and can range from modified vegetarian to large portions of animal fat. Concerns are the lack of scientific evidence and the potential deficiencies in needed nutrients with some recommended plans.</p>
Beverly Hills	<p>A rapid weight loss plan with no long-term goals. The premise is that an individual can lose 10–15 pounds in 35 days. There is a heavy initial emphasis on fruits that will result in fluid loss but possible diarrhea. The claim is that eating one type of food in combination with another type, such as a protein with a carbohydrate, destroys specific digestive enzymes, leading to weight gain and poor digestion. Therefore, the contention is that eating food types separately encourages weight loss. Concerns are the same for all diets that emphasize rapid weight loss with severe food restrictions and no long-term approach.</p>
Fit For Life	<p>Main focus is specific food combinations eaten at specific times of the day; emphasis is on fruits and vegetables. There is no restriction specifically on calories or grams of fat due to the types of foods recommended (i.e., fruits/vegetables). A vegetarian-based diet with restrictions of protein, including lean protein meats and low-fat dairy products, may have an effect of imbalance or deficiency in certain needed nutrients. This is less of a weight loss diet than an approach to healthy eating with weight loss as a side benefit.</p>
Jenny Craig	<p>This is a highly structured program focused initially on prepackaged foods, weekly counseling that promotes lifestyle changes and teaches meal planning, exercise, and managing stress as important elements in maintaining weight loss. The advantages are the convenience of prepackaged foods and personal support. The disadvantages are the initial cost and the difficulty of following the initial plan while dining with others. More convenient for single individuals. Due to prepackaging and nutritional considerations, there are no concerns from a nutritional perspective. Slow, consistent weight loss with a focus on healthy lifestyle are important pluses.</p>
Mayo Clinic	<p>The diet is not endorsed by the Mayo Clinic. The focus is on eating large amounts of grapefruit, meat, and high fat until satiated. The contention is that grapefruit aids in the digestion of fat. Cautions are from the imbalance and restriction of complex carbohydrates. Also, some studies indicate that high amounts of grapefruit intake may promote kidney stones.</p>
Nutrisystem	<p>Another plan focused on prepackaged food. Some store-</p>

	bought items are allowed. Advantage is the prepackaging and the online support. Disadvantages are cost and concern about the addition of appetite suppressants sold along with the food.
Optifast	This is a medically supervised weight loss approach with a focus on low-calorie liquid shakes and supplements. The diet is intended for the markedly obese (i.e., BMI over 30). Advantages are the medical supervision, which includes regular blood work, counseling with registered dietitians, and maintaining nutritional balance. Optifast quotes a study that indicated weight loss in 600 patients who lost 5%–10% of body weight and maintained this loss for up to five years. However, much of the weight was gained back during this time frame. In other words, initial weight loss was greater, but then weight was gained back to a plateau.
Pritikin	A low-fat diet, the Pritikin diet focuses on unprocessed fruits and vegetables, lean animal foods, and nonfat dairy products. Calorie intake is based on “calorie density,” which is the amount of calories per pound, with a restriction to foods that contain 400 calories or less per pound. A generally healthy diet, the primary concern is long-term compliance (as with many diets).
Scarsdale	Another rapid weight loss approach to be used for only two weeks, this diet emphasizes lean animal foods, fruits, vegetables, and the use of herbal appetite suppressants. There is an extreme carbohydrate restriction with no snacks allowed. This provides rapid weight loss through fluid loss. As with all rapid weight loss approaches, the vast majority of individuals gain weight back. There is also some increased risk of the development of kidney stones and gallstones.
South Beach	An MD-developed program that has three phases. The first phase is two weeks long and focuses on normal-sized helpings of lean meats (e.g., chicken, turkey, fish, and shellfish) and vegetables. Carbohydrates are restricted based on their glycemic index, so that the first two weeks eliminates alcohol, fruit, bread, rice, potatoes, pasta, baked goods, sugar, and pastries. Wine, fruits, and whole grains are phased in during the later two phases. Although considered a low-carb, low-fat diet, it is more about “good carbs” versus no carbs based on their glycemic index.
Weight Watchers	Weight loss is based on a point system for calorie restriction. Foods can be chosen within the point system restrictions. Prepackaged foods are available. There is also an emphasis on weekly support meetings that encourage healthy lifestyle

	choices and make use of weekly weigh-ins and associated peer pressure/support. Generally, a healthy diet approach.
Zone	This diet is a very low caloric diet (800-1200 calories) based on low carbohydrate, high protein, and moderate fat intake, emphasizing a balance of foods at each meal to stay within "the zone." Focus is on foods with a low glycemic index. Restricts refined carbohydrates low in nutrition and emphasizes fruit and low-starch vegetables. Low in whole grains and calcium.

The solution to permanent weight loss is total management by a specific individual or team with inclusion of a sensible exercise routine coupled with a sensible diet (see **Exhibit 29-1**). The time demand for education, exercise and diet prescription, and counseling/support may be well beyond the time availability and expertise of the chiropractor. Comanagement with a medical doctor or a clinic specializing in weight loss is often more appropriate. The newest medical approach is with a new class of drugs called lipase inhibitors. Orlistat (Xenical) prevents the breakdown of some fat (up to 30%) so that it can be excreted in the feces without being absorbed. Some degree of weight loss was achieved and maintained after 18 months in a study comparing treatment with orlistat compared to placebo.<sup>20</sup> Approximately 33% of patients on orlistat versus 25% of patients on placebo lost weight initially. Long-term maintenance of weight loss ( $\geq 10\%$  of initial weight) was 28% for those on orlistat versus 14% on placebo.

Referral for medical consultation is warranted when drugs are suspected as the underlying cause or when metabolic problems such as Cushing's disease or hypothyroidism are suspected.

### **Exhibit 29-1 Low-Fat Foods**

## Here Are Some Low-Fat Foods To Choose More Often:

	Serving	Calories	Grams of Fat
<i>Dairy Products</i>			
Cheese:			
Low-fat cottage (2%)	1/2 cup	100	2
Mozzarella, part skim	1 oz	80	5
Parmesan	1 tbsp	25	2
Milk:			
Low-fat (2%)	1 cup	125	5
Nonfat, skim	1 cup	85	trace
Ice milk	1 cup	185	6
Yogurt, low-fat, fruit flavored	1 cup	230	2
<i>Meats</i>			
Beef:			
Lean cuts, such as trimmed bottom round, braised or pot-roasted	3 oz	190	8
Lean ground beef, broiled	3 oz	230	16
Lean cuts, such as eye of round, roasted	3 oz	155	6
Lean and trimmed sirloin steak, broiled	3oz	185	8
Lamb:			
Loin chops, lean and trimmed, broiled	3 oz	185	8
Leg, lean and trimmed, roasted	3 oz	160	7
Pork:			
Cured, cooked ham, lean and trimmed, baked	3 oz	135	5
Center loin chop, lean and trimmed, broiled	3 oz	195	9
Rib, lean and trimmed, roasted	3 oz	210	12
Shoulder, lean and trimmed, braised	3 oz	210	10
Veal:			
Cutlet, braised or broiled	3 oz	185	9
<i>Poultry Products</i>			
Chicken, roasted:			
Dark meat without skin	3 oz	175	8
Light meat without skin	3 oz	145	4
Turkey, roasted:			
Dark meat without skin	3 oz	160	6
Light meat without skin	3 oz	135	3
Egg, hard cooked	1 large	80	6
<i>Seafood</i>			
Flounder, baked, no butter or margarine	3 oz	85	1
Oysters, raw	3 oz	55	2
Shrimp, boiled or steamed	3 oz	100	1
Tuna, packed in water, drained	3 oz	135	1
<i>Other Foods</i>			
Salad dressing, low calorie	1 tbsp	20	1

## Osteoporosis

### Context

The signs of osteoporosis often appear suddenly with the development of a painful kyphosis or hip fracture. Over half of women over age 50 years will have a fracture due to osteoporosis.<sup>1</sup> There are approximately 700,000 vertebral fractures and 300,000 hip fractures per year in the United States with an annual cost of \$18 billion. Less than 50% of patients with hip fracture recover prefracture function. There is a wide variation in reported mortality rates for individuals who suffer a hip fracture. This variation is due in part to differences between men and women and differences based on the time included in the measure. Most studies indicate an approximate range of 13% to 21.5%.<sup>2, 3</sup> Risk may be as high as 24% in women and 26% in men when measured at five years postfracture. It appears that if hip fractures are treated within 48 hours, this risk decreases.<sup>4</sup> Surprisingly, less than one-quarter of women who have sustained an osteoporotic fracture currently receive appropriate therapy.<sup>5</sup> The chiropractor's role with osteoporosis is both diagnostic and preventive. It is estimated that 50% of osteoporotic hip fractures and 90% of vertebral compression fractures are preventable.<sup>6</sup> Prevention should not be thought of as crisis intervention but a lifelong attempt at development and preservation of bone mass.

Osteoporosis is a loss of bone mass associated with deterioration of the microarchitecture of bone tissue. Osteoporosis is generally divided into bone loss associated with age, called senile or senescent osteoporosis (type II) and postmenopausal osteoporosis (type I). Women are susceptible to both types. Radiographically, osteoporosis is classified based on the area or region of involvement. Generalized osteoporosis is the most common form, found with both senile and postmenopausal causes. A regional osteoporosis may occur that is restricted to a bone or a portion of a limb. This is most often found with immobilization and Sudeck's atrophy (associated bone changes found with reflex sympathetic dystrophy). Localized osteoporosis may occur in specific areas of bone as a result of infection, neoplasm, or an inflammatory arthritis.

Osteoporosis is often classified as primary or secondary. Primary causes include senile and postmenopausal types. Secondary causes include hormonal dysfunction such as hyperthyroidism and hyperparathyroidism as well as the effect of reduced bone mass associated with the use of thyroid medication, corticosteroids, smoking, and alcohol.

The World Health Organization (WHO) distinguishes the degree of loss of bone mass by two terms:<sup>7</sup>

- osteopenia—bone density greater than 1 standard deviation (SD) below the normal mean but less than or equal to 2.5 SD below the normal mean
- osteoporosis—bone density greater than 2.5 SD below the normal mean

Women with a hip bone mineral density (BMD) T-score of  $-2.5$  or less and an existing vertebral fracture had a 56% chance of additional vertebral fracture whereas those with normal BMD and no prevalent vertebral fracture had only a 9% risk.<sup>8</sup>

The difficulty with diagnosing and managing osteoporosis is that it is radiographically hidden until 30% to 50% of bone mass is lost. It is therefore important to be aware of more sensitive imaging options that allow for screening of high-risk patients. When osteoporosis is inadvertently discovered on radiographs, it is necessary to include a list of less common but possible differentials. The main differentials include osteomalacia, renal osteodystrophy, hyperparathyroidism, Paget's disease, and multiple myeloma. When an underlying pathologic process is discovered, referral for medical management or comanagement is warranted.

## **General Strategy**

### **History**

- Determine whether the patient has any known risk factors.
- Determine whether the patient has any indications of hormonal dysfunction.
- Determine whether the patient is taking corticosteroids, thyroid supplementation, estrogen, or calcium and Vitamin D supplementation or has adequate calcium content in his/her diet.
- Determine the patient's exercise routine, if any.
- Determine whether there is any history of cancer.

### **Evaluation**

- Evaluate radiographs for vertebral compression fractures.

- Differentiate osteopenia caused by osteoporosis from other diffuse processes such as hyperparathyroidism or osteomalacia, and more regional processes such as reflex sympathetic dystrophy or bone cancer.
- Determine the degree of bone mass loss via dual energy x-ray absorptiometry (DEXA) for those patients at high risk or with known osteoporosis to establish a baseline for future determinations.

## **Management**

- Establish a health-style habit of adequate calcium and exercise for all females beginning in adolescence.
- Refer patients with a suspicion of cancer, hyperthyroidism, adverse effects of corticosteroids, alcohol abuse, or hyperparathyroidism.
- Educate the patient with primary osteoporosis regarding management options such as estrogen replacement, calcitonin, or alendronate.
- Comanage patients with primary osteoporosis with an emphasis on exercise, diet, and precautions for falling.

## **Relevant Anatomy and Physiology**

Osteoporosis is a consequence of bone quantity loss without an associated decrease of bone quality (mineralization is normal). Generally it is the result of increased resorption in the face of normal bone formation. The process of bone formation and resorption is a delicate balance governed by the interplay of a number of environmental, nutritional, and hormonal factors. Eighty percent of bone mass variation is

due to genetics, whereas lifestyle factors account for only 20%.<sup>9</sup>

A productive imbalance occurs in early life when bone formation exceeds resorption. This peaks during and soon after puberty, gradually declining in the mid-20s to early 30s. A relatively small period of balance occurs when production equals resorption. Particularly in women, an imbalance in favor of resorption begins in the late 30s and early 40s. The rate of bone loss in women exceeds that of men, so that women lose about 50% of their total bone mass in a lifetime; men lose only about 25%.

Bone is composed of two-thirds mineral (mainly hydroxyapatite); the remaining one-third is a combination of collagen, water, proteoglycans, and other noncollagenous proteins. Type I collagen acts as a framework for deposition of minerals. The process of bone formation and repair is determined by an interaction of three cell types: osteoblasts, osteocytes, and osteoclasts. The role and cross-talk of these cells are not completely understood. Osteoblasts secrete the precursors that help form type I collagen. Osteocytes appear to be osteoblasts that serve more of a coordinating function, perhaps helping to mobilize bone minerals. Osteoclasts are multinucleated giant cells that use collagenases and proteolytic enzymes to break down bone. Osteoclasts are stimulated by a number of factors, including parathyroid hormone (PTH), cytokines (interleukin 1 and tumor necrosis factors), growth factors, and prostaglandin E<sub>2</sub>.

Although it is known that a decrease in estrogen at menopause causes cortical bone loss and therefore increases the risk of fracture, evidence seems to suggest that some of the increased risk of fracture is mitigated by periosteal apposition. Periosteal apposition occurs with age-related bone loss and, to some extent, with menopause. The effect is an increase in bone size. A recent study indicates

that this effect increases the ability of the distal radius to accommodate bending forces by up to 30%.<sup>10</sup> The explanation is that through periosteal apposition, the cortical shell is placed farther away from the long axis of bone, improving resistance to both bending and rotational forces.

Calcium metabolism is an important link in the chain of bone formation. Calcium intake must meet the demands of peak bone formation and exceed the daily loss of 100 mg to 250 mg. Calcium absorption is dependent on a normally functioning gastrointestinal environment. Key to absorption is adequate amounts of vitamin D (more closely resembles a hormone). Vitamin D is produced by the body through several conversion reactions beginning with ultraviolet stimulation of epidermal 7-dehydrocholesterol, which forms an unstable form of vitamin D. Further conversions in the liver and subsequently the kidney produce a potent form of vitamin D. Without sufficient sunlight, vitamin D production is halted, requiring supplementation. Almost half of healthy women who have none of the standard risk factors may still be at risk for osteoporosis. This risk is primarily due to low levels of vitamin D.<sup>11</sup> Known risk factors for osteoporosis include the following:

## Evaluation

## History

- female gender
- white or Asian background
- early menopause
- family history
- lean body habitus
- lack of exercise or excessive exercise in the young

- glucocorticoids, phenytoin, aluminum antacids, lithium, loop diuretics, tetracycline, warfarin
- heavy alcohol consumption; smoking; low calcium intake or vitamin D deficiency; high phosphate, fiber, or sodium intake; more than four cups of coffee per day; carbonated drinks (several a day); and possibly a high animal-protein diet (although a low-protein diet may also place the female at risk)

Ethnicity percentages of osteoporosis as defined by WHO criteria are:<sup>12</sup>

- African American women = 12%
- Mexican Americans = 18.8%
- Other ethnic groups = 28.3%

For white females aged:

- 50-59 years = 14.8%
- 60-69 years = 21.6%
- 70-79 years = 38.5%
- 80 years and older = 70%

Interestingly, in skilled nursing homes, regardless of race and sex, those older than 75 years had a prevalence of 50% or more.<sup>13</sup>

Patients on any of the following medications may be at increased risk either due to the drug or the disease being managed:

- Steroids
- Aromatase inhibitors (e.g., Arimidex, Aromasin, Femara)
- Proton pump inhibitors
- GnRH inhibitors (e.g., Lupron)
- SSRIs
- Lithium

- Anticonvulsants

Given the popularity of proton-pump inhibitors for acid-reflux and duodenal ulcers, there is an increasing concern about their effect on decreasing acid secretion and the related effect of decreasing calcium absorption (among other minerals). A meta-analysis<sup>14</sup> published in 2011 found an increased risk of fracture related to the use of proton-pump inhibitors but not with the use of H<sub>2</sub> antagonists. Increased gastrin levels may cause histamine production through hypertrophy of gastric enterochromaffin-like cells, which could lead to bone loss. In younger females, osteoporosis may be part of the “female athlete triad” (disordered eating, menstrual irregularity, and osteoporosis/osteopenia; see **Table 30-1**). Disordered eating has been estimated to occur in as many as two-thirds of young female athletes. Disordered eating is classified as restricted eating behaviors that do not necessarily become a clinical eating disorder such as anorexia nervosa.<sup>15</sup> In young competitive female runners, for example, disordered eating has a strong correlation to menstrual irregularity that is associated with a low BMD.<sup>16</sup> However, disordered eating is associated with a low BMD regardless of whether there is an associated menstrual irregularity.

In many patients, osteoporosis is a silent disorder until fracture occurs. Physical examination findings are usually the result of these fractures. An increased, acute-angle kyphosis is suggestive, especially if associated with an acute onset of spine pain following sneezing, coughing, or a sudden jolt to the body such as stepping heavily off a curb. However, even vertebral fractures can be clinically silent. As many as two-thirds of vertebral fractures are asymptomatic; however, these fractures represent a two- to three-fold increased risk of future fracture. Green et al.<sup>17</sup> found that the following were helpful, in a review of clinical examination procedures that may assist in detecting occult

fracture, or screen for those who may need further evaluation:

**Table 30-1** Terminology Used with Bone Densitometry

<b>Term</b>	<b>Definition</b>
Bone density or bone mineral density (BMD)	The average concentration of mineral in a 2- or 3-dimensional image or defined section of bone. Also used to refer to the results of bone densitometry.
Bone mass	The amount of bone in the entire skeleton or in one specific location. There is no technology that measures bone mass.
Bone mineral content	The average concentration of mineral per unit area; also referred to as areal BMD.
Broadband ultrasound attenuation	The slope of the line of attenuation of sound energy across a spectrum of sound frequencies.
Speed of sound	The faster transmission of a specific frequency of sound through a given section of bone.
Trabecular bone density	Mineral density of bone that is trabecular only.
T-score	The difference in number of SDs below the mean BMD between a given individual patient value compared to a group of young adults of the same sex. The mean value and size of an SD vary with different techniques and sites that are measured.
Z-score	The difference in number of SDs above or below the mean BMD between that of a given patient and group of people of the same sex and age.
Osteopenia	WHO defines as a T-score between -1.0 and -2.5.
Osteoporosis	WHO defines as a bone density T-score at or below 2.5 standard deviation of normal. Also used is the finding of a vertebral fracture on radiographs.
Volumetric bone density	The bone mineral content divided by the volume of the bone section measured; measured with QCT.

WHO = World Health Organization

- A wall-occiput distance greater than 0 cm (in other words, with the patient standing with their heels and back to the wall, they are unable to touch the occiput to the wall).
- A rib-pelvis distance of less than two finger breadths (the examiner places his or her fingers between the lower rib and pelvis in the midaxillary line).
- Low teeth count.
- Self-reported humped back.

Additional examination findings will be found if the underlying cause of the osteoporosis is, for example, endocrine. Hyperthyroidism may be associated with osteoporosis, and either a history of previous diagnosis or physical examination findings may be suggestive. If the patient complains of intolerance to heat, fatigue, palpitations, and/or a change in the appearance of the eyes (exophthalmos), hyperthyroidism should be investigated. Hyperparathyroidism may also be associated with osteoporosis. Physical signs are generally absent; however, joint pains, especially of the knee, hip, wrist, or shoulder, may be reported. Radiologic confirmation is necessary.

## **Examination**

The primary tools for evaluation of osteoporosis are radiographic. Physical examination focuses on indirect indicators of compression fractures such as an increased kyphosis. Signs of secondary causes of osteoporosis focus on hyperthyroidism and Cushing's disease or Cushingoid appearance due to long-term corticosteroid use. From a preventive perspective, it is important to screen the elderly for proprioceptive deficits. This would include an evaluation of balance, vision, and sensory function.

BMD is an excellent predictor of fracture risk; however, there is no known threshold that indicates fracture risk. Therefore, BMD is considered a “continuous” risk factor, meaning that the lower the BMD, the higher the risk of fracture, with no specific point that reflects a dramatic increase in risk. Although there are numerous methods of measuring BMD, and the BMD can be used to predict fracture, its use is still controversial as to who should be screened. A recent scientific review found evidence for measuring BMD in white women older than 65 years.<sup>18</sup> It may also be valuable to measure BMD in younger postmenopausal women with risk factors. Other guidelines from the National Osteoporosis Foundation and U.S. Preventive Services Task Force (USPSTF) recommend screening of women 65 years or older regardless of ethnicity.<sup>19</sup> Both groups suggest that women aged 60 to 65 years with risk factors should also be screened. Risk factors include personal history of hip fracture, current cigarette smoking, use or planning on use of oral corticosteroids for longer than three months, body weight less than 57.2 kg, and any metabolic condition such as hyperthyroidism or malabsorption that places the patient at risk.

There are classic radiographic findings with osteoporosis; however, their appearance indicates advanced involvement. Loss of between 30% and 50% is necessary before osteopenia becomes radiographically evident as an increase in radiolucency. Additional findings are cortical thinning (pencil-thin cortex) and trabecular changes. Trabecular resorption may leave the remaining stress-surviving trabeculae more visible, in contrast to a background of radiolucency. The remaining trabeculae of the spine are the vertical, stress-bearing ones. The horizontal trabeculae are preferentially lost. Changes in the vertebral shape with osteoporosis include vertebra plana (pancake vertebra), wedged vertebra, and biconcave (fish, hourglass) vertebra.

More sensitive techniques include single- and dual photon absorptiometry (SPA and DPA), quantitative computed tomography (QCT), DEXA, and possibly ultrasonography (US).<sup>20</sup>

- SPA and DPA use a radionuclide source measuring photon attenuation at the examination site. The SPA beam can be used only where soft tissue thickness is constant. It measures only the appendicular skeleton primarily at the distal radius and calcaneus. DPA is similar but emits photons at two different energy levels and has a better record in predicting future fractures. DPA is also able to evaluate axial and appendicular loss. Although both cortical and trabecular bone can be evaluated, DPA cannot distinguish between the two. Other limitations include the scan time (20 to 40 minutes), which may introduce distortion of image quality if the patient moves.
- DEXA—Although DPA, QCT, and DEXA measure both types of bone, DEXA is now the measurement tool of choice because it replaces the nuclide source with an x-ray source with a reduction in scan time and improvement in image quality. Although having some of the same disadvantages of DPA, DEXA can compensate by including both lateral and posterior images of the spine. DEXA is known to have a low level of error and high degree of accuracy. DEXA is used to assess the bone mineral density and estimate the degree of standard deviation compared to a normal mean. Vertebrae L1 through L3 or L4 are used to measure spine BMD. Spine BMD may increase after age 65 years due to degenerative arthritis.
- QCT requires a long scan time, resulting in more irradiation than with DEXA and DPA. It is also more expensive. The advantage is in measuring and distinguishing between cortical and trabecular bone in

the spine. Use of dual-energy or bipolar QCT may improve some limitations with regard to fat and water content variations. Peripheral scanners are also available; however, their value has not yet been established.

- **Ultrasonography**—The newest approach to bone assessment is US. The U.S. Food and Drug Administration (FDA) has approved US as a screening tool to determine which patients might need further evaluation with DEXA. US provides broadband ultrasound attenuation, which is a value indicative of bone integrity. Due to the use of sound waves instead of radiation, US is safer. US may provide valuable information about future fracture risk, and it has been shown to provide a strong correlation with DEXA measures of bone density.
- **Peripheral densitometry**—These are smaller devices that use DXA or SXA to measure bone density at the forearm or heel. Although they take less time and cost much less than DEXA, they are less predictive for vertebral fractures, and the T-scores vary from one type of device to another.
- **Quantitative ultrasound**—The patterns of absorption of different sound frequencies (broadband ultrasound attenuation) are derived from sampling at the calcaneus and femoral neck. The combination of these BMD assessments is a good predictor of hip fracture risk.

Most major medical groups do not recommend screening all women with these techniques.<sup>21</sup> Recommendations for the use of one of these specialized tools include the following:

- as an aid in decision-making regarding the need for estrogen replacement therapy (high-risk individuals)

- for monitoring patients on long-term glucocorticoids
- for monitoring patients with hyperparathyroidism who are at risk for skeletal disease (i.e., those who may need parathyroid surgery)

Laboratory evaluation is valuable only in the differential evaluation. Most bone-related lab levels, such as calcium, phosphorus, and alkaline phosphatase, are usually normal unless there has been a recent fracture. Urinary hydroxyproline levels may be elevated. Newer approaches include measures of specific biochemical markers. Bone density is estimated based on these indicators of bone turnover. Serum and urinary markers include enzymes associated with either osteoblastic or osteoclastic activity, elements released during resorption, or proteins that are produced by osteoblasts. These include:

- bone formation markers—bone-specific alkaline phosphatase, osteocalcin (protein found in bone and dentin measured by enzyme-linked immunosorbent assay [ELISA] technique), and pro-collagen I extension peptides
- bone resorption markers—urinary pyridinoline and deoxypyridinoline (collagen phosphate crosslinks), total and dialyzable hydroxyproline

## **Management**

- For all women, establish a lifestyle habit of maintaining an adequate amount of calcium and vitamin D combined with an appropriate level of exercise; also recommendations for avoidance of known contributors to osteoporosis acceleration including smoking, alcohol, caffeine, carbonated drinks, etc.

- When a secondary cause of osteoporosis or a compression fracture is found or suspected (i.e., cancer, Paget's disease, hyperparathyroidism, or osteomalacia) medical consultation is necessary.
- If a compression fracture appears radiographically unstable, refer for medical consultation (see [Chapter 6](#) for details).
- For all older women, establish a prevention program for falls including an environmental evaluation, exercise program, and nutritionally supportive regimen.
- For all osteoporotic patients, provide a comprehensive program including patient education, appropriate exercise, and appropriate nutrition (see [Table 30-2](#)) coupled with psychosocial support.

Management decisions are based primarily on several factors including age, BMD, previous fracture, and 10-year fracture risk. Smoking and rheumatoid arthritis are also important considerations in management.

Medical management strives to maintain the T-score, as opposed to improving it, in all cases. An improvement of one on the T-score value is equal to a 10% improvement in bone strength. In judging the effect of medical management, comparisons can be made only if the follow-up DEXA is performed on the same machines due to variations in equipment. Also there is a 2% to 3% standard deviation factor that must be accounted for. Therefore, there must be at least a 3% change in the vertebral measurement and a 3% to 4% change in the hip to be considered significant (either plus or minus). If the BMD is normal, most guidelines recommend rechecking in three to five years. If a patient is under medical management, checking every two years is required. Drug therapy is highly effective at reducing vertebral and sometimes hip fractures, yet that reduction is still in the 50% range.

Education of the osteoporotic patient is a key component to management. In addition to the educational advice of the doctor, several organizations such as the National Osteoporosis Foundation (NOF), the Older Women's League (OWL), and the National Dairy Council provide educational pamphlets and materials to patients and doctors.

Although there is some debate as to the degree of effect, a combination of calcium supplementation and exercise can, at the very least, reduce bone loss in the majority of postmenopausal females. Supplemental calcium not only decreases bone loss in postmenopausal females but also reduces the risk of vertebral fracture by up to 45% (nonvertebral fracture and hip fracture are also reduced by about 25%).<sup>9,22</sup> The amount of calcium intake is generally recommended to be 1,000 mg for premenopausal women and 1,500 mg for postmenopausal women. Although dairy products are a common source of calcium, other options exist for those patients with lactose intolerance or a concern about the high cholesterol/calorie content of some + dairy products.

**Table 30-2** Nutritional Support for Osteoporosis

Substance	How Might It Work?	Dosage	Special Instructions	Contraindications and Possible Side Effects
Ipriflavone	Decreases bone turnover rate by inhibiting bone resorption.	200 mg capsule, 3 times/day.	Best taken with meals.	None at recommended dosage.
Calcium/magnesium/CitraMate	Most absorbable form of Ca/Mg. Calcium—reduces bone loss. Magnesium—enzyme responsible for conversion to active form of vitamin D is Mg-dependent.	1–3 capsules, 3 times/day.	Best taken with meals.	None at recommended dosage; however, increase in magnesium may cause diarrhea.
B6, B12, folic acid (homocysteine factors)	Decrease homocysteine (homocysteine contributes to defective bone matrix).	1 capsule, 2 times/day.	Best taken with meals.	None at recommended dosage.
Vitamin D3	Calcium absorption of 700–800 IU of D3			None at recommended dosage.

*Note:* These substances have not been approved by the FDA for the treatment of this disorder.

The debate over which calcium supplementation is best continues. Part of the prescription decision is clarified when considering the following:

- Those with lactase deficiency may not tolerate calcium lactate.
- Calcium carbonate is an acceptable choice because it is inexpensive and relatively effective; however, it may cause bloating or constipation.
- Supplements derived from bone meal or dolomite sometimes contain contaminants such as lead, mercury, and arsenic.<sup>23</sup>
- Calcium citrate is a good alternative and is available in some orange juices; however, some patients may not tolerate citric acid.

It is important that patients be educated about the misleading trappings of advertising. For example, although

the product may be labeled as containing 1,500 mg of calcium carbonate, it may contain only 500 mg of elemental calcium.

African Americans, those with darker skin, and those using sunblock are less able to absorb sunlight and therefore may have inadequate levels of vitamin D. In northern latitudes above 51°, and in the spring, summer, and fall, if an individual is exposed to sunlight for at least 15 minutes, two to three times per week adequate vitamin D can be made. However, in the winter at the same latitude, individuals may go three months without being able to make vitamin D; at 71° latitude it may take as long as five months.

Only recently, the value and need for vitamin D supplementation for osteoporosis has surfaced in the literature and guideline recommendations. As many as 64% to 69% of osteoporotic postmenopausal females are vitamin D deficient (<30 ng/ml).<sup>24,25</sup> Although the recommended minimally desirable serum concentration is 25(OH)D to 40 nmol/l, it is likely that the desirable level will be suggested as 75 nmol/l.<sup>26</sup> At this level, only one-third of seniors in the United States and even fewer European seniors will meet this requirement. To achieve this level, daily intake should be between 700–800 IU of D3 (cholecalciferol) with even higher doses recommended for osteoporotic females (1,000 IU/daily). Levels of up to 2,000 IU are considered safe. Treatment with 50,000 IU of D2 over several weeks is also considered safe and effective. Calcium intake should be a minimum of 1,200–1,500 mg/D. However, D2 (ergocalciferol) is clearly less effective with a potency of about one-third that of D3. Unfortunately, D2 (usually derived from plants) is the cheapest form used in milk and probably the majority of supplements. The oil-based gel cap packaging of D3 is the best absorbed.

Higher circulating homocysteine levels have been associated with increased fracture risk. Folic acid and B

vitamin supplementation are being investigated to determine their effect, mediating this risk by decreasing homocysteine levels.

Estrogen replacement therapy (ERT) is controversial, yet it is the most effective treatment for postmenopausal osteoporosis.<sup>27</sup> Because of its demonstrated effectiveness in bone preservation, some physicians feel that all postmenopausal women should be placed on ERT; others feel that it should be a decision based on risk. There are some known contraindications to ERT, including the following:

- undiagnosed vaginal bleeding
- pregnancy
- breast cancer
- estrogen-dependent neoplasm
- active thromboembolic disorders or past history of thrombus related to estrogen

Relative contraindications include gallbladder and liver diseases and a history of menstrual migraines. To reduce the chance of uterine cancer, estrogen is combined with progesterone in women with an intact uterus.

Although it is clear that estrogen replacement therapy has a dramatic effect on BMD and bone turnover, there is increasing concern regarding the elevated risk of developing breast cancer, heart disease, stroke, and deep vein thrombosis. One recent study indicates that low-dose estradiol showed increased BMD of the spine, hip, and total body, as well as reduced bone turnover without any apparent increased occurrence of breast cancer.<sup>28</sup> A recent large randomized trial, the Women's Health Initiative (WHI) study, compared estrogen plus progestin to placebo in postmenopausal women to determine any differences in risks for various diseases.<sup>29</sup> Those women taking estrogen plus progestin had an increased risk compared to the

placebo group for breast cancer (26%), coronary heart disease (29%), stroke (41%), and pulmonary embolism (113%). This is a monumental study that followed patients for 5.2 years, and due to its strong experimental design has stimulated serious concerns about the risks/benefits of HRT.

Although ERT and calcitonin have been the mainstay for the prevention of further bone loss in postmenopausal females, three new therapies are now becoming first-line approaches to management:

- Selective estrogen receptor modulators (raloxifene)
- Bisphosphonates (alendronate and risedronate)
- Parathyroid hormone

Both raloxifene and the bisphosphonates comprise a group of medications classified as antiresorptive. These medications inhibit bone resorption but eventually reduce bone formation due to a decrease in overall bone turnover. A standard intermittent treatment program with parathyroid hormone is intended to increase bone formation; however, it also increases bone resorption. The net effect, however, is bone formation. It is clear that prolonged exposure to parathyroid hormone, such as in hyperparathyroidism, causes osteoporosis. Intermittent use through daily subcutaneous injections has an anabolic effect, particularly with trabecular bone. The effect on cortical bone may be an increase in cortical porosity, yet most of this occurs at the endocortical surface (partially at the Haversian canals), having little mechanical effect (i.e., no increased risk of fracture). A recent study confirmed the effect of increased trabecular bone content in parathyroid treated patients versus combination treatment with alendronate and parathyroid.<sup>30</sup> A separate study in men confirmed the same effect. Additional findings indicate that any initial benefit of combined therapy changes over time, so that those treated with parathyroid hormone had higher bone mineral density

than with combination therapy.<sup>31</sup> In fact, it appears that alendronate may reduce the beneficial effects of parathyroid treatment. The positive effect of parathyroid hormone therapy on reducing the risk of fracture has been demonstrated in one study.<sup>32</sup> Although it appears that 5-reductase inhibitors (statins) have been demonstrated to increase bone formation in vitro and in vivo in some studies, a recent study indicated that this had no effect on fracture risk for postmenopausal females.<sup>33</sup>

Calcitonin appears to have two effects. In addition to increasing bone density, it may reduce pain significantly in some patients. The infrequent complaints of nausea and flushing are usually managed by beginning with a low dose given at bedtime. Newer approaches that are being investigated are fluoride and parathyroid hormone use.

**Table 30-3** lists the common medications used in the management of osteoporosis.

**Table 30-3 Osteoporosis Medications**

Drug Class	Examples	General Mechanism	Interactions/Side Effects
Bisphosphonates	Ibandronate  Boniva	A nitrogen-containing bisphosphonate used in the management of osteoporosis. Bisphosphonates inhibit osteoclast-mediated bone resorption. Advantage over other similar medications is the once-per-month dosage. Requires adequate intake of calcium and vitamin D.	Upper GI problems such as esophagitis, dyspepsia, esophageal or gastric ulcers
	Alendronate  Fosamax	Bisphosphonate; antiresorptive used in the treatment of osteoporosis and Paget's disease. These medications inhibit bone resorption but eventually reduce bone formation due to a decrease in overall bone turnover. A standard intermittent treatment program with parathyroid hormone is intended to increase bone formation; however, it also increases bone resorption. The net effect, though, is bone formation. It is clear that prolonged exposure to parathyroid hormone such as in hyperparathyroidism causes osteoporosis.	Hypocalcemia, GI effects include esophageal irritation/ulceration with abdominal pain, nausea, vomiting, diarrhea/constipation, arthralgias, myalgias, headache, and rash. Dairy products decrease absorption.
	Etidronate  Didronel	Bisphosphonate; antiresorptive used in the treatment of osteoporosis and Paget's disease. Decreases vascularity of bone with Paget's. These medications inhibit bone resorption but eventually reduce bone formation due to a decrease in overall bone turnover. A standard intermittent treatment program with parathyroid hormone is intended to increase bone formation; however, it also increases bone resorption. The net effect, though, is bone formation. It is clear that prolonged exposure to parathyroid hormone such as in hyperparathyroidism causes osteoporosis.	May cause hypocalcemia, hyperphosphatemia, elevated serum phosphatase. GI effects include esophageal irritation/ulceration with abdominal pain, nausea, vomiting, diarrhea/constipation, arthralgias, myalgias, headache, and rash. Dairy products decrease absorption.
	Risedronate  Actonel	Bisphosphonate; antiresorptive used in the treatment of osteoporosis and Paget's disease. These medications inhibit bone resorption but eventually reduce bone formation due to a decrease in overall bone turnover. A standard intermittent treatment program with parathyroid hormone is intended to increase bone formation; however, it also increases bone resorption. The net effect, though, is bone formation. It is clear that prolonged exposure to parathyroid hormone such as in hyperparathyroidism causes osteoporosis. Risedronate is believed to be more effective than other bisphosphonates at blocking bone dissolution.	Fewer GI side effects than other bisphosphonates
	Selective estrogen receptor modulator  Raloxifene  Evista	Selective estrogen receptor modulator; antiresorptive used in the treatment of osteoporosis. These medications inhibit bone resorption but eventually reduce bone formation due to a decrease in overall bone turnover. A standard intermittent treatment program with parathyroid hormone is intended to increase bone formation; however, it also increases bone resorption. The net effect, though, is bone formation. It is clear that prolonged exposure to parathyroid hormone such as in hyperparathyroidism causes osteoporosis. Raloxifene is believed to decrease total cholesterol and LDL cholesterol but does not raise HDL or lower triglycerides. Also, the selective estrogen receptor inhibition effect prevents tissue proliferation in the uterus and breasts.	May cause flu-like symptoms, also hot flashes, migraine headache, insomnia, depression, weight gain, vaginitis, breast pain, and vaginal bleeding.
Parathyroid hormone agonist	Teriparatide  Forteo	A parathyroid hormone agonist used in the management of postmenopausal osteoporosis.	Pain, transient increases in calcium levels, headaches, dizziness, arthralgias, myalgias, leg cramps, rash, swelling

An interesting study measuring the long-term effects of exercise on risk for compression fracture in osteoporotic females determined that after a two-year program of back strengthening exercises (back pack with maximum manageable weight used for prone extension exercises), there was a difference in back strength between the exercise and control group but no significant differences in BMD.<sup>34</sup> However, after an eight-year follow-up, both back strength and BMD were increased. Also, at eight years' follow-up there was a 2.7 times greater risk for compression fracture in the control (non-exercise) group.

Exercise prescription for the osteoporotic patient should meet two goals. First, it is important to stimulate bone production and prevent loss. Second, it is important to strengthen muscles to provide support and to train the patient proprioceptively to prevent falls. The increases in bone mass seen with exercise are mild to modest, on the order of 1% to 3%. However, it must be kept in mind that simply preventing further bone loss is a major goal of an exercise prescription. The general rule of thumb for inducing a bone mass response is that the exercise must provide mechanical loading either through pull of muscle on bone or weight-bearing. Some important considerations are as follows:

- Walking alone does not seem to provide enough stimulation for increased bone mass; walking must be combined with resistance exercise.<sup>35</sup>
- Non-weight-bearing exercises including swimming and cycling are relatively ineffective approaches.<sup>36</sup>
- Resistance exercise must exceed that provided by daily activities.<sup>37</sup>
- The effects of exercise are site-specific (e.g., running does not provide stimulation for bone in the upper extremities).<sup>38</sup>

- Impact activities that apply relatively large loads on bone quickly are the most osteogenic and are the most risky; therefore, a progression of exercise up to the level of these types of activities is the ultimate goal.

The exercise prescription must take into account the degree of current bone loss, presence of compression fractures, the strength and balance level of the patient, accessibility to exercise equipment, and motivation of the patient. The response to exercise is dependent on type of exercise, diet, and, most important, hormonal status. In general, at least one hour of physical activity is needed to provide and maintain a response. Initial prescription would include some weight-bearing and mild resistance exercise progressing to more weight-bearing and more resistance slowly. Spinal exercises should focus on extension with avoidance of the compressive effects of flexion exercises. Also, initial high-impact and twisting should be avoided.

In addition to the prevention of further bone loss, it is equally important to prevent falls in the elderly. An assessment of physical risks that are the consequence of the individual's health status and those that are a consequence of the patient's living environment should be identified and utilized in patient education. Addressing the patient's balance, posture, and muscle strength, combined with modification of environmental hazards, can decrease the risk of falling by as much as 30%.<sup>39</sup>

An interesting approach is gaining some literature evidence for efficacy in improving BMD and strength. Devices on the market such as Power Plate vibrate at low frequency (20–90 Hz). Preliminary evidence in both animals and humans suggests a possible benefit.<sup>40,41</sup>

## Part IV

# Gastrointestinal Complaints

# CHAPTER 31

## Abdominal Pain

### Context

Chiropractors are sometimes faced with a dilemma regarding whether or not to accept a patient. A patient may present with a chief complaint or secondary complaint of abdominal pain. The first concern is whether the pain is due to a visceral source; the second concern is whether the chiropractor can appropriately manage the patient. Delayed referral for appropriate diagnostic testing and care may have serious consequences for the patient (and inevitably for the chiropractor). Each year more than 3 million Americans seek medical care for abdominal pain<sup>1</sup> in hospital emergency departments. Inappropriate or unnecessarily early surgical referral may result in nonessential or inappropriate surgery with its consequences. At the core of this issue, for many chiropractors, is the belief or experience that management of apparently viscerally caused abdominal pain results in successful resolution under chiropractic care. A debate on whether spinal dysfunction is the cause of referred abdominal pain or an actual dysfunction of an organ still ensues. This issue is well addressed in a review by Nansel and Szlazak.<sup>2</sup> The reader is referred to this source for a more in-depth discussion. The issue is clouded when a patient presents with a back complaint associated with a “viscerally” associated symptom. Is the back pain the cause of the visceral

symptom or is it the reverse? The remainder of this discussion is based on the assumption that serious, surgically treatable disease is the domain of the surgeon and will more likely present to the emergency department and rarely present in the chiropractic setting. The remaining conditions that do present may be in need of medical treatment, may respond to conservative measures, or are self-resolving. The task for the chiropractor is to determine which of these conditions the patient has.

## General Strategy

# Acute Abdominal Pain

Determine whether the condition requires referral:

- Determine the onset and severity of the pain (abrupt pain suggests rupture or blockage of a nonintestinal lumen such as a ureter [kidney stones] or the gallbladder [gallstones]).
- Determine whether other acquaintances of the patient have similar symptoms (gastroenteritis or food poisoning). (See [Table 31-1](#).)
- Determine any relationship to ingestion of food (food poisoning).
- Determine, in women, recent history of sexual contact (pelvic inflammatory disease) and menstrual history (ectopic pregnancy).
- Determine whether there is any past history of surgery (postsurgical adhesions causing obstruction). (See [Table 31-1](#).)
- Determine whether the patient maintains a position of relief (fetal position indicates pancreatitis; flexed hip position may indicate appendicitis).

- Attempt to localize the pain by patient description and palpation.
- Determine whether there are any peritoneal signs (pain with movement or jarring, central pain that has progressively localized, rebound tenderness, or rigid abdomen suggests appendicitis, perforated ulcer, or another peritoneal problem).
- Determine the timing of associated symptoms such as vomiting, constipation, or diarrhea.
- Attempt to narrow the differentials to a system, such as genitourinary (radiation from thoracolumbar area to groin or associated dysuria, increased frequency, hesitancy, or hematuria), gastrointestinal (nausea, vomiting, constipation, diarrhea, or rectal bleeding), gynecologic (change in menstrual period, vaginal discharge or bleeding, or dyspareunia), or cardiovascular (history of hypertension, atrial fibrillation, or sickle cell disease).

**Table 31-1** Causes of Intestinal Obstruction

<b>Type</b>	<b>Summary</b>
Ileus	Two types: adynamic and obstructive. Adynamic is usually due to the side effects of CNS depression from anesthesia or narcotics and may also be related to pain-inhibition. Obstructive is due to mechanical blockages from atresia or stenosis, gallstones, fecaliths, or meconium (in infants with cystic fibrosis, adhesions secondary to surgery or peritonitis). May also be related to other causes of intestinal obstruction such as hernia, intussusception, or volvulus.
Hernia	Hernias result from a weakness or defect in the abdominal wall. Inguinal hernia is more common in males; femoral hernias more common in females. Other hernias include periumbilical (protrudes around the umbilicus), and diaphragmatic (hiatal) hernia.

Volvulus	Volvulus is a rotary twisting of the intestine leading to infarction and necrosis. This occurs most frequently in the small intestine or sigmoid colon.
Intussusception	A telescoping or invagination of one segment of the intestine into the other. The danger is vascular compromise, which may lead to necrosis. In children this occurs due to hyperperistaltic activity or enlargement of lymphoid tissue. In adults, the leading cause is tumor.
Adhesions	Adhesions are secondary to prior infection, peritonitis, and prior surgery.
Neoplasms	Neoplasms may entangle the intestines, causing a constricted area that prevents passage.

- Determine whether laboratory tests (for acute infection or urinary tract involvement) or radiographic studies (free air or obstruction) are necessary. H<sub>2</sub> receptor antagonists that help the pain suggests esophageal, gastric, or duodenal pathology).
- Ask about any associated diarrhea (inflammatory bowel disorders, parasitic infections, or a drug reaction) or alternating diarrhea and constipation (irritable bowel syndrome).
- Ask about any blood in the stool, weight loss, change in caliber of stool (colon or other cancer). (See **Table 31-2.**)

## **Chronic, Recurrent Abdominal Pain**

Determine the following:

- Determine whether the pain is associated with the timing of meals (empty stomach implies ulcer; full stomach implies reflux) or meal content (similar foods affect both ulcer and reflux).
- Determine whether the patient has traveled recently, locally on camping trips (giardiasis, amoebic dysentery), or abroad to a foreign country (parasitic infection).

- Determine whether there is a relationship to a woman's menstrual cycle (primary dysmenorrhea or endometriosis).
- Obtain the medication history of the patient (use of nonsteroid anti-inflammatory drugs [NSAIDs] or aspirin suggests gastric bleeding; use of antacids or

## **Relevant Anatomy and Physiology**

Visceral pain is characteristically different from somatic pain. There may be overlaps, however. Visceral afferent receptors serve a function different from that of somatic receptors. Somatic receptors signal the brain about external threats and in so doing need to have a high degree of localization and reflex response capabilities. Visceral receptors are designed more to provide information that helps maintain homeostasis. In the abdominal area, the most important information for homeostasis is distention, constriction, and vascular status. Whether these nerve endings or specific nociceptors relay pain is still unknown. It is known, however, that the types of stimuli that will produce a sensation of pain are often extreme events of normal stimuli such as overdistention (e.g., gas in the intestine or a stone in a nonintestinal lumen) or ischemia. This is in part due to the fact that nerve endings are located in muscular walls of the gut and organs such as the gallbladder and urinary bladder. Other irritating factors causing visceral pain are probably chemical in nature, such as pH changes or toxic irritation. This pain reaction is probably stimulated by local release of bradykinin, serotonin, histamine, and other substances. Also, the rate at which distention occurs often determines whether pain is felt at all. For example, gradual distention that occurs from

malignancy (such as malignant biliary obstruction) may be painless, whereas acute blockage from cholelithiasis is painful. If the capsule of an organ such as the liver (Glisson's capsule) is involved, pain will be produced somatically. The organ itself, having no muscular component, is insensitive to pain. This is true not only of the liver, but also of the lungs, brain, kidneys, and intestines. Interestingly, the walls of most organs are insensitive to malignant involvement unless obstruction or ulceration also occurs.

**Table 31-2** Some Gastrointestinal Cancers

<b>Type</b>	<b>Summary Information</b>
Carcinoma of the esophagus	<ul style="list-style-type: none"> <li>• Accounts for 4% of all malignant neoplasms in U.S. Three times more common in African Americans, with a male-to-female ratio of 4:1 in the U.S.</li> <li>• 95% of patients die within 2 years.</li> <li>• In China, Iran, and South Africa, incidence is 10%–15% higher than U.S. due possibly to a carcinogen in the soil or food.</li> <li>• A large percentage of individuals have a history of chronic alcoholism and tobacco use.</li> <li>• Clinical presentation may be pain on swallowing, bad breath, dysphagia, and bleeding; being locally invasive, by the time symptoms/signs develop most tumors have spread into the lymph nodes; 90% are squamous cell carcinomas found in the middle or lower portions; 10% are adenocarcinomas originating from Barrett's esophagus.</li> <li>• Dx is by barium-swallow x-ray or esophagoscopy with biopsy.</li> <li>• Management is surgical resection.</li> </ul>
Carcinoma of the stomach	<ul style="list-style-type: none"> <li>• Incidence in U.S. is 10 per 1,000,000, which is 8 times lower than Japan or Chile.</li> <li>• Believed to be an environmental carcinogen, most likely in the food, specifically nitrosamines as is found in smoked fish. Also, processing of food in U.S. may decrease bacterial causes.</li> <li>• Some increased risk with atrophic gastritis, pernicious anemia, and gastric adenomatous polyps.</li> <li>• 60% found in distal stomach (pylorus and antrum); cardia in 25% of cases.</li> </ul>

	<ul style="list-style-type: none"> <li>• Four types: polypoid, fungating, ulcerating, and diffusely infiltrating (linitis plastica); histologically all adenocarcinomas; metastasis is through regional lymph nodes and the liver.</li> <li>• Symptoms are nonspecific with weight loss, anemia, weakness, and signs of local gastric irritation similar to peptic ulcer.</li> <li>• May have a supraclavicular lymph node involvement called a Virchow or sentinel node (may also metastasize to ovaries [bilateral involvement referred to as Krukenberg's tumor] and other distal sites).</li> <li>• Dx from gastroscopies with gastric brushing and cytologic examination.</li> <li>• The 5-year survival rate is only 10%–15%.</li> </ul>
Carcinoma of the intestine	<ul style="list-style-type: none"> <li>• 95% of malignant tumors of the intestine are adenocarcinomas.</li> <li>• Adenocarcinoma is 50 times more common in the large intestine.</li> <li>• Colorectal cancer is more common in the U.S. and other Western countries compared to Asia and Africa.</li> <li>• Incidence increases with age, with rectal cancer ratio of male to female 2:1; colonic ratios are equal.</li> <li>• Although most cancers appear insidiously, risk groups include those with familial predisposition such as hereditary nonpolyposis colorectal cancer (HNPCC), familial adenomatous polyposis (FAP), and Gardner's syndrome.</li> <li>• Findings vary, but most early cancer is asymptomatic. May have constipation; narrow, pencil-like feces; or blood in the stool. Hematochezia may also occur later in the disease profile.</li> <li>• Screening of those over age 50 years should include digital rectal examination, fecal occult testing, and colonoscopy and sigmoidoscopy (dependent on family risk and which is chosen).</li> <li>• Dx is via the screening methods mentioned above combined with barium enema and computed axial tomography using histologic evaluation of the suspected tissue for confirmation.</li> <li>• Staging morphologically is based on the Dukes system using four stages (A–D) with progressive involvement and decreasing risk for survival. Dukes A have an 85% 5-year survival; B have 55%; C have 30%; D have 10%.</li> </ul>
Neoplastic polyps	<ul style="list-style-type: none"> <li>• In addition to neoplastic polyps, there are some non-neoplastic lesions including hyperplastic, hamartomatous, and inflammatory or lymphoid polyps.</li> <li>• Neoplastic polyps occur usually as multiple lesions and are classified as tubular, villous, and tubulovillous. They are, as a group, considered premalignant because each has the possibility of progressing to adenocarcinomas; the highest risk is with tubulovillous and villous.</li> </ul>

	<ul style="list-style-type: none"> <li>• Incidence increases with age and is more common in males than females (2:1), with 70% located in the rectosigmoid colon.</li> <li>• Dx is with sigmoid and colonoscopic.</li> <li>• Endoscopic removal of precancerous has a high success rate; resection may be needed for some lesions dependent on degree of involvement.</li> </ul>
Carcinoid	<ul style="list-style-type: none"> <li>• These neuroendocrine tumors are malignant; however, less so than carcinomas.</li> <li>• The GI tract is where 90% of carcinoid tumors originate; specifically the intestines.</li> <li>• Typically located in the submucosa.</li> <li>• Metastasis is most common in tumors &gt;2 cm located in the right colon, small intestine, or stomach.</li> <li>• The secretions from these tumors are detoxified by the liver; however, if they metastasize to the liver, the secretory products are released into the venous system producing a disease called carcinoid syndrome.</li> <li>• Symptoms of carcinoid syndrome include facial blushing, wheezing, diarrhea, and colic. This is likely due to the release of serotonin, bradykinin, and histamine.</li> <li>• Carcinoids are slow-growing, with a survival rate for treated patients of at least 80%.</li> </ul>

The quality and location of visceral pain are in part determined by the neurology of the afferent supply. Localization to the center of the body is known to occur initially with most organ pain. Embryologically, the gastrointestinal tract and related structures originate as midline organs that receive bilateral innervation. Therefore, if a visceral afferent is activated, transmission occurs to both the right and the left sides of the spinal cord, making localization (lateralization) impossible. In other words, most stimulation is projected so that only a central recognition is possible. Overlapping of innervation to more than one organ and the multilevel input at the spinal cord make vertical localization difficult. For example, the lower esophagus, stomach, proximal duodenum, gallbladder, liver, and pancreas are innervated from the same levels of the spinal cord (T5-T10). (See **Table 31-3**.) This overlap in segmental innervation also accounts for the phenomenon of referred pain, either somatovisceral or viscerosomatic. About 75% of

thoracic and lumbar dorsal horn neurons receive both somatic and visceral input. It appears that no specific group of spinal neurons responds to visceral input.<sup>3</sup>

The quality of pain is also a reflection of the neurologic logic behind a system designed for retreat and one for homeostasis. Somatic pain is often sharp and localized, with a reflex response of retreat. Visceral pain is usually due to an existing process such as inflammation or infection. Given that an individual cannot escape from his or her body, the purpose seems more to provide a reflex splinting resulting in immobilization. The quality is often dull and aching (prior to peritoneal or capsular irritation), and there is no retreat response.

**Table 31-3** Some Hepatobiliary Diseases

<b>Condition</b>	<b>Summary Information</b>
Immune disorders Autoimmune (lupoid) hepatitis	<ul style="list-style-type: none"> <li>• A form of chronic hepatitis that is believed to be immune mediated.</li> <li>• Affects primarily females in the age group of 20–30 years.</li> <li>• ANA and other auto-antibodies are elevated.</li> </ul>
Primary biliary cirrhosis	<ul style="list-style-type: none"> <li>• An immune disorder involving T-cells that destroys the intrahepatic bile ducts, affecting females in the age group of 30–60 years.</li> <li>• Found in hepatic transplant patients and those having bone marrow transplantation.</li> <li>• An abrupt onset characterized by nonspecific complaints of fatigue, anorexia, and weight loss; also may have mild hemolytic anemia, atrophic gastritis, and thyroiditis, jaundice, and steatorrhea with small yellow subcutaneous lesions called xanthomas.</li> <li>• Dx with demonstration of antimitochondrial antibodies and with liver biopsy results.</li> <li>• Only chance for survival is liver transplantation.</li> </ul>
Primary sclerosing	<ul style="list-style-type: none"> <li>• Found primarily in young males (ages 20–40)</li> </ul>

cholangitis	<p>years), this immune disorder destroys both intra- and extrahepatic bile ducts via cell-mediated immune reaction.</p> <ul style="list-style-type: none"> <li>• A cellular phase followed by a fibrous stage that destroys bile ducts, leading to obstructive jaundice.</li> <li>• Some patients may also have inflammatory bowel disease with cholangiocellular carcinoma occurring in 10% of patients.</li> <li>• Treatment is with liver transplantation.</li> </ul>
Carcinomas Liver cell adenoma	<ul style="list-style-type: none"> <li>• These benign tumors resembling normal hepatocytes are almost exclusively seen in women.</li> <li>• There appears to be a relationship to the use of oral contraceptives.</li> <li>• Tumors are highly vascular and as a result may bleed, leading to death in some patients.</li> </ul>
Hepatocellular carcinoma	<ul style="list-style-type: none"> <li>• The male-to-female ratio is approximately 5:1, with the highest incidence in Asia and Africa (low in the U.S. and Europe); usually occurs in middle age (30-50 years of age).</li> <li>• Risk factors include those with cirrhosis secondary to hepatitis B, hepatitis C, hemochromatosis, and <math>\alpha</math>1-antitrypsin deficiency.</li> <li>• Initial symptoms may be nonspecific, such as weight loss, loss of appetite, and nausea.</li> <li>• Further symptoms/signs may be related to several events: hepatomegaly with tenderness, bloody ascites and splenomegaly from portal hypertension, intravenous thrombosis (Budd-Chiari syndrome), various manifestations of paraneoplastic syndromes including insulin-like secretions leading to hypoglycemia, erythrocytosis from erythropoietin secretion, hyperestrinism, hypercholesterolemia, and hypercalcemia.</li> <li>• The diagnosis is made through liver biopsy and an assay for alpha-fetoprotein (AFP) for early detection.</li> <li>• The 5-year survival rate is 10%.</li> </ul>
Cholangiocellular carcinoma	<ul style="list-style-type: none"> <li>• A malignant adenocarcinoma tumor of the bile ducts; this tumor is rare in the U.S.</li> <li>• Associated with infection from the liver fluke, <i>C. sinensis</i>; primary sclerosing cholangitis is also a risk factor, although rare.</li> <li>• May originate from either intrahepatic or extrahepatic bile ducts, with the extrahepatic duct producing jaundice early on with a resultant</li> </ul>

	<p>increase in survival rate due to the early recognition.</p> <ul style="list-style-type: none"> <li>• 5-year survival for intrahepatic is 10%, whereas it is 35% for those involving the common bile duct and papilla of Vater.</li> </ul>
Gallbladder carcinoma	<ul style="list-style-type: none"> <li>• This carcinoma is more common in older patients and those with gallstones, such as Native Americans, with a female-to-male ratio of 2:1.</li> <li>• It appears that individuals with a body mass index (BMI) <math>\geq 25 \text{ kg/m}^2</math> combined with low total physical activity have a higher risk, likely due to hyperinsulinemia.</li> <li>• Initially restricted to the gallbladder, symptoms are minimal. Extension into the liver may herald onset of jaundice or intestinal obstruction.</li> <li>• Late Dx leads to a poor prognosis with the opportunity for resection passed.</li> <li>• The 5-year survival rate is only 5%.</li> </ul>
<b>Hereditary disorders</b>	
Gilbert's syndrome	<ul style="list-style-type: none"> <li>• An autosomal dominant disorder of bilirubin metabolism involves an enzyme defect related to uptake of bilirubin from the blood to the liver; occurs in 5% of population.</li> <li>• More common in males, the only sign of disease is intermittent jaundice that appears around puberty.</li> <li>• Unconjugated hyperbilirubinemia is found.</li> <li>• No treatment is required.</li> </ul>
Hemochromatosis	<ul style="list-style-type: none"> <li>• An autosomal recessive defect in iron absorption leading to excess accumulation of iron in the liver and other organs.</li> <li>• Although the gene defect is found in 10% of the population, only 0.4 are homozygous and a small proportion of those individuals are symptomatic. Males are more commonly affected than females (10:1 to 20:1).</li> <li>• Triad includes bronze skin, liver cirrhosis, and diabetes mellitus.</li> <li>• When joints are affected there may be pain, stiffness, and swelling; usually bilateral, however, may begin in a single joint.</li> <li>• Laboratory includes elevated ESR and serum iron, increased saturation of plasma iron binding and liver biopsy findings.</li> <li>• Radiographically, usually bilateral involvement with osteoporosis, CPPD crystal deposition, and involvement</li> </ul>

	of MCP joints. • Weekly phlebotomies are the treatment approach to prolong lives.
Wilson's disease	• An autosomal recessive disorder of copper metabolism producing lesions in the eye, brain, and liver; believed to be due to inability to excrete copper into bile. • Incidence is 3 in 100,000. • In eyes, copper deposition is seen as a Kayser-Fleischer ring (brownish discoloration of the iris). • In the brain, closely resembles basal ganglia disease. • Chelating agents are used such as D-penicillamine for prevention and management.

The afferent supply to internal organs follows a path similar to that of the sympathetic nervous system, often in close proximity to blood vessels. The nerve cell bodies are located in the dorsal root ganglion (similar to the somatic system). The fibers of these splanchnic nerves follow the sympathetic chains and enter the cord via the white rami communicants. The fibers enter the dorsal horn, and, through the tract of Lissauer, travel several segments cranially and caudally to end in laminae I and V. There are a small number of visceral fibers and receptors compared with those in the somatic system (such as the skin or even peritoneum). This sparse innervation often allows small, localized damage to be asymptomatic. The stimulus must be strong enough to involve an area large enough to stimulate enough receptors to produce a conscious perception of pain.

Organ pain may become somatic pain and allow localization. This occurs when a somatic structure around an organ is stimulated, such as the peritoneum, pleura, pericardium, or capsule (liver and kidneys). These somatically innervated structures allow cortical or thalamic localization as a result of the unilateral innervation afforded by the spinal nerves of the thoracolumbar area and the phrenic nerve. Specifically, the phrenic nerve (C3-C5) innervates portions of the pericardium, the biliary tract, and

the central zone of the diaphragm. The thoracic and upper lumbar spinal nerves innervate the parietal pleura, the parietal peritoneum, the outer diaphragm, and the roots of the mesentery of the intestines. The parietal peritoneum and the segmentally related dermatome (skin), sclerotome (bone), and myotome (muscle) are truly overlapping. Irritation of one of these structures may refer pain to its segmentally related partner(s) (see **Figure 31-1**).

**Basic considerations:**

- Back pain may be the earliest manifestation of visceral disease.
- Pain due to metastatic lesions may be severe before x-ray confirmation.
- Visceral origin of back pain should be considered when there is an absence of muscular spasm, tenderness, and impaired mobility.
- Persistent backache due to extraspinal pathology is rare in children, common in adults.
- Backache may occur in any acute systemic infection.
- Myocardial infarction can cause back pain.
- Lumbar spasm may accompany the severe pain of certain retroperitoneal diseases.
- Radicular pain may occur with visceral lesions, as in sciatic radiation due to hypernephroma.
- Just as visceral disease may suggest spinal pathology, so may the radiation of spinal lesions suggest a visceral origin of pain.
- Do not overlook the possibility of rectal and bladder lesions in persistent coccygodynia.

**Figure 31-1** (A) Extraspinal causes of back pain: some basic considerations. (B) General visceral map in backache.

The appendix serves as a review of the above concepts. If the appendix is distended or inflamed, visceral afferents will be stimulated, usually leading to a perception of periumbilical, central pain. This is more likely to occur if the distention is rapid. If, however, the appendix were inflamed or distended enough to irritate the local peritoneum,

somatic afferents would be stimulated, localizing the pain to the right lower quadrant (McBurney's point). Similar events could occur with the gallbladder, with referred pain to the right scapula due to a segmentally related overlap.

## Evaluation

## History

Pain localization is often quite valuable in narrowing down the possibilities. **Figure 31-2** summarizes some possible causes based on pain localization to a specific quadrant.

## Acute Abdominal Pain

*Acute abdominal pain* is a generic term. In other words, a patient may present with a pain that began within a few seconds, a few minutes, or over hours to days; all are called acute. This distinction may be a relevant starting point in deciding whether or not to make a medical referral. Abrupt pain that begins within seconds to a matter of minutes is often due to a serious disorder, such as the following:

- rupture of an organ (perforated ulcer, ruptured abdominal aneurysm, or ectopic pregnancy)
- torsion (testicular or ovarian)
- blockage of a nonintestinal lumen (cholelithiasis, ureteral stone, and rarely acute appendicitis)
- vascular occlusion (mesenteric infarction in the elderly or sickle cell crisis)

The seriousness of the situation is not lost on the patient who calls 911 or rushes to the emergency department.

Pain that appears rather abruptly over minutes and builds over hours to a few days is characteristic of a number of processes such as cholecystitis, pancreatitis, appendicitis, pelvic inflammatory disease, food poisoning, and diverticulitis. Also, many of the conditions that become chronic and recurrent have their advent as an acute pain such as in peptic ulcer, endometriosis, diverticulitis, and inflammatory bowel disorders. Pain that grows slowly over days or longer suggests an underlying inflammatory process or intestinal obstruction.

Still, the majority of patients with pancreatitis, cholecystitis, and appendicitis will have a belated trip to the emergency department, not the chiropractor's office. If the chiropractor inadvertently is present at the time of onset (or has had a personal attack of acute abdominal pain), however, it is important to determine what was eaten within 24 hours, past history of similar attacks, alcohol ingestion, and any premonitory signs.

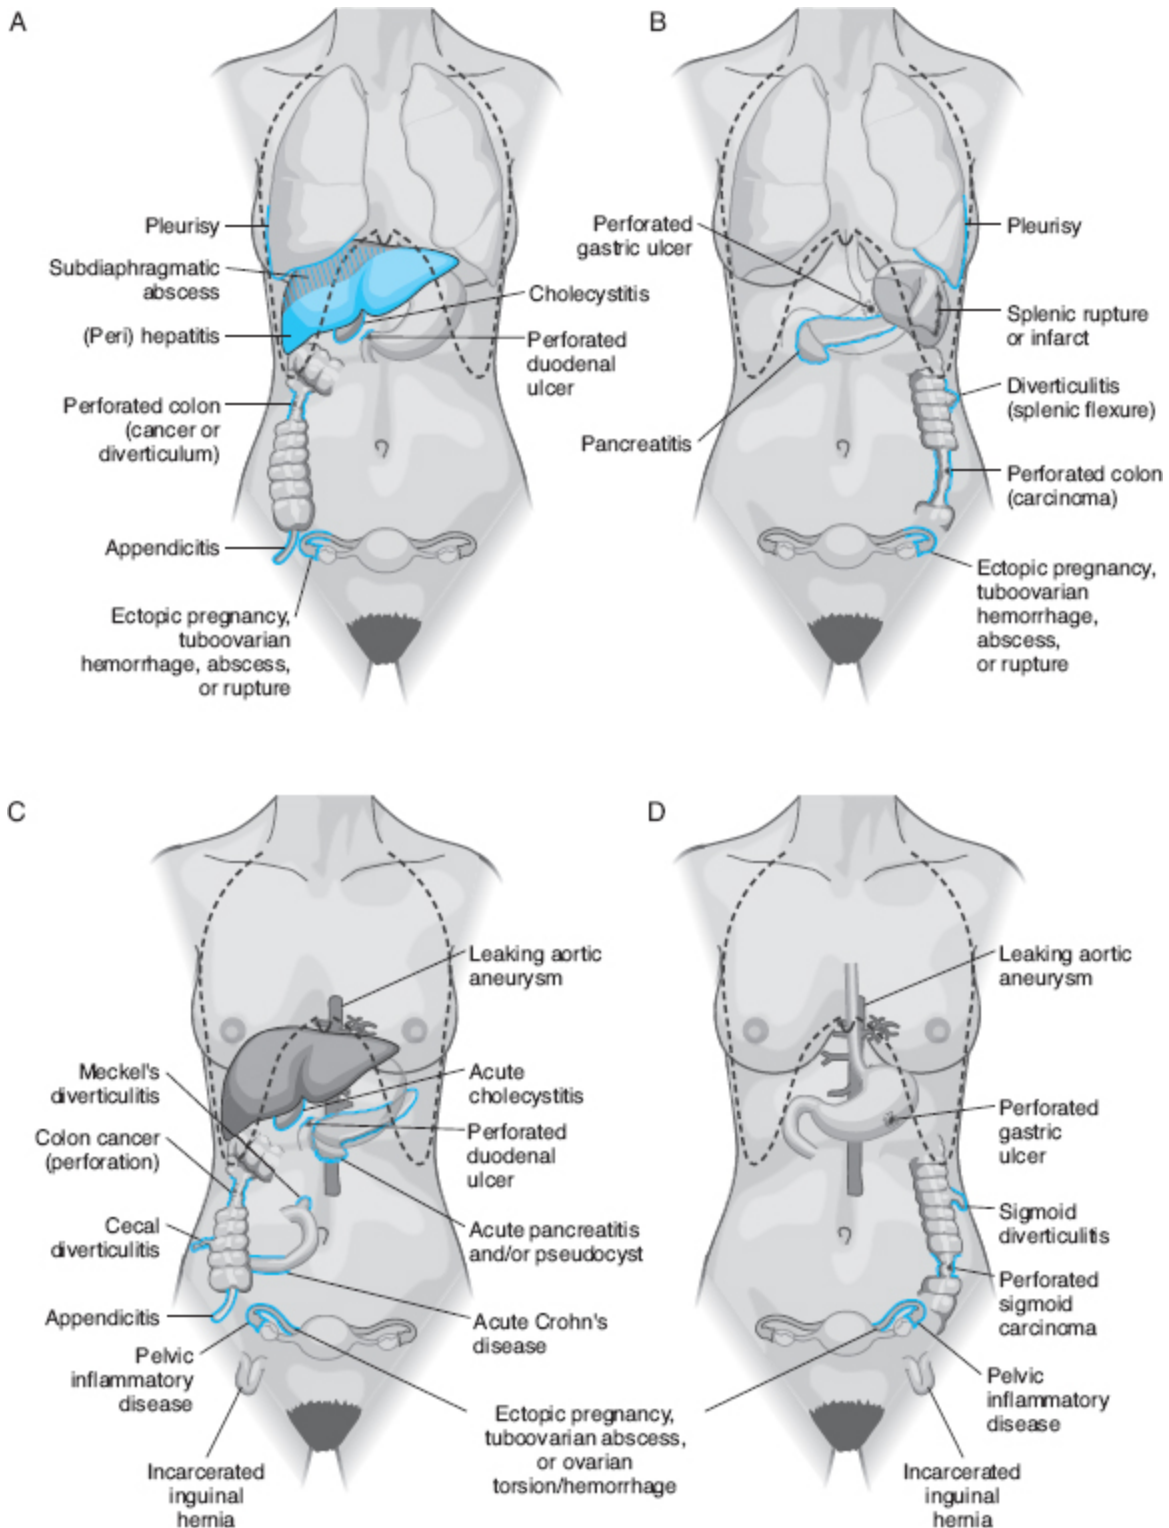

The quality and location of the pain are obviously important. Dull, aching central pain in the epigastric, umbilical, or hypogastric area is nonspecific, but it indicates visceral involvement. If this pain migrates to a specific quadrant, and especially if this is accompanied by a change in the quality of the pain, local peritoneal or capsular involvement is likely. The classic example, as mentioned above, is the sequence of appendicitis that begins in the central abdomen and localizes to the right lower quadrant when the local peritoneum is irritated. If the appendix ruptures into the peritoneum, a more diffuse, peritoneal response with a rigid abdomen will result. Pain that begins anteriorly and radiates to the back is often felt in a region segmentally related to the organ. For example, pain from a perforated ulcer is referred to the T6-T10 area; uterus, to the lumbopelvic area; esophagus, to the central midthoracic area; and gallbladder, to the inferior angle of the right scapula.

Associated symptoms may be useful indicators of the underlying process. Although it may appear as though vomiting is a purely gastrointestinal (GI) symptom, it is important to remember that in addition vagal stimulation, intracranial pressure, vestibular dysfunction, and metabolic processes (uremia, acidosis, chemotherapy, hypoxia, and toxins) may also induce vomiting. The timing of vomiting may be important. If vomiting occurs before abdominal pain, a “surgical” cause is less likely. Early gastroenteritis, food poisoning, and drugs may present this way. If vomiting relieves abdominal pain, peptic ulcer disease (less commonly upper intestinal obstruction) is often the cause in a patient with epigastric pain. Vomiting does not relieve the pain of many other acute abdominal conditions such as pancreatitis and cholecystitis. The content of vomit may indicate where the process is located in the alimentary tract. If the vomit contains undigested food, gastroesophageal obstruction is likely. If the vomit smells like feces, intestinal obstruction is high on the list. Coffee-ground vomit indicates GI bleeding.

Mallory-Weiss syndrome is the primary cause of hematemesis. It is due to excessive pressure that causes tearing of the gastric mucosa and the esophagus. There may be extreme bleeding. Alcoholics are one of the at-risk groups. Bleeding usually spontaneously resolves. Management with vasopressin or angiographic embolization may be necessary, with surgery used in only rare cases.

Constipation and diarrhea are less specific indicators. If constipation precedes abdominal pain, the rectum or colon is probably involved. However, abdominal pain often causes a decrease in peristalsis; therefore, many patients with abdominal pain are constipated. For the same reason, anorexia is also nonspecific; however, if the patient has an appetite, serious disease is unlikely.

**Figure 31-2** Common and uncommon conditions that may cause “parietal” pain and localized peritonitis in the various quadrants of the abdomen. (A) Right upper quadrant. (B) Left upper quadrant. (C) Right lower quadrant. (D) Left lower quadrant.

When the patient reports that family members or friends who shared a common meal have similar symptoms, food poisoning is likely. The onset of symptoms is highly variable depending on the underlying causative organism. This time frame varies from as little as two hours to as much as 48 hours; however, the average time is between four and eight hours.

In the female patient, the relationship to the menstrual cycle may be helpful. For example, a missed period or spotty last period may be a clue to ectopic pregnancy. Increase in pain during or soon after menstruation is suggestive of pelvic inflammatory disease in a sexually active female. Pain between menstrual periods may represent mittelschmerz, indicating an ovarian cyst or rupture.

## **Recurrent Abdominal Pain**

When abdominal pain is recurrent, the differential list is decreased substantially. It is important to ask some general questions regarding alcohol abuse (pancreatitis, esophageal, hepatic, and gastric problems), medication intake (NSAIDs or other drugs causing gastric bleeding), predominance of diarrhea or constipation (irritable bowel syndrome versus inflammatory bowel disease), and a menstrual history (primary or secondary dysmenorrhea). (See **Table 31-4**.)

With epigastric pain, reflux esophagitis, peptic ulcer, or (much less commonly) pancreatitis is possible. Historical clues that help differentiate reflux from peptic ulcer include the relationship to meals. In general, food will relieve the pain of a duodenal ulcer (depending on the food type), whereas with reflux, pain is increased after a heavy meal and especially with tight garments or recumbency. Antacids may help both. It is important to question the patient regarding diet. Common foods may irritate a duodenal ulcer

and increase reflux. Foods that lower the tone of the lower esophageal sphincter, leading to reflux, include chocolate, caffeine, fat, garlic, onions, and alcohol. Other substances include nicotine, theophylline, calcium channel blockers, and anticholinergic drugs.

**Table 31-4** History Questions for Recurrent Abdominal Pain

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Is the pain in your upper abdomen?	Reflux esophagitis, peptic ulcer, pancreatitis, cholecystitis, or cholelithiasis	<p>Is the pain worse on an empty stomach?</p> <p>Are you taking large doses of aspirin or other NSAIDs?</p> <p>Do you drink alcohol often? (Perhaps use CAGE approach.)</p> <p>Do you feel worse after lying down after a heavy meal?</p> <p>Did a severe pain occur rather suddenly and last for several hours, associated with nausea or vomiting?</p> <p>Did you notice a relationship to fatty meals?</p> <p>Does vomiting relieve the pain?</p> <p>Did others in your family or did your friends also become sick after eating the same food?</p>	<p>Duodenal ulcer likely</p> <p>Gastric irritation, possible ulcer</p> <p>Alcohol-related pancreatitis or ulcer irritation</p> <p>Reflux esophagitis</p> <p>Biliary colic (cholecystitis)</p> <p>Possibly cholecystitis if severe; if epigastric and less severe consider reflux esophagitis</p> <p>Peptic ulcer if it does; if it does not, consider pancreatitis or cholecystitis</p> <p>Food poisoning</p>
Is the pain lower in your abdomen?	Irritable bowel syndrome, inflammatory bowel diseases, dysmenorrhea, diverticulitis	<p>Do you have constipation that alternates with diarrhea?</p> <p>Do you mainly have recurrent diarrhea?</p> <p>(For females in reproductive years) Is the pain associated with your period?</p> <p>If the pain is related to your period, is it much worse than previously felt pain?</p> <p>Lower left quadrant abdominal pain (in an older patient) with apparent change in stools?</p>	<p>Irritable bowel syndrome likely</p> <p>Inflammatory bowel disease (most likely ulcerative colitis)</p> <p>Dysmenorrhea</p> <p>Secondary dysmenorrhea (most likely endometriosis)</p> <p>Consider diverticulosis or colon cancer</p>

Severe upper abdominal pain lasting for several hours and associated with nausea and sometimes vomiting is highly suggestive of cholelithiasis. A profile of female, fat, forty, and flatulent may be found; however, it is not an exclusive descriptor of the patient with biliary colic. The association of onset with a fatty meal also is not consistent. Alcoholic fatty liver is another possibility with upper right quadrant pain. Non-alcoholic fatty liver, also a cause of

upper right pain, is becoming more common due to its association to obesity.

With the exception of menstrually related pain, recurrent lower abdominal pain generally can be grouped historically into those with bowel habit change and those without. Irritable bowel syndrome commonly causes alternating bouts of diarrhea and constipation. Usually constipation is the predominant symptom, with a characteristic passage of small, marble-sized stool in the morning that is associated with some mild diarrhea that may have mucus attached. The inflammatory bowel diseases often have diarrhea as a major complaint, often more than the abdominal pain with ulcerative colitis. Diverticulitis usually does not cause a change in bowel movement.

Recurrent cyclic pain in menstruating women is usually dysmenorrhea. Dysmenorrhea may be a “normal” problem that has established a baseline of pain for most females by their 20s. Any change in this pattern to a more severe menstrual pain is suggestive of secondary causes. High on this list is endometriosis.

## **Examination**

# **Acute Abdominal Pain**

With acute abdominal pain there are several clues with regard to the patient's posturing. Patients who are cautious to move for fear of increasing pain may have a peritoneal problem. Patients doubled over in pain or seeking relief by the fetal position are likely to have pancreatitis if the pain is upper abdominal. A patient who keeps the right leg in flexion and avoids extension may have appendicitis with irritation of the psoas muscle. Patients who cannot find a comfortable position and continue to move around or are

writhing in pain will probably have a ureteral stone (if associated with radiation into the groin) or cholecystitis (if the pain is upper abdominal).

Although a rare chiropractic office presentation, a patient with acute abdominal pain should be evaluated immediately for shock. Hypotension, tachycardia, impaired mentation, and oliguria are indications of volume loss from intra-abdominal bleeding or fluid loss. Shock requires an emergency department evaluation.

The yield on plain abdominal films (scout, kidney/ureter/bladder [KUB], flat plate) is usually quite low. Even in an emergency department setting, one study<sup>4</sup> indicated positive findings on only 10% of films. Most GI pathology is not visible on film. Free air from a perforated organ and bowel obstruction are the only nonstone indicators visible. Radiopacities indicating stones occur with gallstones, kidney stones, and fecaliths (with appendicitis). The yield is approximately 70% of the time with kidney stones, 10% to 15% with gallstones, and only 5% with fecaliths.<sup>4</sup> With gallstones, it is also important to recognize that finding stones does not always mean that the cause of the patient's abdominal pain has been found. There are significant numbers of asymptomatic patients with radiographic evidence of gallstones.

Laboratory studies may give general or very specific indications of an underlying process. On a general screen, a finding of leukocytosis with a shift to the left is an important indicator of an inflammatory reaction and, coupled with the history and location of pain, often will point to appendicitis or cholecystitis. Many acute inflammatory reactions may cause a similar finding, however. Acute pancreatitis also will raise the white blood cell (WBC) count and may have associated hyperglycemia, increased lactate dehydrogenase (LDH), and increased aspartate transaminase (AST) levels. With pancreatitis measurement of the specific isoenzyme *p*-

amylase or, when measured later, lipase may assist in the diagnosis, but this is often performed in the hospital.

More specific are the urinalysis findings that may demonstrate an increase in red blood cells (RBCs) or WBCs. Microscopic hematuria (more than three cells per high-power field) is strong evidence of a ureteral stone in a patient with flank pain. Microscopic pyuria (more than five WBCs per high-power field) is suggestive of a urinary tract infection (UTI). Therefore, in a patient with pyuria, hematuria, and flank pain, pyelonephritis is likely. For patients with suspected ectopic pregnancy, a serum human chorionic gonadotropin (hCG), b-subunit test (pregnancy test) should be performed.

The abdominal examination is a sequential approach beginning with auscultation, progressing to percussion, then palpation.<sup>5</sup> The primary purpose of auscultation is to determine whether bowel sounds are present or absent. This may require up to three minutes. Complete absence is found with peritonitis and paralytic ileus. Although it may seem logical that bowel obstruction would also be a consideration, partial bowel obstruction often causes high-pitched rushes of bowel sounds. When bowel sounds are “hyperactive,” gastroenteritis or intestinal bleeding should be considered. Percussion may be used to distinguish between air and fluid in the abdomen; however, it is more commonly used to detect referred tenderness. A positive rebound tenderness is often found at McBurney’s point with appendicitis. Palpation is used to differentiate among masses that are superficial and deep. Superficial masses are still present with abdominal contraction. This is most common with incisions, umbilical hernias, or diastasis of the abdominals. Next, deeper palpation may distinguish among fat/feces, fluid, and masses that represent a tumor or fetus. In general, if there is lower abdominal tenderness that improves with a sustained pressure, feces or gas is likely the

cause (especially when the patient reports relief with either passage of gas or a bowel movement).

The chiropractor should be conscious of the need for pelvic, testicular, and rectal examinations in patients with acute abdominal pain. If the chiropractor is unfamiliar or uncomfortable with these procedures, it is imperative that they be performed by a trained health professional. All indicators of pelvic inflammatory disease, testicular or ovarian torsion, and rectal masses indicating cancer will be missed without this portion of the examination.

Occasionally, mechanical testing will reproduce or exacerbate abdominal pain. Two apparently muscular responses may indicate underlying visceral irritating processes. The psoas sign is sometimes seen in patients with appendicitis.<sup>6</sup> The patient keeps the hip flexed and is reluctant to extend the leg. Resisted flexion or passive extension increases the pain. Another sign is the obturator sign. This is found more often with pelvic pathology in women. Internal rotation of the flexed hip may increase the abdominal pain in these patients.

Further evaluation with more sophisticated testing such as ultrasound, endoscopic ultrasound, transvaginal ultrasound, radionuclide scans, computed tomography (CT), ERCP, magnetic resonance imaging (MRI), or magnetic resonance cholangiopancreatography (MRCP) is dependent on one's underlying suspicion based on a thorough history and examination. In general, ultrasound is often used for appendicitis and cholelithiasis and, in women, to identify and differentiate among various pelvic processes such as tumors and ectopic pregnancy. Ultrasound is between 85% and 90% accurate for the diagnosis of gallstones.<sup>7</sup> Endoscopic retrograde cholangiopancreatography (ERCP) is often used diagnostically and therapeutically when there are stones, strictures, or dilatation of the bile or pancreatic ducts or sphincters. CT is reserved for abscess, tumors, or unexplained causes.

# Recurrent or Chronic Abdominal Pain

The examination of chronic abdominal pain is often unrevealing. Laboratory testing is often necessary for upper right quadrant pain including liver function tests. Lower abdominal tenderness that is improved by slow sustained palpation pressure is suggestive of irritable bowel syndrome (IBS). A stool sample is important in the evaluation for parasites, occult blood, mucus, polymorphonuclear leukocytes (PMNs), and unprocessed food. Hemoccult testing must include three samples in an effort to increase the yield of the test.

Occult blood in the stool is not found with IBS but may be found with colon cancer and inflammatory bowel disease (IBD). Crohn's disease often has associated findings of fistulas and other anorectal disease. The stool sample will help differentiate between IBD and other causes of colitis such as parasitic infections (see [Chapter 33](#)).

Referral for sigmoidoscopy or colonoscopy is necessary with persistent diarrhea or suspicion of colorectal cancer or diverticulitis. Barium studies are occasionally used, but not during an acute attack of diverticulitis. Ultrasound may be helpful in the diagnosis of a number of disorders including, hepatobiliary, and genitourinary pathologies such as secondary dysmenorrhea, specifically with endometriosis. More recently, MRI with gadolinium may be used to accentuate the locations of endometrial implantation.

## Management

A general rule of thumb is that if the pain has been present for two to three days and the physical examination shows

no signs of abdominal distention, localized peritoneal irritation, or palpable masses, it is highly unlikely to be a “surgical” case.

Referral is still necessary when the pain is severe, or there are related signs of GI or genitourinary infection. Cases of gastroenteritis or food poisoning are often self-resolving, but the degree and abruptness of symptoms may cause the patient to seek medical attention.

The chiropractor’s role in management of acute cases is to determine the need for referral for surgery or further investigation. The role in chronic or recurrent pain is to do the same; however, comanagement of patients with irritable bowel syndrome, inflammatory bowel syndromes, and diverticulitis may be appropriate. **Table 31-5** is a brief overview of common medications used in the management of some common chronic abdominal disorders. The focus of comanagement is the suggestion of or support of medical recommendations for lifestyle modifications and treatment of associated musculoskeletal complaints. These may include the following:

- high-fiber diet for diverticulosis
- avoidance of alcohol for pancreatitis
- avoidance or substitution for NSAIDs and other causes of gastric bleeding
- stress relaxation techniques and a balanced diet for patients with IBS
- avoidance of smoking, tight garments, high-fat meals, chocolate, and caffeine for reflux
- recommendation that the patient eat more frequent, smaller meals, and lose weight if necessary

An interesting phenomenon has developed with regard to management of peptic ulcer disease. Previously prescription-only medications, H<sub>2</sub> antagonists and proton-pump inhibitors are now available over the counter. The

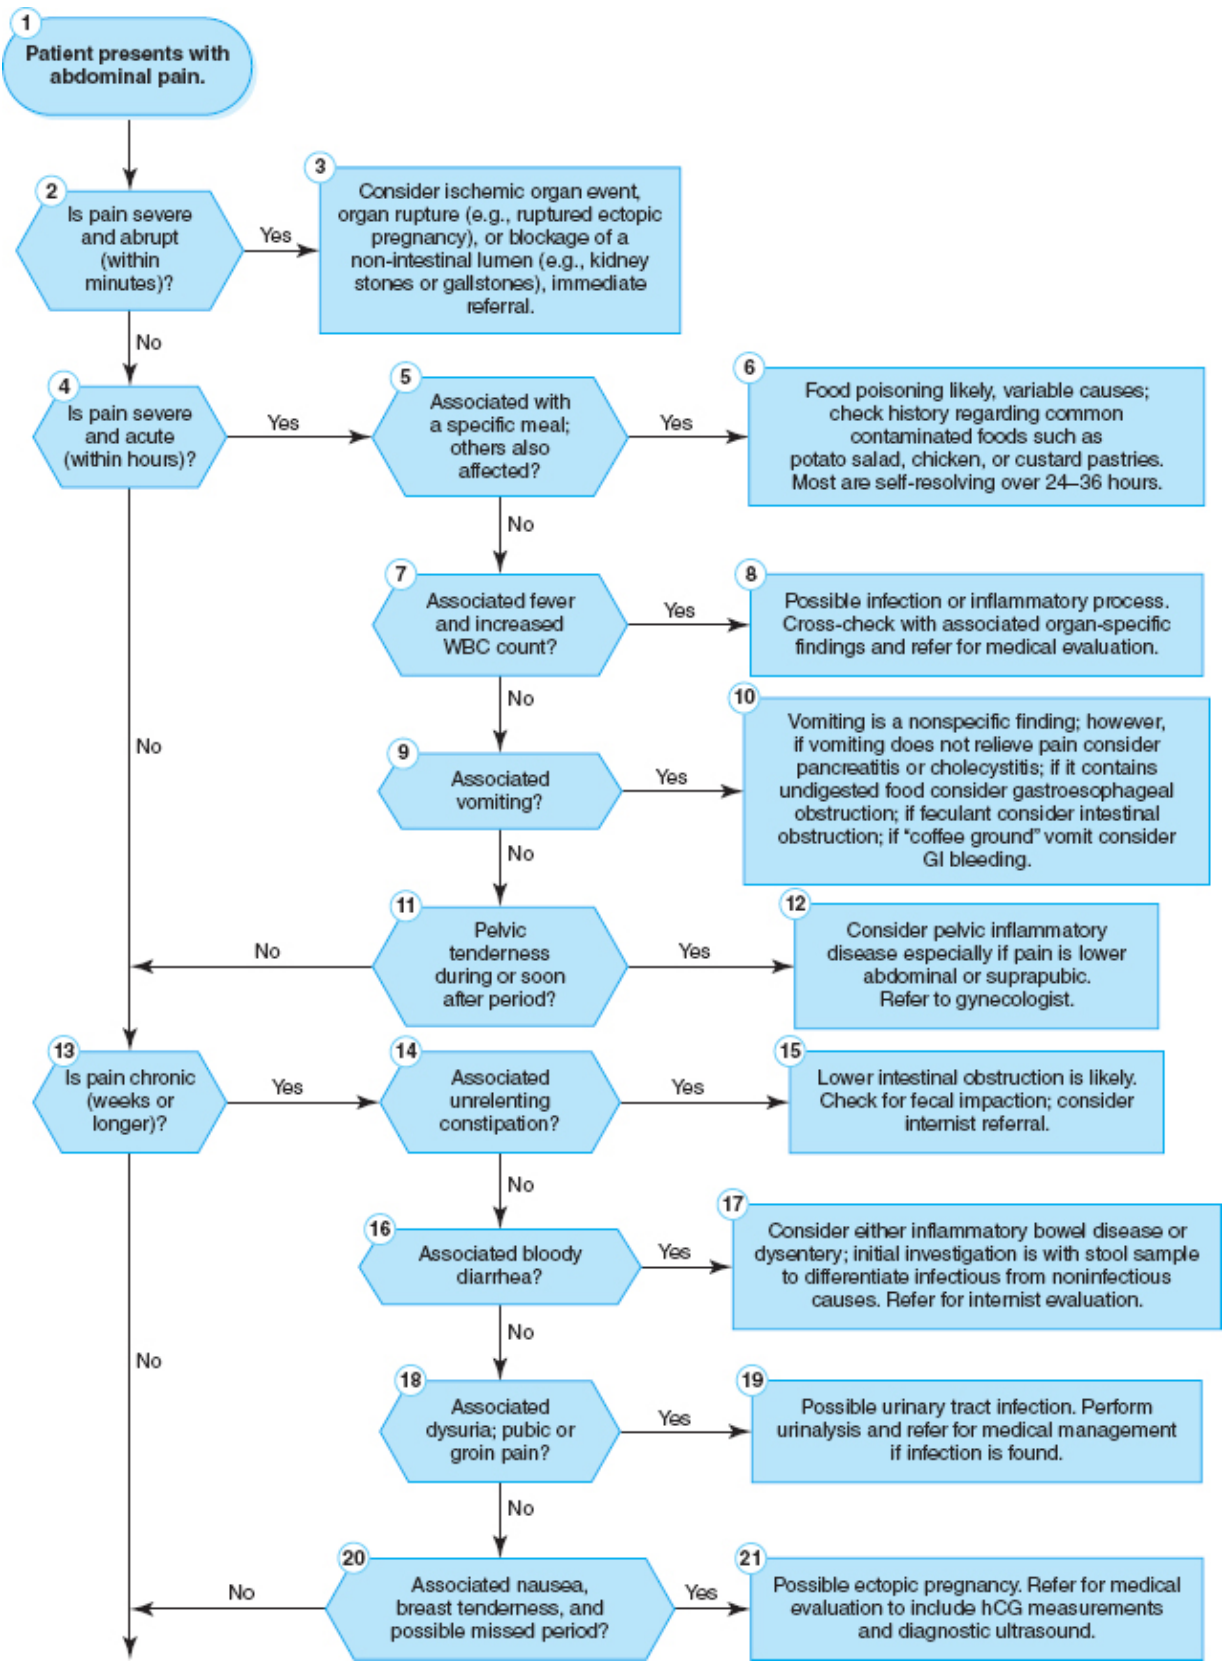

effectiveness of these medications in peptic disease and esophageal disease may make the patient reluctant to seek medical care. If the underlying cause of epigastric discomfort is peptic ulcer disease, however, the most effective treatment for long-term cure is a triple medication regimen that includes an antibiotic. Endoscopic evaluation is often suggested in patients over age 40 years or with an atypical pain presentation to rule out gastric carcinoma.

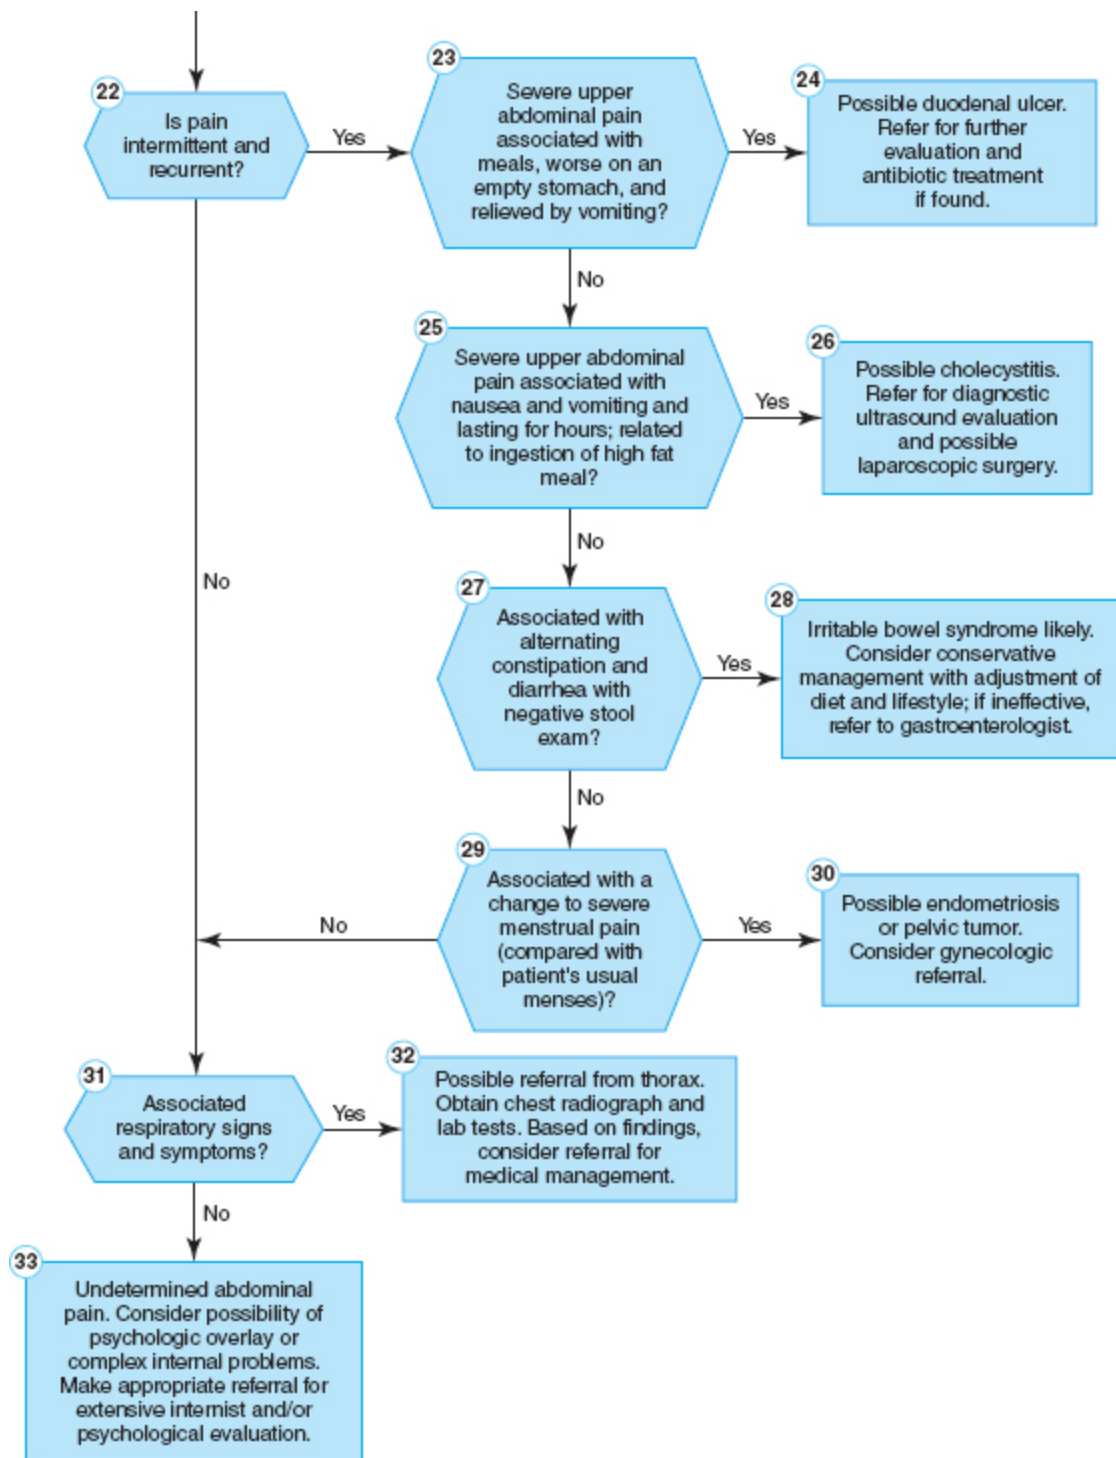

## Algorithm

An algorithm for initial screening for abdominal pain is presented in **Figure 31-3**.

**Table 31-5** GERD and Peptic Ulcer Medications

Drug Class	Examples	General Mechanism	Interactions/Side Effects
H2 Antagonists	Cimetidine	An H2 (histamine) inhibitor blocking gastric acid secretion, raises pH of the stomach decreasing pepsin secretion. Used as an OTC medication in the management of ulcers, GERD, and Zollinger-Ellison syndrome.	May cause the usual GI symptoms, increase pain in joints for patients with pre-existing arthritis, rash, Stevens-Johnson syndrome, neutropenia, increase in uric acid, BUN, and creatinine, feminizing effects, and rarely aplastic anemia, or cardiac arrest.
	Novo-Cimetidine Peptol Tagamet		
	Famotidine	An H2 (histamine) inhibitor blocking gastric acid secretion, raises pH of the stomach decreasing pepsin secretion. Used as an OTC medication in the management of ulcers, GERD, and Zollinger-Ellison syndrome.	May cause dizziness, headache, confusion, diarrhea, constipation, thrombocytopenia, rash, and may increase uric acid, BUN, and creatinine.
	Pepcid		
	Ranitidine	An H2 (histamine) inhibitor blocking gastric acid secretion. Used as an OTC medication in the management of ulcers and GERD.	May cause usually GI symptoms, dizziness, depression, reversible leukocytosis, thrombocytopenia, and possible decreases in liver enzymes.
	Zantac		
Proton-pump inhibitors	Esomeprazole	Similar to omeprazole (isomer of Prilosec). A proton pump inhibitor, it inhibits H <sup>+</sup> K <sup>+</sup> -ATPase (acid production from parietal cells of stomach). Used for erosive esophagitis, GERD, and in concert with antibiotics for <i>H. pylori</i> infection with duodenal ulcer management.	May cause headache, nausea, vomiting, constipation, abdominal pain, and dry mouth.
	Nexium		
	Omeprazole	A proton pump inhibitor, it inhibits H <sup>+</sup> K <sup>+</sup> -ATPase (acid production from parietal cells of stomach). Used for erosive esophagitis, GERD, and in concert with antibiotics (usually metronidazole and amoxicillin) for <i>H. pylori</i> infection with duodenal ulcer management.	May cause headache, nausea, vomiting, constipation, abdominal pain, and dry mouth.
	Prilosec Losec		
Other	Sucralfate	Used as part of GI ulcer therapy due to effects of creating a protective mucosal "paste" and inhibits pepsin, decreases bile absorption, and blocks back diffusion of H <sup>+</sup> ions. Valuable for smokers treated for duodenal ulcers.	Very few side effects. May cause constipation.
	Carafate Sulcrate		
IBS Medications			
Drug Class	Examples	General Mechanism	Interactions/Side Effects
Alosetron	Lotronex	Selective serotonin (5-HT <sub>3</sub> ) receptor antagonist. These receptors are located throughout the myenteric plexus and have effect on distension perception, GI motility and secretions. Used in the control of abdominal pain and diarrhea with irritable bowel syndrome in women.	May cause constipation, ischemic colitis, urinary frequency, muscle cramps, weakness, and anxiety.
Tegaserod	Zelnorm	A serotonin 5-HT <sub>4</sub> receptor agonist used in the management of constipation-predominant irritable bowel syndrome. The 5-HT <sub>4</sub> receptor, a serotonin receptor, normalizes intestinal contractions. In addition, this medication acts to increase the pain threshold for distension of the colon.	May cause headache, dizziness, migraine, abdominal pain, nausea, flatulence, or back pain.

# Selected Causes of Acute Abdominal Pain

## Appendicitis

### Classic Presentation

The classic presentation of acute appendicitis follows a sequence. The patient develops anorexia and poorly localized pain over the mid-abdomen that is followed by nausea or vomiting (75% of patients).<sup>8</sup> The pain then localizes to the right lower quadrant over the next 2 to 48 hours. At this point there is constant pain made worse by coughing or jarring. If the patient is not seen at this point, there may be a sudden relief of pain indicating rupture, usually followed by an increase in pain.

### Cause/Occurrence

The cause of appendicitis is somewhat age-dependent. It is obstructed by inflammation (submucosal lymphoid hyperplasia) mainly in children and teens; by a fecalith in adults (most common), and by various other processes such as fruit seeds, worms, or tumor less often. It affects approximately 7% of the population, with the major occurrence in males between the ages of 10 and 30.<sup>9</sup> Atypical presentations occur in about 50% of cases; more often in adults. The appendix may be located in different areas, affecting the clinical presentation. It may lie anterior, posterior, medial, or lateral to the cecum or in the pelvis. Atypical presentation is most common with a pelvic or retrocecal location hidden from the overlying peritoneum.

### Evaluation

In one literature review diagnostic information taken from the physical exam and special imaging were evaluated to determine the sensitivity and specificity for the diagnosis of appendicitis.<sup>10</sup> History findings that were most important were central pain migrating to right lower quadrant (RLQ) pain with anorexia and pain occurring before vomiting. There are two predictive scales used to diagnose appendicitis. One, the Alvarado score, was reviewed by Ohle et al.<sup>11</sup> who found that it was a useful “rule-out” approach if a cutoff score of 5 is used. However, its performance was inconsistent in children and overpredicted in women. To address the inconsistency in children, another

scoring system, the Pediatric Appendicitis Score, was developed. Using the following eight variables, the Pediatric Appendicitis Score had a sensitivity of 1, specificity of 0.92, positive predictive value of 0.96, and negative predictive value of 0.99 with a score  $\geq 6$ . Following are the variables with their respective positive predictive values.

1. Cough/percussion/hopping exacerbate pain in the right lower quadrant of the abdomen (0.96)
2. Anorexia (0.88)
3. Pyrexia (0.87)
4. Nausea/emesis (0.86)
5. Tenderness over the right iliac fossa (0.84)
6. Leukocytosis (0.81)
7. Polymorphonuclear neutrophilia (0.80)
8. Migration of pain (0.80)

Each of these variables was assigned a score of 1, except for physical signs (1 and 5), which were scored 2 to obtain a total of 10.

That being said, Schneider et al.<sup>12</sup> concluded that neither method provided sufficient positive predictive value to be used in the decision of whether surgery is needed or not. Also, using a single test such as rebound tenderness, which has an LR of 3.4, the prevalence is only around 5% to 7%, so that the post-test probability with a positive test is only about 20%.

In a review by Bundy et al.,<sup>13</sup> similar conclusions were drawn. They found that using likelihood ratios, fever was the single most sensitive sign associated with appendicitis, with a positive likelihood ratio (LR) of 3.4 and with no fever, a negative LR of 0.32. If a child appeared to have a classic clinical appearance, rebound tenderness provided an LR of 3.0, with no rebound tenderness resulting in a negative LR of 0.28. A white blood cell count of less than 10,000/ $\mu$ L decreases the likelihood of appendicitis with an LR of 0.22, as does an absolute neutrophil count of 6750/ $\mu$ L or lower with a negative LR of 0.06. As many as 40% of patients with appendicitis will have pyuria, hematuria, or bacteriuria. Urinary erythrocyte counts exceeding 30 cells per high powered field (PHPF), or leukocyte cell counts exceeding 20 cells PHPF suggest a urinary disorder.<sup>14</sup> Bowel sounds are not hyperactive as would be found with gastroenteritis. Because of the various locations of the appendix, some of the classic presentation and peritoneal findings may not be evident. If the appendix is retrocecal, it is hidden from the peritoneum, producing few peritoneal clues; however the psoas sign may be evident, where the patient cannot extend the right hip or resist hip extension without an increase in abdominal pain. The psoas sign is very specific, but not sensitive (not a good screening tool). If the appendix extends into the pelvis, it is less accessible to abdominal palpation and pain may be more easily provoked with a rectal examination or using the obturator sign where resisted rotation of the hip with the hip flexed 90° increases the abdominal pain.

In the elderly, only two-thirds of patients have RLQ pain.<sup>15</sup> Laboratory findings are nonspecific, indicating a mild leukocytosis. The diagnosis in female patients is complicated by possible gynecologic causes including ovarian cysts, ectopic pregnancy, and pelvic inflammatory disease among

others. A pelvic examination should always be performed by an experienced professional on all women with abdominal pain of unknown origin. In one study<sup>16</sup> the false positive laparotomy rate was twice as high in women. This rate has been much improved, however, with the use of ultrasound.

The choice of imaging for appendicitis is based on cost, expediency, availability, and type of patient. The definitive diagnostic tool has for a long time been high-resolution, real-time ultrasonography (US).<sup>17</sup> Interpretation is operator-dependent though.<sup>18</sup> The specificity is about 81% with the sensitivity at around 86%. Currently, CT has been recommended. CT has been demonstrated to have a sensitivity of 91% to 98% and specificity of 95% to 99% with an overall accuracy of 98%.<sup>19</sup> CT with IV contrast has been shown to be as good as rectal or oral contrast without the delayed time to image.<sup>20</sup> CT with contrast is helpful in difficult cases because terminal ileitis can mimic appendicitis even radiographically (without contrast).<sup>21</sup> There is still concern, though, that for young patients, the amount of radiation is too high. MRI is growing in popularity for subgroups of patients—those who are pregnant, are allergic to contrast, or have renal failure. The newest experimental approach, radioisotope-labeled WBC scans, used for atypical presentations of appendicitis, uses leukoscintigraphy with sulesomab (antigranulocyte antibody Fab fragment). This technique has a high sensitivity and specificity in atypical cases. The negative predictive value in one study<sup>22</sup> was 97%, which would theoretically prevent unnecessary surgery in those cases.

## Management

Laparoscopic appendectomy is the standard treatment. The most common abdominal operation performed in the United States is appendectomy, with as many as 250,000 performed annually.<sup>23</sup> In equivocal cases, most commonly in females, an exploratory laparotomy is performed, with 20% of those operated on having a normal appendix. In fact, with females and older patients, the error rate for managing pain in the right lower quadrant has approached 40% in some studies.<sup>24</sup> It has been recommended and demonstrated that for those who do not warrant immediate surgery, waiting 6 to 10 hours to observe and obtain further information has significantly decreased the rate of unnecessary surgery.<sup>25</sup>

A review by Andersson<sup>25</sup> suggests that spontaneous resolution of untreated appendicitis is more common than previously thought. He insists that patients can be managed by active observation in the hospital with a thorough diagnostic workup instead of a rush to surgery in an effort to avert perforation. Yet, treatment with only antibiotics will result in a recurrence of appendicitis within the first year of between 14% to 20%.<sup>26</sup> The rupture rate in pregnant females is 40%. In seniors the rupture rate is much higher at 67% to 90%. Also, a ruptured appendix will result in death about 3% of the time (those >60 years old account for 50% of deaths).

## **Cholecystitis/Cholelithiasis**

### **Classic Presentation**

A middle-aged or older woman complains of severe abdominal pain associated with nausea and vomiting that occurred rather abruptly after eating a fatty meal. The patient may report having had similar attacks in the past that resolved (60% to 75% of patients).<sup>27</sup>

#### **Cause/Occurrence**

The cause of cholecystitis (acute inflammation of the gallbladder) is blockage of the cystic duct by gallstones (90% of the time). Other causes may include pancreatitis or vascular abnormalities of the cystic duct. There are particular patient populations and risk factors to consider. Cholecystitis is more common in women.

Approximately 800,000 hospitalizations and 500,000 cholecystectomies occur each year.<sup>28</sup> Direct costs of over \$2 billion and indirect costs approaching \$5 billion are tied to gallbladder disease in the United States. Estimates are that 10% of men and 20% of women over age 65 years have gallstones; many are asymptomatic. Ethnic groups at high risk are Native Americans of both North and South America. Blacks are at less risk unless they have sickle cell disease. Patients who are obese, lose substantial weight, or take birth control pills or estrogen are at higher risk. Patients who are pregnant or who have Crohn's disease, cirrhosis, or diabetes are also at increased risk. Gallstones are usually classified as cholesterol stones or calcium bilirubinate stones. The cause for cholesterol stone development is suspected to be increased biliary secretion of cholesterol, delayed emptying of the gallbladder, or other factors that allow precipitation of cholesterol. Cholesterol stones account for 75% of all gallstones. Calcium bilirubinate stones are caused by the breakdown products of hemolysis.

### **Evaluation**

Most patients will have an attack of severe pain with nausea and vomiting that lasts between 12 and 18 hours and then resolves. Twenty-five percent of patients are jaundiced, which represents a possible complication of common duct obstruction. Tenderness is in the right upper quadrant (RUQ) with a positive Murphy's sign. This test involves gradually palpating under the lower right rib margins anteriorly and determining whether patient inspiration dramatically increases pain. The patient often has rebound tenderness in the RUQ (essentially the same as a Murphy's sign). The patient may also have referred pain to the inferior border of the scapula. The gallbladder may be palpable 15% of the time. Laboratory evaluation reveals a mild leukocytosis with a shift to the left. Higher ranges suggest gangrene or other

complications. Alkaline phosphatase may also be elevated. Ultrasonography is the definitive diagnostic tool. Results from a review of the literature article indicated that no single clinical or laboratory test is able to establish or exclude cholecystitis without further evaluation with diagnostic ultrasound.<sup>29</sup> Highest on the list for specificity (rule-out) was the Murphy's sign and with laboratory evaluation, a combination of fever with leukocytosis. ALT, AST, alkaline phosphatase, and bilirubin were not very sensitive or specific. Diagnostic US has a specificity of 80% and sensitivity of 88%.

Decisions regarding imaging are now more complex but varied. Dependent on whether there are gallstones in the gallbladder versus in the ducts and whether there is concern regarding other abnormalities of the biliary ductal system, diagnostic approaches other than ultrasound may be utilized. ERCP uses a combination of endoscopy and fluoroscopy. ERCP is often used diagnostically and therapeutically when there are stones, strictures, or dilatation of the bile or pancreatic ducts or sphincters. In fact, given other imaging approaches such as MRCP and endoscopic ultrasound are safer and do not carry the radiation risk of fluoroscopy, ERCP is used less often unless there is a prior assumption that it will be used for both diagnostic and therapeutic purposes.

## Management

There are several treatment options; however, the standard is laparoscopic cholecystectomy.<sup>30</sup> The patient is released in one day and returns to daily activities in a few days. A relatively common residual of cholecystectomy is persistent diarrhea.<sup>31</sup> Due to a decrease in colonic transit time, an increased defecation frequency and/or decreased stool consistency is found in as many as one-third of patients following surgery. Another treatment option is dissolution therapy with bile salts. The success rate is variable, and half of patients have recurrence within five years after stopping therapy. It may take up to two years for dissolution, and the medication often is expensive. Lithotripsy is available for patients with single stones less than 20 mm in size.<sup>32</sup>

Prevention is possible. Losing weight and keeping it off for obese patients will reduce their risk (ping-pong dieting or rapid weight loss over short periods of time will increase the risk). Several studies<sup>33,34</sup> have indicated that independent of obesity, for both men and women, the degree of physical activity is related to gallbladder disease. Men and women who exercise often are at much lower risk of developing symptomatic gallbladder disease. For men, one major study<sup>35</sup> indicated a decreased risk of gallstone development for those individuals who ingested consistently two to four or more cups of coffee per day regardless of which brewing method was used. The effect was not seen with tea or decaffeinated coffee. The proposed mechanism is cholecystokinin release, increased gallbladder motility, large bowel motility,

inhibition of biliary cholesterol crystallization, or through cafestol (lipid component of coffee beans) that might affect bile cholesterol concentration.

## **Ureteral Stone**

# **Classic Presentation**

The patient reports a sudden onset of pain that is severe and often episodic. The pain is often felt at the costovertebral area of the lower ribs posteriorly, radiating anteriorly, often into the groin (testes in men, labia in women). There is associated nausea and vomiting.

### **Cause/Occurrence**

Stones develop for two main reasons: lack of appropriate hydration and dietary factors. There are three common types of stones. The most common are calcium oxalate, uric acid, and cysteine. An environment for stone precipitation is created by excessive intake of calcium, oxalates, or protein.<sup>36</sup> This, in combination with insufficient water intake, sets the stage for stone formation in predisposed individuals. An environmental factor that may play a role is a humid, hot geographic area. Stones are more likely to form in the summer months. Other risk factors are family history of stones, white race, and a diet high in salt. About 80% of stones are composed of calcium salts. Urolithiasis develops in about 12% of the U.S. population each year with about a 75% recurrence, with about half occurring within five years.<sup>37</sup> Stone formation is much more common in men than women (4:1), usually occurring in the 30s or 40s. In the elderly, the ratio is almost even.

# **Evaluation**

The patient is often constantly moving or writhing in pain, unable to find a position of relief. Prior to imaging, pain is addressed through the use of morphine or meperidine, or more recently some NSAIDs. The location of the pain, a urinalysis indicating hematuria, and a plain film of the abdomen indicating a corresponding radiopacity are often diagnostic. If not, noncontrast helical CT is the imaging tool of choice. The diagnostic accuracy is between 94% and 96%.<sup>38</sup> The advantages of helical CT are time (less than 1 minute), ability to detect all calculi regardless of composition, and differential diagnosis for other causes.

A check of creatinine, electrolytes, calcium, and phosphorus may be needed during the attack to determine if the obstruction is impairing renal function. An elevated WBC count may indicate a more serious involvement. After the attack has resolved, a laboratory search for cause may be appropriate. Elevated serum calcium or phosphorous may indicate primary

hyperparathyroidism. Elevated uric acid may indicate gout. High cysteine levels may indicate cystinuria. Also, one to two 24-hour urine collections are recommended, with a third 24-hour urinalysis after dietary restrictions; a calcium load test is recommended to detect any calcium processing abnormality.

## Management

The pain is usually severe enough to warrant an emergency department visit. About 80% of stones pass spontaneously, with about 20% of patients requiring hospitalization. Management is often symptomatic with follow-up monitoring. Stones that are 5 mm or less in diameter will likely pass without need of intervention. To assist the passage of stones, calcium channel-blockers are sometimes given. They have the effect of dilating the ureters. It is important to know that overhydration during an attack will not force the stones out. If the stone is large enough or is caught at an anatomic juncture, lithotripsy or ureteroscopic stone extraction is utilized.<sup>39</sup> Lithotripsy is contraindicated with pregnancy. Success rate with lithotripsy is about 85% and may require a second or third treatment.

The key to prevention is hydration and dietary management. The patient should be advised to double water intake; the patient should drink water between meals, with meals, and before going to bed at night. It is important that the patient understand that water intake is preferred at a level of about ten 10-oz glasses per day. A large retrospective study<sup>40</sup> of women suggests that coffee, tea, and wine, although acting as diuretics, do not seem to increase the chance of recurrence. Grapefruit juice should be avoided though. Interestingly, a high-calcium diet does not seem to predispose an individual to stone formation unless he or she has absorptive hypercalciuria (increased absorption of intestinal calcium). In fact, a low-calcium diet may increase urinary oxalate and increase risk of stone formation. Moderate dietary calcium intake is recommended for most patients. Fifty percent of those who do not follow this advice will have symptomatic stones again within five years. Patient adherence to hydration and dietary advice is generally quite low. Those with uric acid stones may have a return attack within months if therapy is not initiated and fluid advice is not heeded.<sup>41</sup> One herb that has been shown to decrease the formulation of kidney stone in rat studies is *Herniaria hirsuta*.<sup>42</sup> Further research on humans will be needed before knowing whether this medicinal Moroccan plant could be used as prophylaxis for those with recurrent stones.

## Pancreatitis

## Classic Presentation

The patient is often an alcohol abuser who develops a sudden onset of epigastric pain associated with nausea and vomiting. The pain often radiates to the back. The patient is in a bent-forward or fetal position to relieve pain.

## Cause

Although the primary cause is alcohol abuse, there are a myriad of other possibilities including but not limited to:<sup>43</sup>

- Gallstones
- Many medications including ACE inhibitors, corticosteroids, statins, and diuretics, among others (the symptoms may not develop for weeks after initiating therapy)
- Sudden stoppage of medications for diabetes and hyperlipidemia
- Surgical procedures including ERCP
- Infection including most commonly, mumps

It appears that edema or obstruction of the ampulla of Vater causes a reflux of bile into the pancreatic ducts or acinar cells. The result is the release of pancreatic enzymes into the surrounding tissue. This sequence is often initiated by heavy alcohol intake.

## Evaluation

There is often a mild fever, a tender and often distended upper abdominal region, and possible signs of hypotension. Because the pancreas is retroperitoneal, a palpable mass or rebound tenderness is not a common feature. Bowel sounds are often absent, and the patient may demonstrate a mild degree of jaundice. In rare cases, there may be hemorrhage, resulting in third-spacing, and clinically evident with flank discoloration (Grey Turner's sign) or discoloration surrounding the umbilicus (Cullen's sign). Although the laboratory may demonstrate mild leukocytosis, proteinuria and glycosuria (25%), hyperglycemia, and elevated bilirubin, the classic tests are serum amylase and lipase; both elevated more than three times normal. Although sensitive to pancreatitis, these tests are not always specific. The isoenzyme *p*-amylase is more specific. When transaminases rise dramatically, there is a 95% chance of bile duct obstruction as a cause of the pancreatitis. Imaging is not as valuable as with other abdominal problems. Plain films usually show indirect signs, including an air-filled small intestine or transverse colon. The sequence of imaging ordered is usually ultrasound followed by CT. CT is broadly the best tool because it can rule out other causes of abdominal pain, assess the damage associated with pancreatitis, and establish a baseline for follow-up imaging. Ultrasound is less valuable because of the artifact of gas distention but may still be helpful in evaluating gallbladder and stone involvement. MRCP is also used when available and can determine ductal changes. A grading system developed by Ranson is often used to estimate

the prognosis with pancreatitis; however, its sensitivity is quite low at 40%.<sup>44</sup> The more positive criteria met, the higher the morbidity rate. In general, in an older patient with high glucose and elevation of liver enzymes, the prognosis is poorer. The APACHE II approach is more accurate but is considered more difficult to apply.<sup>45</sup>

## Management

There are two main complications of acute pancreatitis: (1) hypovolemia secondary to intravascular fluid loss to the bowels, and (2) adult respiratory distress syndrome (ARDS). These usually occur within a few days to one week after the acute attack. In general the treatment for pancreatitis is bed rest with no food or fluids by mouth and pain medication. A nasogastric tube is often required. Follow-up imaging is usually necessary several weeks after the episode. Spontaneous resolution occurs in 85% to 90% of cases; mortality occurs in approximately 3% to 5%. After resolution, the preventive program is simply avoidance of the causative agent if medication- or alcohol -induced. Continued attacks may lead to chronic pancreatitis. This may be demonstrated on radiographs as pancreatic calcification. Also, being obese or overweight predicts severity of attacks if recurrent; therefore, dietary considerations should be discussed.<sup>46</sup>

## Pelvic Inflammatory Disease

### Classic Presentation

The patient is a woman of childbearing years who is sexually active (often with multiple partners) and who presents with a complaint of lower abdominal pain with associated chills and fever, dyspareunia (painful intercourse), and vaginal (cervical) discharge.

### Cause

There are several major organisms that cause pelvic inflammatory disease (PID) of the upper genital tract in women. The primary organisms are *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. Other organisms include *Haemophilus influenzae* and some enteric organisms. PID is more likely to occur in nonwhites and those who smoke or douche. Oral contraceptives or barrier methods of protection may help prevent infection. However, use of an intrauterine device (IUD) will increase the risk of PID for several months after insertion unless preinsertion counseling and proper selection of patients is followed.<sup>47</sup> Because vaginal douching is associated with bacterial vaginosis,

PID, and ectopic pregnancy, and because there are no proven benefits, douching should be discouraged for adolescent girls and young women.<sup>48</sup>

## Evaluation

The diagnosis may be difficult because many women are relatively asymptomatic. For asymptomatic, sexually active adolescent and young women, screening using urine-based ligase chain reaction (polymerase chain reaction [PCR] assay) is recommended as a cost-effective strategy to detect chlamydial and gonococcal genital infection, allowing early treatment and avoidance of the possible complications of PID, ectopic pregnancy, and bacterial vaginosis.<sup>49</sup> In acute scenarios, the differentiation of PID from appendicitis and other causes is sometimes necessary. The most predictive clues for PID are:<sup>50</sup>

- a history of the disorder
- a history of vaginal discharge
- vaginal discharge upon examination
- urinary symptoms and an abnormal urinalysis
- tenderness outside the RLQ
- tenderness upon cervical motion during pelvic examination

The patient may describe a slow onset of pain that begins during or soon after menstruation. The presentation of lower abdominal pain is relatively nonspecific; however, a pelvic examination will usually reveal adnexal and cervical motion tenderness or a palpable mass. Sometimes the presentation is bilateral lower abdominal pain and suprapubic pain. Laboratory testing is rarely helpful; however, if a woman with lower abdominal pain, adnexal tenderness, fever, and an elevated WBC count also presents with cervical discharge, PID is high on the list. Culdocentesis or Gram staining of discharge may reveal the underlying cause. Most patients will undergo ultrasound, which may help differentiate any masses felt on examination. The definitive diagnosis is with laparoscopy, but most women are treated with antibiotics with an assumption of PID. One study<sup>51</sup> indicated that the diagnoses of only 65% of women with PID were confirmed laparoscopically.

## Management

Treatment is with appropriate antibiotics. Failure to recognize the diagnosis or to treat the disease may result in an ascending infection to the capsule of the liver called the Fitz-Hugh-Curtis syndrome. Also, the long-term consequences may include scarring that interferes with fertility or leads to an ectopic pregnancy. Chronic pelvic pain is also more likely in these patients.

## Ectopic Pregnancy

# Classic Presentation

The patient is a woman of childbearing years who complains of lower abdominal pain and a missed or “spotty” period over six to eight weeks prior to the pain onset.

## Cause

Implantation of the ovum outside the uterine cavity occurs in approximately 1% of pregnancies. Ninety-eight percent of the time this is in the fallopian tubes. Predispositions include prior PID, IUD use (especially with progesterone), douching, progesterone-only contraceptives, endometriosis, or tubal ligation.<sup>52</sup>

## Evaluation

The classic findings include adnexal tenderness on the pelvic examination coupled with a positive pregnancy test (b-hCG). The b-hCG level is higher than 5,000 to 6,000 mIU/mL with uterine pregnancies; ectopic pregnancy usually produces levels less than 3,000 mIU/mL. Also, if the test is followed over several days, the levels will rise slowly with an ectopic pregnancy, whereas they usually double with a normal pregnancy. A low b-hCG level (<1,500 mIU/mL) with an associated low progesterone level (<10 ng/mL) is highly supportive of an ectopic pregnancy.<sup>53</sup> For further differentiation, a transvaginal ultrasound examination is used in an effort to visualize an ectopic mass.

## Management

Treatment is usually through laparoscopy. Recent studies indicate a role for methotrexate to destroy the placenta.<sup>54</sup>

<h3>Selected Causes of Recurrent Abdominal Pain</h3>
--

## UPPER ABDOMINAL PAIN

## Peptic Ulcer (Duodenal and Gastric)

### Classic Presentation

Usually onset begins in a young man (teenage or the 20s; however, may occur from ages 30 to 50 years with duodenal ulcer; over age 50 years for gastric ulcer) and is felt as epigastric pain that is often reported as waking the patient from sleep. The pain is intermittent and recurrent. Antacids and over-the-counter (OTC) H<sub>2</sub> antagonist or proton-pump inhibitors seem to provide relief. Classic presentations and classic relationships to pain on an empty stomach that is relieved by food are not consistent. Sixty percent of patients with complications such as bleeding or perforation have had no prior history of symptoms. As many as half of patients with NSAID ulcers are asymptomatic.

### Cause

The major cause of gastric ulcers is NSAID use. The main cause of duodenal ulcer is *Helicobacter pylori* infection. Although gastric ulcers are due to a breakdown of the protective mechanisms in the stomach against acid and pepsin, the *H. pylori* role with duodenal ulcers is not yet defined. Ninety-five percent of duodenal ulcers occur at the bulb or pyloric channel. Benign gastric ulcers occur mainly at the antrum.

### Evaluation

The physical examination is usually unrevealing. Laboratory testing may reveal anemia from blood loss or leukocytosis if the ulcer is perforated. Noninvasive testing for *H. pylori* infection includes office-based antibody testing, stool antigen testing, and nonendoscopic urease tests. Due to problems of false positives and the inability to distinguish between active disease versus those who have had infection in the past, stool *H. pylori* antigen testing (HpSA) and urea breath testing are the most commonly used tests.<sup>55</sup> Although the urea breath test is expensive, it is not as expensive as invasive testing. The urea breath test identifies urease, an enzyme produced by *H. pylori*. The most accurate diagnostic procedure is endoscopy with biopsy for *H. pylori* and cytologic brushings of ulcer margins for potentially (5%) malignant gastric ulcers. Endoscopy is generally reserved for those with recurrent symptoms. If an upper GI series is performed in lieu of endoscopy, any gastric lesions should be followed up with endoscopy in two to three months.

# Management

There is now a general consensus that an antibiotic regimen to eradicate *H. pylori* is the most effective means of dealing with duodenal ulcer. Compared with standard therapy of H<sub>2</sub> antagonists, antibiotic therapy demonstrated only a 5% recurrence (largely due to use of NSAIDs), compared with a 70% to 85% recurrence in the standard H<sub>2</sub> group.<sup>56,57</sup> This “triple therapy” is a combination of omeprazole or lansoprazole (proton-pump inhibitor) with metronidazole (Flagyl) and amoxicillin (antibiotics). For gastric ulcers, discontinuing NSAIDs combined with a two- to three-month course of H<sub>2</sub> antagonists or sucralfate (a drug that acts locally as a mucus bandage) is usually effective. Discontinuing smoking is often necessary. If the ulcers do not heal, Zollinger-Ellison syndrome is suspected.

One study<sup>58</sup> provides some preliminary support for the use of spinal manipulative therapy in the treatment of patients with ulcers. This small study indicated that clinical remission occurred 10 days earlier with spinal manipulation than with medical treatment. Cautions to interpretation must include that both groups were given an “ulcer diet” and that the medical treatment consisted of the now out-of-date use of H<sub>2</sub> antagonists, sucralfate, antacids, etc. Also there was no clear description or apparent consistency in the manipulative treatment procedures.

## Gastroesophageal Reflux

### Classic Presentation

The patient is often an older, overweight individual complaining of epigastric pain after eating large meals and lying down.

### Cause

The tone of the lower esophageal sphincter (LES) may decrease with age and also with ingestion of certain foods, including chocolate, caffeine, fat, and alcohol. In addition, smoking, theophylline, calcium channel blockers, and anticholinergic medications will decrease the tone of the LES, leading to reflux.<sup>59</sup>

Increased pressure from obesity, heavy meals, and recumbency may aggravate symptoms. In addition to overweight individuals, esophageal reflux is common in healthy athletes, such as conditioned runners, cyclists, and weightlifters.<sup>60</sup> Several mechanisms may account for this, including position, Valsalva, indirect effects of exercise and position on lower esophageal tone.

# Evaluation

The diagnosis is mainly historical. The patient may report that by eating smaller, frequent meals, going to bed on an empty stomach, and avoiding chocolate, caffeine, and alcohol, the pain is better. Antacids or the newer OTC H<sub>2</sub> antagonists (Tagamet, Zantac, etc.) usually help. A hiatal hernia may predispose the individual to a reduced LES tone. This may be seen on a chest or anterior-to-posterior thoracic film indicated by an air lucency above the diaphragm. Note that reflux is more common in asthmatics regardless of medication regimen. The main differential is peptic ulcer, Barrett's esophagus, and esophageal cancer. Patients with recurrent symptoms of GI reflux (especially those over age 50 years) should have upper GI endoscopy to detect Barrett's esophagus (potential precursor to esophageal adenocarcinoma).<sup>61</sup> For those with Barrett's, providing an acid-reduced environment (using high-dose proton pump inhibitors) allows endoscopic ablation using laser and nonlaser approaches. Otherwise, a high-risk attempt at removal of the distal esophagus is an option.

# Management

Recommend to the patient that he or she avoid alcohol, caffeine, fatty meals, smoking, and eating large meals. Switching to smaller meals eaten more frequently and going to bed with a partially full stomach may help. If there is an associated hiatal hernia, chiropractic manipulation in the epigastric region may help reflexly. Weight loss is important for obese patients. Omeprazole (a proton pump inhibitor) is the standard for treatment of GI reflux. However, long-term use may lead to problems with absorption of calcium and other important nutrients. Most importantly, gastroesophageal reflux should not be confused with the temporary reflux with infants. A concern that has warranted strong editorial warnings is that medical doctors are prescribing proton-pump inhibitors for infants with reflux. The critics of this approach feel that this practice is more for the parents than the infant and may harm the infant with regard to important nutritional absorption and potentially increase risk for infection.

## ABDOMINAL PAIN

### Irritable Bowel Syndrome

## Classic Presentation

Generally patients present with complaints of abdominal pain (usually lower left or suprapubic) and distention that is relieved with defecation. Patients

often report early-morning constipation that results in the passage of small-sized feces. Signs and symptoms often begin in the late teens or 20s.

### ***Clinical Categories Based on Presentation***

IBS is often divided into three general classifications including an A type (alternating) that is a combination of diarrhea and constipation, a C type (constipation predominant), and a D type (diarrhea predominant). Classification systems have been developed including the Manning criteria, Kruis criteria, and the Rome criteria (I, II, and III). A JAMA review<sup>62</sup> found that the Kruis and Manning criteria have modest accuracy and that no single test is of value. Using the Rome criteria is a popular approach but only Rome I and II criteria have been evaluated extensively. A 2013 review<sup>63</sup> compared these criteria and found that for identifying patients with IBS, the sensitivities ranged from 61.9% for Manning criteria to 95.8% for the Rome I criteria, and specificities included 70.6% for Rome I and 81.8% for Manning. Positive LR<sub>s</sub> ranged from 3.19 (Rome II) to 3.39 (Manning), and negative LR<sub>s</sub> from 0.06 (Rome I) to 0.47 (Manning). Clearly, this performance is only modest in identifying patients with IBS, yet there are no laboratory tests to assist so that history findings are the only information available. Manning et al.<sup>64</sup> determined six symptoms that occur together more often in patients with IBS than in patients with other GI disorders. The other systems including the Rome criteria include these elements, and recent studies<sup>65,66</sup> confirm this observation and add that the likelihood increases with the number of positive criteria; the predictive value decreases with age and is less valuable with men. Also abdominal pain usually occurs two to three times per week for at least several months. These criteria are as follows:

- pain relief with bowel movement
- more frequent stools with the onset of pain
- looser stools with the onset of pain
- passage of mucus
- sensation of incomplete defecation
- abdominal distention sensed through tight clothing or visibly evident

Symptoms compatible with IBS are found in 10% to 22% of adults.<sup>67, 68</sup> Onset is as early as adolescence and tends to peak in the 30s and 40s; unlikely after age 50 years.<sup>69</sup> Only 14% to 50% of this group seek medical advice. Some studies<sup>70,71</sup> have classified patients into two subgroups: (1) abdominal pain predominant that seems to be related to meals and stress; (2) bowel habit predominant and usually constipation is the main complaint, but diarrhea may be; abdominal pain is not the chief complaint. Some studies describe a prototype patient who is often angry, depressed, or stressed.

## **Cause**

The cause is unknown. However, there appears to be abnormal myoelectric activity in the intestines (and sometimes other structures) that results in a

change in peristaltic activity. Studies indicate that a normal six-cycle-per-minute slow-wave rate is more often three cycles per minute in patients with IBS. Colonic spike activity peaks about 60 to 90 minutes after meals, which seems to correlate with a common complaint of pain after meals.<sup>72</sup> It also appears that patients may have a lower visceral pain threshold, perceiving what would be considered normal bowel distention as pain.<sup>73</sup>

IBS is viewed by many as a problem of central-modulated pain with what is termed the brain-gut axis where emotional stimulation may have a direct effect on gut motility but also the threshold of stimulation for pain. An emotional nociceptive area in the cingulate gyrus may be activated by stressful or aversive stimulus from internally in the body. It is proposed that preganglionic neurons from the parasympathetic nervous system may be tied to this response and instead of synapsing (or in addition to synapsing) on motor neurons in the intestinal wall, they synapse on interneurons related to visceral afferents. There may be a heightened sensitivity of nociceptors due to previous infection or perhaps an autoimmune response that causes hyperproliferation of enterochromaffin cells in the walls of the intestinal crypts and may also include mast cells in the lamina propria. Serotonin is released from enterochromaffin cells normally in response to distension, which then increases peristaltic activity. It is proposed that for patients with IBS, there is a stimulation also of nociceptors by serotonin, which in turn causes the release of substance P, which causes mast cells to release histamine, which then causes the release of more serotonin in a vicious cycle.

Patients with IBS may also have an increased colonic motor response to corticotrophin-releasing hormone (RH).<sup>74-76</sup> There are differences in CRH-R1 and CRH-R2. R1 is pro-inflammatory whereas stimulation of R2 is anti-inflammatory. Also, CRH-R1 is pronociceptive for visceral pain whereas CRH-R2 is antinociceptive.

## Evaluation

IBS is largely a historical diagnosis and one of exclusion. The patient should have had symptoms for at least three to six months before considering IBS in the differential. Other causes of constipation should be screened historically, and education in proper fluid/fiber intake combined with proper bowel habits should be used initially for patients who are constipation predominant.<sup>77</sup> Patients with bowel-predominant symptoms should have a rectal and stool examination. Stool that is nonbloody (occult or frank) and free of fecal leukocytes, parasites, and ova suggests IBS. Mucus, seen as a stringy substance covering the stool, is often found in the stool of patients with IBS. In older patients, sigmoidoscopy is sometimes warranted if colon cancer is suspected.

## Management

The patient should be counseled regarding the chronicity of IBS, and that there will be periods of exacerbation and remission. Primary conservative focus is on stress relaxation and dietary factors. Keeping a diary with relation to the onset of symptoms may be helpful. Chocolate milk products and alcohol are common triggers. Patients often benefit by avoidance of lactose, fructose, and sorbitol. In addition, gas-producing foods such as cabbage, cauliflower, raisins, grapes, raw onions, sprouts, coffee, red wine, and beer should be eliminated initially to determine effect. Many small meals throughout the day versus two or three large meals are recommended. A high-fiber diet may help, although if the fiber is bran, increased gas production may worsen symptoms. Exercise may be helpful as indicated by some uncontrolled studies.<sup>78</sup>

Pharmacologically, it is interesting that placebo agents result in improvement in up to 70% of patients. When medication is used, anticholinergic, antidiarrheal, or anticonstipation agents are sometimes prescribed. Also, there is a focus on calcium channel blockers, H<sub>2</sub> antagonists, and 5-HT<sub>3</sub> receptor antagonists.<sup>79,80</sup>

Prescription is based on the type of IBS. If there is diarrhea dominance in the presentation, muscarinic receptor anticholinergics (M<sub>3</sub>) or serotonin receptor antagonists (5-HT<sub>3</sub>) (e.g., Alostrone) are used. Most recently, various forms of intestinal-specific calcium channel blockers such as pinaverium bromide (Dicetel), and trimebutine maleate (Modulon), are utilized to prevent smooth muscle contraction and therefore peristaltic activity. The purpose of this approach is to reduce pain and bloating with less of a focus on either diarrhea or constipation. For constipation, serotonin receptor agonists (5-HT<sub>3</sub>) or cholinergics are prescribed. Obviously if the patient has the combination of diarrhea and constipation that alternates, prescription is a difficult if not impossible dilemma.

A study<sup>81</sup> published in 2013 compares the effect of Chinese manipulation to Dicetel in the management of IBS pain. The manipulation as described in the study appears similar to side-posture chiropractic manipulation. The study protocol utilized both thoracic and lumbar manipulation. The outcome measures included a visual analog pain scale and the bowel symptom scale (BSS). The results indicated a far superior effect for manipulation over the calcium-channel blocker at a ratio of 3:1.

Acupuncture has been proposed as an approach to IBS. Studies seem consistent with regard to a comparison of sham acupuncture to real acupuncture in relation to effect. Also, the time spent with the patient has an effect with increasing success rates related to longer time spent with the patient. Although acupuncture seems effective, a Cochrane review<sup>82</sup> summarized this effect by stating that acupuncture, whether real or sham, is significantly better than antispasmodic calcium channel blocking medications, yet given both real and sham acupuncture are effective, how to apply these findings is problematic. It would seem that if patients benefit, acupuncture should be utilized.

There is some evidence that hypnotherapy may also be beneficial.<sup>83</sup>

## **Diverticulitis**

### **Classic Presentation**

Usually, the patient will be elderly with complaints of left lower abdominal pain and tenderness and associated low-grade fever; bloody stool and/or nausea and vomiting may occur. Most patients will have symptoms mild enough that they will wait a few days before seeking medical attention. Patients with a large perforation will present with generalized abdominal pain and peritoneal signs.

### **Cause/Occurrence**

Diverticula are herniations of the mucosa and submucosa into the colonic muscle wall at the site of mesenteric vessel penetration primarily in the sigmoid colon. Diverticular disease appears to be the result of years of colonic high pressure due to contracted segments of bowel that are undistended; thus it is believed that a chronic fiber-deficient diet is the cause. A high-fiber, low-fat diet increases stool volume, reduces intraluminal pressure in the colon, and decreases colonic transit time. The prevalence is higher in Western countries. Diverticular disease occurs in approximately 10% of individuals in the United States over age 40 years, 50% of individuals over age 60 years, and up to 66% of individuals in their 80s. Eighty percent to 85% of individuals with diverticulosis are asymptomatic. Patients become symptomatic when the diverticula become inflamed, accounting for more than 130,000 hospitalizations each year.<sup>84</sup> It should be noted that corticosteroid use or chronic NSAID use may mask symptoms of diverticular disease.

### **Evaluation**

Lower-left abdominal tenderness with a palpable mass is a common finding. A low-grade fever, occult or frank blood, and a mild to moderate leukocytosis often are found. Abdominal and chest x-rays in the supine and upright positions may be used to determine free air (evidence of perforation) or obstruction in acute presentations. Referral for medical management will usually result in a limited hospitalization, followed 7 to 10 days later with either an outpatient barium study and sigmoidoscopy, or, more recently, CT. CT is the procedure of choice for the diagnosis of diverticulitis.

### **Management**

In patients who have diverticular disease discovered incidentally, a high-fiber diet is recommended. Recommended levels range from 10 to 35 g/day of

insoluble fiber. Bran is recommended because it improves oral glucose tolerance and increases fecal fat excretion. It is recommended to introduce fiber into the diet gradually to avoid cramping. For those with active diverticulitis, antibiotic therapy and intravenous fluids are initial approaches. Twenty percent to 30% of patients eventually will require surgery.

## **INFLAMMATORY BOWEL DISEASE**

### **Ulcerative Colitis**

## **Classic Presentation**

Generally a younger patient presents with complaints of frequent bloody diarrhea, lower abdominal cramping, mild pain, and rectal urgency. Approximately 10% to 20% will complain of multiple joint pains. Variation in presentation is based on the number of bowel movements per day from less than four (mild) to more than six (severe).

## **Cause**

The cause of ulcerative colitis (UC) is unknown. It appears that there may be some predisposition that somehow interacts with other factors to create varying degrees of inflammatory reaction. One theory is that a defect in the intestinal glycosaminoglycan (GAG) protective barrier allows penetration of infective agents, toxins, and antigenic protein moieties leading to a local inflammatory response cascading into a host of biochemical and immunologic changes (leaky-gut syndrome).<sup>85</sup> Individuals who have had Salmonella or campylobacter risk in the following year for developing IBD. Half of all patients with UC have involvement of the distal colon, 30% of patients have extension to the splenic flexure, with 20% of patients extending into the more proximal bowel.<sup>86</sup>

In many patients there is also an effect on the biliary system including fatty liver, cirrhosis of the liver, and sclerosing cholangitis. Patients with long-standing disease are at higher risk for colon cancer. An association with HLA-B27 explains the occurrence of peripheral arthropathies and uveitis in some patients. Oddly enough, smokers have half the risk of nonsmokers of developing UC (the opposite for Crohn's disease).

## **Evaluation**

The patient with mild ulcerative colitis may have no more discriminating findings clinically than patients with other causes of colitis such as infection

or antibiotic colitis. However, those with severe UC may also have signs of hypovolemia such as an increased pulse rate. Severe forms will also cause weight loss, a decreased hematocrit and albumin, and an increased erythrocyte sedimentation rate (ESR) and temperature. Anemia due to blood loss is usually iron-deficiency anemia.

For detecting UC and distinguishing it from Crohn's, the following single tests or combined tests in panels may be ordered:

- pANCA (perinuclear antineutrophil cytoplasmic antibody) for UC; found in about 50% to 85% of patients (only 5% to 20% of patients with Crohn's disease).
- Anti-I-2 (*Pseudomonas fluorescens* antibodies)

The diagnosis is established with sigmoidoscopy with characteristic findings of a granular mucosa with edema, erosions, and friability.

Colonoscopy is reserved for patients who are not acutely ill to determine the extent of involvement. Laboratory testing of the stool is used to rule out other causes of colitis, usually infectious.

## Management

Exacerbations seem related to stressful events, or may be activated by NSAIDs or aspirin, but they may occur without an obvious cause. The mainstay of medical management is similar to that for Crohn's disease, consisting of anti-inflammatory (sulfasalazine or mesalamine and corticosteroids), antidiarrheal, and immunosuppressive drugs used either to induce remission, such as infliximab, or for preventing relapse, such as azathioprine and 6-mercaptopurine (6-MP).

There are a number of dietary recommendations that to date do not have strong literature support but are nonetheless incorporated by most physicians. This includes decreasing the amount of meat and alcohol in the diet and increasing omega-3 fatty acids, cod liver oil, dietary lactulose, and wheat grass juice. Also, many patients report problems with chocolate, dairy products, fats, and artificial sweeteners.<sup>87</sup> The prognosis in most patients is good. Those acquiring the disease in infancy or after the age of 60 years have the poorest prognosis. Pregnancy often worsens UC; however, the use of medication does not seem to affect the fetus.

## Crohn's Disease (Regional Enteritis)

### Classic Presentation

The patient is often young with an insidious onset of intermittent bouts of right lower quadrant pain, some diarrhea, and a low-grade fever. In some patients, the initial presentation is with extra intestinal manifestations such as

perianal fistulas, fissures, or abscesses. Eventually, the patient may appear anemic with weight loss.

## Cause

The cause is unknown. It appears that some predisposition exists due to either genetically acquired sensitivity (e.g., Ashkenazy Jewish patients) and/or environmentally triggered reaction (e.g., live vaccines such as MMR, varicella, zoster) leads to varying degrees of inflammatory reaction. One theory is that a defect in the intestinal GAG protective barrier allows penetration of infective agents, toxins, and antigenic protein moieties leading to a local inflammatory response cascading into a host of biochemical and immunologic changes (leaky-gut syndrome).<sup>85</sup> Individuals who have had Salmonella or campylobacter are at higher risk in the following year for developing IBD. Specifically, it appears that there is an environment that allows chronic T-cell activation, which causes damage through secondary macrophage activation.<sup>88</sup> What activates the T-cells remains controversial. Current interest is in the role of measles and the measles vaccine as one potential instigator.<sup>89,90</sup> There is transmural involvement with extension possible through to the serosa. This patchy, segmental involvement is isolated to the ileum in about one-third of patients, with half of patients also having involvement of the colon. In 15% to 20% of cases only the colon is affected. The process may extend, however, from the mouth to the anus. The inflammatory reaction includes infiltration of lymphocytes and plasma cells. Fibrosis is often extensive, causing obstruction. Sarcoid-like granulomas occur in 30% to 40% of patients within involved intestinal segments. This involvement affects absorption of fat-soluble vitamins and B12, often leading to deficiencies. An association with HLA-B27 explains why some patients have peripheral arthropathies and uveitis.

## Evaluation

Evaluation findings are contingent on the degree and location of involvement. The abdominal examination may reveal a tender right quadrant, anal-rectal disease, and weight loss. Laboratory examination is relatively nonspecific, showing an increase in ESR, macrocytic anemia (with terminal ileum involvement), leukocytosis, and occasionally decreased albumin. Stool examination for ova, parasites, and other pathogens is used to differentiate from other causes of diarrhea. Immunological evaluation for Crohn's includes tests that are not specific or sensitive enough to confirm the diagnosis but could be an initial step prior to colonoscopy. The ASCA test (*Saccharomyces cerevisiae* antibodies), IgG and IgA is positive in about 40% to 50% of patients with Crohn's. Using the Anti-CBir1 test (*Clostridium* species antibodies) about 50% of patients with Crohn's will have a positive test. Antiglycan antibody is

found positive in about 75% of patients with Crohn's (only 5% with UC patients). The Anti-Omp C test (*Escherichia coli* antibodies) is used for rapidly progressing Crohn's disease.

Colonoscopy and barium studies are diagnostic. Colonoscopy allows direct visualization and biopsy. Barium studies may demonstrate "skip" lesions (areas of involvement adjacent to normal mucosa). Narrowing of the barium stream in involved areas may be referred to as the "string sign."

## Management

In the National Cooperative Crohn's Disease Study, it appears that one-third of patients on a placebo went into remission within four months and remained in remission for two years.<sup>91</sup> This is important information for all who attempt to treat Crohn's disease with alternative approaches. Medical care varies based on patient presentation. In the armamentarium of medications the primary drugs are anti-inflammatory including strong NSAIDs such as 5-aminosalicylics (sulfasalazine and mesalamine), prednisone (also used to induce remission), and antidiarrheals. Immunosuppressive medications are used either to induce remission such as methotrexate or infliximab or for preventing relapse such as azathioprine and 9-mercaptopurine (6-MP). The two extremes of initial therapy are either to treat symptomatically prior to more aggressive therapy or the opposite end of the spectrum, beginning with immunomodulators and/or anti-TNF (tissue necrosis factor) agents.

Avoidance of potential risk factors includes cessation of smoking, which has been shown to increase frequency and severity of attacks. Diets high in refined sugars and animal protein have also been associated with a risk of recurrence. Also, many patients report problems with chocolate, dairy products, fats, and artificial sweeteners. Dietary management is important because of malabsorption. Vitamin supplementation is frequently necessary, often including parenteral vitamin B12. However, this does not appear to alter the disease course. Approximately 70% of all patients with Crohn's disease must have some surgery.

## DYSMENORRHEA

### Primary Dysmenorrhea

## Classic Presentation

The patient is often one to two years postmenarchal with increasing pain associated with menses. The pain is felt in the lower abdomen and pelvis, sometimes radiating to the back or inner thighs.<sup>92</sup>

# Cause

Pain is mediated via prostaglandins. The cause is a combination of vasoconstriction and myometrial contraction. Increased discomfort may be caused by fluid retention (estrogen causes salt retention).

# Examination

No examination usually is necessary unless the pain is “new” or suddenly increased. Then a pelvic examination is warranted. With primary dysmenorrhea there are no obvious pathologic findings, but the examination may be more uncomfortable during menses.

# Management

Medical management focuses on decreasing of certain prostaglandins. NSAIDs (ibuprofen, ketoprofen, naproxen) are usually helpful.

One study<sup>93</sup> demonstrated chiropractic manipulation of the spine or pelvis to be effective in reducing pain and a prostaglandin F-2a metabolite. A follow-up study,<sup>94</sup> however, showed similar improvement with either manipulation or a low-force treatment intended to act as a placebo-like comparison. Future research may be able to indicate what is the effective element of the treatment episode. Stimulation of sacral and low-back reflex points through acupressure, electrical stimulation,<sup>95</sup> or acupuncture may provide relief.<sup>96</sup> Dietary formulas, including omega-3 polyunsaturated fatty acids,<sup>97</sup> and B12 may provide relief. One study<sup>98</sup> indicated benefit from the use of magnesium pidolate (4.5 mg/daily). There is mounting evidence that exercise is beneficial for primary dysmenorrhea.<sup>99</sup>

## Secondary Dysmenorrhea

# Classic Presentation

A female patient in her late 20s or 30s (as late as 40s) presents with a complaint that her menstrual pain is much worse than it had been previously. Suspicion is increased when the patient is infertile. Depending on sites of endometrial implantation, endometriosis may also cause dyspareunia and/or rectal pain with bleeding.<sup>100</sup>

## Cause

The two most common causes are endometriosis (implantation of uterine tissue outside the uterus) and pelvic inflammatory disease (salpingitis). Endometriosis appears to be somewhat dependent on a dysfunction of cell-mediated immunity. One study<sup>101</sup> observed that women with endometriosis were more sensitive to the stimulatory effects of peripheral blood monocytes on proliferation of endometrial tissue. Other causes include submucous myoma, IUD use, and cervical stenosis (often post-induced abortion).

## Examination

The pelvic examination may reveal pelvic tenderness or discrete nodules in the cul-de-sac (with endometriosis). Transvaginal ultrasonography is often used to identify lesion sites. However, the definitive diagnosis may rest on laparoscopy to differentiate between PID and endometriosis. Cervical stenosis should be suspected with a presentation subsequent to an induced abortion.

## Management

The focus of management is to suspend ovulation for four to nine months. This is accomplished via a regimen similar to birth control pills or danazol (androgenic effects). This will usually result in a decrease in size of the endometrial implants.

Conservative management options for endometriosis that might be attempted and show some literature evidence, although weak evidence scientifically, include acupuncture,<sup>102</sup> Chinese herbal therapy,<sup>103</sup> and osteopathic manipulation.<sup>104</sup>

When extensive, surgery is often necessary. The approach is dictated by age and desire for reproductive function. Under age 35 years, resecting lesions and freeing adhesions laparoscopically allow fertility in about 20% of patients.<sup>105</sup> After age 35 years or for those not wishing to conceive, treatment involves bilateral salpingo-oophorectomy and hysterectomy if the disease is extensive.<sup>106</sup>

## COLORECTAL CANCER

### Classic Presentation

Patients are often asymptomatic. When symptomatic, an older patient complains of abdominal pain and cramping and notices narrowing of stool and possible blood in the stool.

# Cause

Colorectal cancer (CRC) represents the second most commonly diagnosed cancer. It may result from the progression over years of high-risk polyps into cancer (i.e., multiple polyps, villous polyps, and large polyps). Contributing factors are both genetic and environmental. Smokers, those who are physically inactive, and those with a diet high in red meat and low in fruits and vegetables are at higher risk. Most patients are over the age of 50 years. Those patients with prior GI disorders such as inflammatory bowel disease are at higher risk as are African Americans. The lifetime risk is about 5.4% in the United States.

# Exam

Recommendations vary dependent on the healthcare organization. The U.S. Preventive Services Task Force recommends screening men and women between the ages of 50 and 75 years with either fecal occult testing, sigmoidoscopy, or colonoscopy. The American Cancer Society has a broader and more prescriptive recommendation for this age group with fecal occult blood testing and fecal immunochemical testing (FIT) every year, stool DNA testing (sDNA), flexible sigmoidoscopy and double-contrast enemas every five years and colonoscopy every 10 years. Screening at age 40 years is recommended for those with a family history of CRC or polyps. Screening for those genetically predisposed may begin in their 20s. Digital rectal exam alone is insufficient for screening.

# Management

Patients with polyps discovered on colonoscopy have biopsy and follow-up. Even those with noncancerous lesions are evaluated more frequently. When discovered, imaging for metastasis is utilized including CT scanning, endoscopic US, and intraoperative US. The American Joint Commission on Cancer (AJCC) TNM criteria and Duke's criteria are the most commonly utilized staging tools. For TNM staging, Stages I through IB do not involve lymph nodes with Grade III with lymph node involvement but no distant sites involved, and Stage IV with distant sites involved. Surgical resection is the primary approach to CRC with chemotherapy for metastatic involvement. When there is metastatic involvement, chemotherapy may extend survival from 6 to 24 months. Other medications used include Avastin, a monoclonal antibody with the intent of inhibiting angiogenesis.

Prevention includes dietary changes to include increasing fruits and vegetables, decreasing red meat intake, reducing heavy alcohol intake, and possible increased intake of calcium, vitamin D, and folate. Increasing

physical activity and smoking cessation are important lifestyle factors that many patients need to incorporate in their approach to cancer prevention.

## CELIAC DISEASE

### Classic Presentation

A young patient complains of chronic abdominal cramping, explosive flatulence, weight loss, and diarrhea.

### Cause

Celiac disease (also called sprue and celiac sprue) is a malabsorption syndrome caused by sensitivity to gluten-containing foods such as wheat, barley, rye, and some oat-based products. Reaction is specifically to the gliadin portion of gluten and may be related genetically to HLA-DQ2 and/or DQ8. The estimated number of U.S. individuals with celiac disease is approximately 3 million. Signs and symptoms are related to malabsorption and its consequences of diarrhea and vitamin deficiencies.

### Exam

Historically, in addition to abdominal cramping and diarrhea, consider celiac disease in pregnant females with anemia and in pediatric patients who have delayed growth or stature. On physical exam there may be abdominal distention, aphthous stomatitis and *dermatitis herpetiformis* manifesting as symmetrical papules and blisters of the elbows, knees, buttocks, or back.

Due to malabsorption, general lab testing would include a search for iron-deficiency anemia, elevated liver function tests, d-Xylose test for malabsorption, and decreases in protein, calcium, and vitamins A, D, C and folic acid (sometimes B12). There is also often a decrease in cholesterol and neutral fats with a >7% fat malabsorption wst.

For the evaluation/detection of celiac disease, the following tests have been utilized:

- IgA class of Anti-tissue Transglutaminase Antibody (anti-tTG): Anti-tTG, IgA is the most *sensitive* and *specific* blood test for celiac disease; however, it may be test negative in children under 3 years old who have celiac disease. For this group, Deamidated Gliadin Peptide (DGP) Antibodies, IgA, called the Anti-DGP test may prove useful.
- Anti-Gliadin Antibodies (AGA), IgG and IgA classes
- Quantitative Immunoglobulin A (IgA)
- Antiendomysial Antibodies (IgA)

Other tests that are either new or used less often for celiac disease include:

- Anti-Endomysial Antibodies (EMA), IgA class
- Anti-Reticulin Antibodies (ARA), IgA class
- Anti-Actin (F-actin), IgA class

## Management

The key factor is avoidance primarily of wheat, barley, rye, and some oat products and substitution with rice, corn, and/or soybean flour. Many alternatives are now available at some stores and many restaurants for those with gluten intolerance. Patients will generally feel better with a week of a gluten-free diet, with most symptoms resolving over a two-month period. Refractory celiac disease is often treated as a typical autoimmune inflammatory disease with the utilization of prednisone or immunosuppressants.

# CHAPTER 32

## Constipation

### Context

There is a wide range of reported prevalence of constipation, from 2% to 27% in Western countries.<sup>1</sup> Although considered a benign problem that generally self-resolves, it is interesting to note that constipation accounts for at least 2.5 million office visits to physicians and 92,000 hospitalizations per year in the United States.<sup>2</sup>

Although many patients complain of constipation, it is important to remember that constipation is a relative term. Most physicians would classify a normal bowel movement as one bowel movement per day without straining; others may find passage every three to five days acceptable. The answer lies in the patient's history. If the patient has always had bowel movements every three days, this may likely be his or her normal pattern. A clear definition of constipation is difficult given the wide variation of "normal" patterns. Several factors may be included in the definition of constipation, including:

- Hard stools
- Infrequent stools (fewer than three per week)
- Need for excessive straining
- A sense of incomplete bowel evacuation
- Excessive time defecating

More formal criteria are presented with the Rome II criteria<sup>3</sup> which, in essence, includes the above for at least 12 weeks in the preceding year for at least 25% of bowel movements. In one study that used the criteria of no more than two bowel movements per week and/or straining on more than one in four bowel movements, only 62% of self-reporters met the criteria, although 47% of all patients reported constipation.<sup>4</sup> Self-reporters took twice as many laxatives as those who did not report constipation. The self-reported rate of constipation is as high as 60% among the elderly. Thirty percent of healthy elderly persons report using laxatives, although the majority of these patients have never gone more than three days without a bowel movement (\$400 million per year in cost for laxatives).<sup>5</sup>

Most causes of constipation are benign and are the result of external or internal influences that are easily identifiable. In the context of chiropractic practice, it is a common observation that patients with low back pain are also constipated. The assumption is that this is due to either increased pain with bearing down or simply neural inhibition without straining. In either case, it is important for the chiropractor to rule out more serious causes. When not present, assist the patient with what may be an aggravating factor to his or her low back pain.

## General Strategy

### History

Careful questioning of the patient during the history taking can lead to appropriate management (**Table 32-1**).

- Determine the patient's definition of constipation.

- Determine the degree of constipation and whether it is acute or chronic.
- Determine any additional signs or symptoms that may indicate a systemic disorder such as hypothyroidism or diabetes.
- Determine the patient's current medication history, including over-the-counter (OTC) drugs.
- Determine the amount of dietary fiber and fluid intake and also iron supplementation.
- Determine whether laxatives are being used if so, and how often.

**Table 32-1** History Questions for Constipation

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
How often do you have a bowel movement?	Determine what is normal for the individual.	How long have you had constipation? Did it occur over the last few weeks, months, or years?	Determine in an older patient whether there is a gradual decrease in the frequency of bowel movements as opposed to a recent change.
Is it painful to defecate?	Local pathology is causing pain; pain is increased due to muscle contraction or increase in intrathecal pressure.	Do you have hemorrhoids or other local problems around the anorectal area? Does bearing down cause local back pain? Does bearing down cause pain radiating into the legs?	Pain inhibits defecation urge or there is conscious inhibition due to fear of pain. Muscle spasm or other local irritation. Consider intrathecal pressure increase indicating disc lesion or tumor.
Do you take medications?	Direct action of medication or medication indicates underlying medical condition associated with decreased bowel function.	Have you been diagnosed with diabetes, irritable bowel syndrome, depression, or hypothyroidism (based on medication prescribed)? Did you have constipation before or after starting the medication? Are you taking medications with codeine in them (e.g. Percocet or Oxycontin) or iron supplementation?	Underlying disease may be cause of constipation. Many medications may cause constipation as a side effect. Many seniors take laxatives out of habit, not necessarily because they need them; also some laxatives can cause constipation.
What are your eating and drinking habits?	Low-fiber diet.	What do you eat on an average day?	Get a sense of dietary fiber intake.
(For children) Do you go to the bathroom when you feel the urge?	Too busy, does not like bathroom facilities, defecation hurts.	Does it hurt to go to the bathroom?	Either too little fiber or hydration causes hard stools; or an anal fissure causes local pain.

- Note whether the patient is pregnant.
- Determine the patient's status with regard to abdominal muscle tone; immobilized, incapacitated, or

sedentary individuals may have less propulsive ability.

- Determine whether there is any soiling of undergarments (may be more suggestive of constipation than fecal incontinence).

## Evaluation

- On physical examination determine whether any anorectal disease is present and the status of the rectum (empty or impacted); 25% of colorectal cancer may be found on rectal examination.
- Testing for occult blood is often warranted; referral for sigmoidoscopy is warranted in chronic constipation.

## Management

- If the bowel is impacted, use digital disimpaction or an enema, or refer for disimpaction.
- Educate the patient on proper bowel habits, including proper fluid and dietary fiber intake, mild exercise, avoidance of laxatives, strengthening pelvic/abdominal musculature, allowing enough time for bowel movement, and avoiding inhibition of gastrocolic reflex.

## Relevant Anatomy and Physiology

For the regular, unstrained passage of stool, it is necessary to have the proper balance of fluid, dietary fiber, and normal motility and transit time. The colonic mucosa usually absorbs 95% of intestinal sodium and water.<sup>6</sup> Interestingly,

this function is usually normal in constipated patients. Increased desiccation, however, may occur as a result of increased mucosal contact due to slowed colonic transport time.<sup>7</sup> It would seem logical that this would be due to a decrease in colonic motor activity; however, investigators have actually found contraction of the pelvic colon to be increased.<sup>8</sup> The colonic myoelectric activity of patients with idiopathic constipation is usually normal, but this activity seems to be abnormally responsive to several outside stimuli, such as emotional stimulation, eating a meal, and hormonal stimulation. The intestinal smooth muscle cells have an inherent property that results in cyclic depolarization and repolarization. This occurs at what is referred to as a slow wave rate. There are two observed rates of six and three cycles per minute. Although normal individuals have an almost exclusive six-cycle-per-minute frequency in the colon and rectum, patients with irritable bowel syndrome have almost half the contractions occurring at three cycles per minute.<sup>9</sup>

Diseases that affect the central nervous system (CNS), spinal cord, and autonomic nervous system may have an effect on intestinal motility. A common example is the ileus that develops after abdominal surgery. This is due to effects of anesthesia (CNS depression) and manipulation of the organs. Diabetes may also affect bowel movements through dysfunction of the autonomic nervous system.

Most cases of constipation can be assigned to two general problems: ineffective filling and ineffective emptying. Ineffective filling is most often due to inadequate amounts of fluid and/or dietary fiber. Other common causes are CNS depression, which is usually the effect of medications, or clinical depression.

Another classification of cause is to divide constipation into four broad categories in relationship to colon transport time and defecation:<sup>10</sup>

- 1.** Normal transit through the colon (accounts for 50%): Symptoms usually respond to increased dietary fiber or the addition of an osmotic-type laxative.
- 2.** Slow transit through the colon (accounts for 13%): Most common in young women beginning around puberty and associated with bloating, abdominal pain, and an infrequent urge to defecate. Colonic inertia is a related disorder that is characterized by slow colonic transit. In this condition there is no response of increased motor activity with either a meal or medication stimulation.
- 3.** Disorders of defecatory or rectal evacuation (accounts for 25%): Most commonly due to pelvic-floor dysfunction or anal sphincter dysfunction. Structural problems include anal fissures or hemorrhoids and, less commonly, rectal intussusception, rectocele, and excessive perianal descent. If defecation dysfunction is suspected, defecography may be ordered. Reduced descent of the perineum (less than 1 cm) and a reduced change in the anorectal angle (usually less than 15°) are found on simulated defecation.
- 4.** Combination of defecatory disorder and slow transit (accounts for 3%).

For patients with slow transit problems, studies have shown that there is often a problem of several regulatory mechanisms:[11](#), [12](#), [13](#)

- Fewer number of myenteric plexus neurons producing the neurotransmitter substance P that acts as a stimulator for transit.
- Abnormalities in vasoactive intestinal peptide and nitric oxide that are inhibitory transmitters.
- A reduction in the number of interstitial cells of Cajal that help regulate GI motility.

An extreme example of slow transit is Hirschsprung's disease whereby ganglion cells in the distal bowel are absent. This is due to a failure of neural-crest cells to migrate caudally during embryonic development.

The main stimulus to defecate is distention of the rectum by the colon contents. This initiates the rectoanal inhibitory reflex and internal sphincter relaxation.<sup>14</sup> The resultant urge to defecate is voluntarily controlled. Through contraction of the external sphincter and pelvic musculature, defecation can be prevented. To defecate, a combination of intra-abdominal pressure through bearing down and external sphincter and pelvic floor muscle relaxation is voluntarily employed. Ineffective emptying is usually due to suppression of the defecation urge. This suppression may be due to painful anorectal disorders or circumstantial detractors. For example, children who are playing rarely want to interrupt their play to go to the bathroom. Additionally, they may find a restroom away from home unpleasant, which causes them to suppress the urge to defecate. In adults, commuting at the time of the defecation urge, being in a meeting, exercising, and a host of other interferences may be a reason to suppress the urge. Unfortunately, in all cases, this suppression becomes a habit, which then eventually decreases the sense of urge.

## Evaluation

## History

For most cases of constipation a simple line of questioning will quickly uncover the cause. Determining a patient's dietary fiber, fluid, and medication intake often will reveal the problem. Most patients do not understand that coffee, tea, and sodas do not have the same hydrating effect as

water and often result in a diuretic effect. Dietary fiber is harder to determine; however, the amounts of fruits, vegetables, and fiber substitutes will give a general indication of inadequacy. Medications may cause or aggravate constipation through several mechanisms. Many drugs, such as anticholinergics, anticonvulsants, antidepressants, antiparkinsonians, and tranquilizers, act as central or peripheral neural depressants. Nonsteroid anti-inflammatory drugs (NSAIDs) may inhibit motility through prostaglandin blockade. Diuretics decrease the water content of stool. Calcium channel blockers and angiotensin-converting enzyme (ACE) inhibitors decrease smooth muscle contraction. Several laxative types (especially anthraquinones) may cause megacolon and decreased response to distention; sometimes with damage to the intramural nerve plexuses (**Table 32-2**).

The next avenue of investigation is the degree to which the urge to defecate is suppressed. Children, in particular, will avoid defecation, although adults may be found to have similar habits. Usually this falls into three categories: (1) too busy or having too much fun to stop to go to the bathroom, (2) unpleasant bathroom environment (while traveling or at school), and (3) painful defecation. Overriding the defecation reflex will eventually lead to a habit that is difficult to reestablish. If defecation is painful, questions regarding the aggressive use of rough toilet paper can often expose the cause of anal fissures.

## Examination

- Determine whether there is any anorectal disease that might suppress the urge to defecate.
- Determine whether there is an empty rectum (ineffective filling disorders) or a full rectum and whether this is impacted.

- Laboratory testing is usually not necessary unless there is a suspicion of either an ionic imbalance or a specific underlying disorder such as diabetes or hypothyroidism.

**Table 32-2 Laxatives**

<b>Type</b>	<b>Important Considerations</b>
<b>Bulk—psyllium, husk, methylcellulose</b>	Natural and semisynthetic polysaccharides and cellulose derivatives. Form emollients and gels when mixed with intestinal water. May produce colonic gas (especially bran), causing distention and pain. Risk of impaction if fluid intake is not increased.
<b>Lubricants—mineral oils</b>	Nonabsorbable hydrocarbons lubricate the colon, allowing easier passage. These have limited use because chronic use may decrease absorption of fat-soluble vitamins or cause perianal inflammation.
<b>Osmotic—two types: saline cathartics (Milk of Magnesia) and synthetic disaccharides (lactulose)</b>	Salts or nonabsorbable sugars act to draw fluid into the intestines. Lactulose is safe, but sorbitol is less expensive. Both are considered safe for the elderly. The saline cathartics also stimulate the release of cholecystikinin (CCK). Watch electrolyte levels, especially calcium and magnesium. Magnesium and phosphate laxatives should be avoided with renal insufficiency.

<b>Stimulants and surface active—castor oil, anthraquinones (senna; Senokot), diphenylmethane derivatives, docusate</b>	Decrease colonic absorption and increase secretion. Stimulate adenylate cyclase and synthesis of prostaglandin E, inhibit sodium-potassium absorption, and alter mucosal permeability. Castor oil may cause cramping. Docusate is a stool softener and is usually only effective when patients must avoid straining (postsurgically). Docusate side effects are largely due to an increased absorption of toxic drugs (gastritis with aspirin ingestion).
<b>Enemas—glycerin, bisacodyl, tap water, saline, or soapsuds (castile soap)</b>	Must be watchful of electrolyte losses, mucosal damage with repeated use of soaps, and hyperphosphatemia with abuse of Fleet enemas.

- If radiographs are taken for low back pain, determine whether there is evidence of gas and fecal stasis.

Although generally it has been assumed that constipation leads to hemorrhoids, which then prolong the constipation, a recent study suggests that constipation is not a risk factor for hemorrhoids, but diarrhea may be.<sup>15</sup>

Special testing may be ordered for those patients unresponsive to increased dietary fiber, hydration, or laxatives and may include the following:

- Patients over age 50 years with chronic constipation should undergo colonoscopy or sigmoidoscopy with barium enema to screen for colorectal cancer.
- Colonic transit testing: Colonic transit is usually less than 72 hours. An approach to measuring transit time is through abdominal radiography 120 hours after the patient ingests radiopaque markers. Retention of more than 20% of the markers indicates prolonged transit.

Suggestion of a defecatory disorder is retention of the markers in the lower-left colon and rectum.

- Anorectal manometry: Detects pressure of the anal sphincter at rest and maximal voluntary contraction, detection of absence of relaxation of the internal sphincter, rectal sensation, and the ability of the sphincters to relax during straining. Generally, patients with defecatory disorders have an inappropriate contraction of the anal sphincter both at rest and when bearing down. A high anal pressure suggests anal fissure, anismus. Rectal hyposensitivity is indicated by an increase in the volume of balloon distention needed to induce a sense of urgency, which suggests a neurologic source.
- Balloon expulsion: A latex balloon is inserted into the rectum, with 50 ml of water or air placed into the balloon. The patient is then asked to expel the balloon into the toilet. Either inability to expel the balloon or inability to do so within two minutes suggests a defecatory disorder.
- Defecography: A radiographic procedure performed using a special commode after instilling a thickened barium into the rectum. This study is able to detect the anorectal angle and perineal descent, the degree of emptying, and certain structural abnormalities such as a rectocele, internal mucosal prolapse, or intussusception.

## Management

- Bowel habit education for all patients.
- Diet recommendations for fiber and fluid intake.
- Referral if significant anorectal pathology is evident.
- Referral if indicators of colon cancer are present.

- Patients with defecatory disorders unresponsive to dietary fiber increases should undergo retraining of defecation with biofeedback.
- Patients with impaction should have manual disimpaction performed.
- Medications may be prescribed with a variety of mechanisms. Generally, osmotic laxatives are used. They take several days to a week to work. Stimulant laxatives work faster but may cause abdominal cramping. Newer approaches are Tegaserod, which is a colonic prokinetic agent (causes stimulation of 5-HT<sub>4</sub> receptors, which increases peristalsis) used for women with irritable bowel syndrome who predominantly have constipation.
- Surgery is reserved for refractory cases and may include colonic resection or, more rarely, anal surgery.

The approach to management is usually conservative. When it appears that there is no evidence of a secondary cause such as medication, laxative abuse, or anorectal disease, patient education regarding proper bowel habits is usually effective. Fluid intake should be at least 1.5 L/d. It is important to define “fluid” as water and not coffee, tea, and sodas, which act more as diuretics and will usually worsen the problem. At least 30 g of fiber should be included in the daily diet. This is preferably provided by bran and vegetables. If the patient admits to a sedentary lifestyle or has been bedridden, activity and exercise (when appropriate) should be encouraged. With inactivity or illness, it is also likely that the tone of abdominal and pelvic musculature is weak. Abdominal exercises need not be strenuous. With the patient lying supine, ask her or him to bend the knees and place the feet flat on the floor or table. Then the patient is asked to lightly press the palms of the hands against his or her thighs. This is enough to give a starting contraction of the abdominals. Sit-ups are the next

step, but they are not necessary if the patient is elderly, overweight, or frail.

It is imperative that patient education include a discussion of how important timing and relaxation are to proper bowel movements. The patient should understand the importance of comfort, privacy, sufficient time to defecate, and the need to “heed the call” of the defecation urge. Setting aside a regular time for bowel movements is helpful. Elevating the legs while on the toilet may also assist.<sup>16</sup>

When medication appears to be the culprit, referral back to the prescribing physician with a note regarding the suspected connection to the patient’s constipation complaint should be made.

If fecal impaction is evident, an attempt at digital removal or recommendation for an enema is usually sufficient. If not, referral to a medical doctor for use of medications or surgery is warranted. When there is evidence of painful but mild anorectal disease (hemorrhoids or anal fissures), correction of dietary habits and bowel habits is usually sufficient; however, referral for medical management is recommended when the patient is noncompliant or the changes are ineffective.

Laxative abuse is certainly an example of too much of a good thing. Although laxative use occasionally may be needed, it is not a recommended method of bowel control. Apparently half of patients who use laxatives chronically would establish a normal bowel habit if the laxative use was discontinued.<sup>17</sup> The effects of laxatives generally can be divided into several categories. **Tables 32-2** and **32-3** list these categories and give examples of various agents and their effects. Bulk-forming agents act similarly to fiber. When ingested, these agents form emollients and gels when they mix with intestinal water, expanding their size. This distention increases peristaltic activity. One side effect with these agents is that they may contribute to gas production,

causing distention and discomfort. Lubricants (i.e., mineral oils) are of limited value. Chronic use may impair fat-soluble vitamin absorption and lead also to a chronic perianal inflammatory response. Salts are used for their osmotic effects of drawing in fluid and increasing reflex colon contractions. They are usually the sulfate or phosphate salts of sodium and magnesium ions (saline cathartics). A similar action occurs with lactulose; however, lactulose has no effect on the small bowel. Another group of agents is referred to as surface-active agents. They act to decrease colonic absorption and increase secretion. Stimulation of adenylate cyclase and prostaglandin E, inhibition of sodium absorption, and alteration in mucosal permeability are all possible mechanisms of these agents. Castor oil is an example of a surface-acting agent.

**Table 32-3 Constipation**

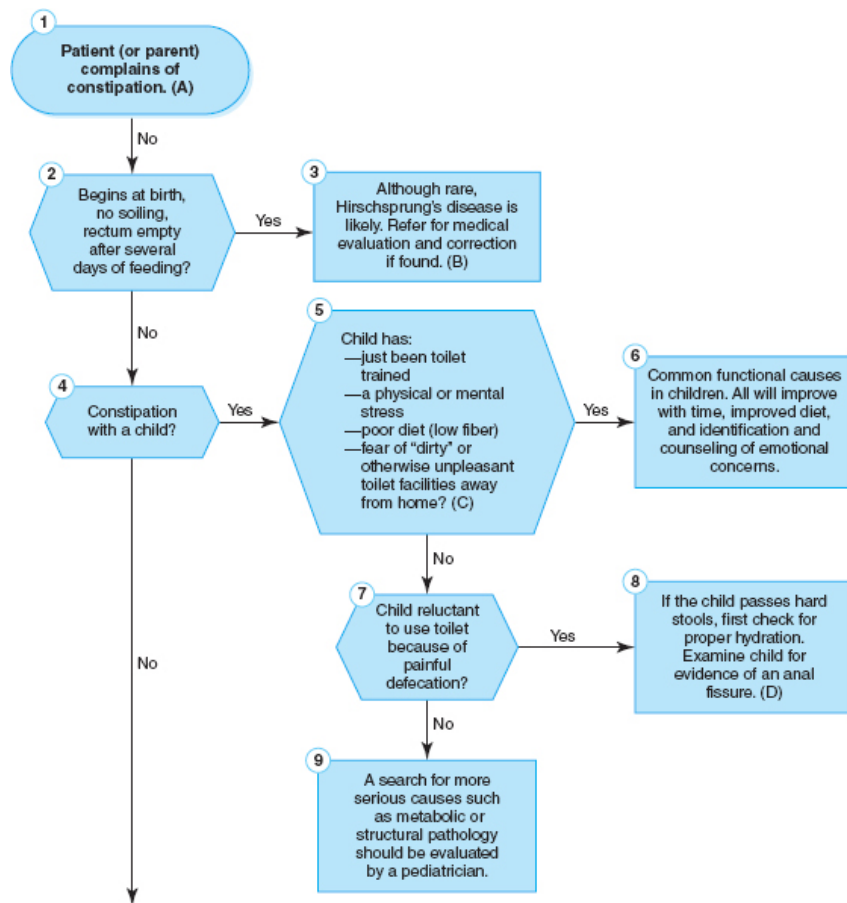

Drug Class	Examples	General Mechanism	Interactions/Side Effects
Bisacodyl	Apo-Bisacodyl Bisacolax Deficol Dulcolax Fleet Laxit Theralax	Used in the management of constipation. It increases intestinal fluid volume through increasing epithelial permeability.	May cause mild cramping or nausea. May cause mild electrolyte disturbances.
Docusate	PMS Docusate Surfak Dialose Colace Regulax Therevac	Used as a stool softener. Through detergent action, lowers surface tension allowing water and fats to penetrate stool.	May cause mild abdominal cramps, diarrhea, bitter taste, and throat irritation.
Psyllium	Hydrocil Instant Karasil Konsyl Metamucil Modane bulk Perdiem Plain Reguloid Serutan Silbin Syllact V-Lax	A bulk-producing laxative made from colloid of psyllium seed. Promotes peristalsis. Used for constipation.	May cause eosinophilia, nausea, abdominal cramps, and GI tract strictures (using dry form).
Senna (sennosides)	Black Draught Gentlax Senexon Senokot Senolax	Dried leaf preparation that is converted to glycone, which causes an increase in peristalsis. Used for acute constipation.	May cause abdominal cramping, flatulence, diarrhea, weight loss, and associated loss of electrolytes.

Rectal enemas or suppositories are usually in the form of glycerin, bisacodyl, water (tap and saline), and soaps (usually castile). These should be reserved for the patient with impaction. Chronic use may lead to colitis.

Pregnancy often results in a complaint of constipation. Although this may be multifactorial, an increase in progesterone has an effect of decreased gut motility. Aggravating this may be the increased weight, which may result in hemorrhoids. Finally, iron supplementation, which often is used in pregnancy, will have a constipating effect.

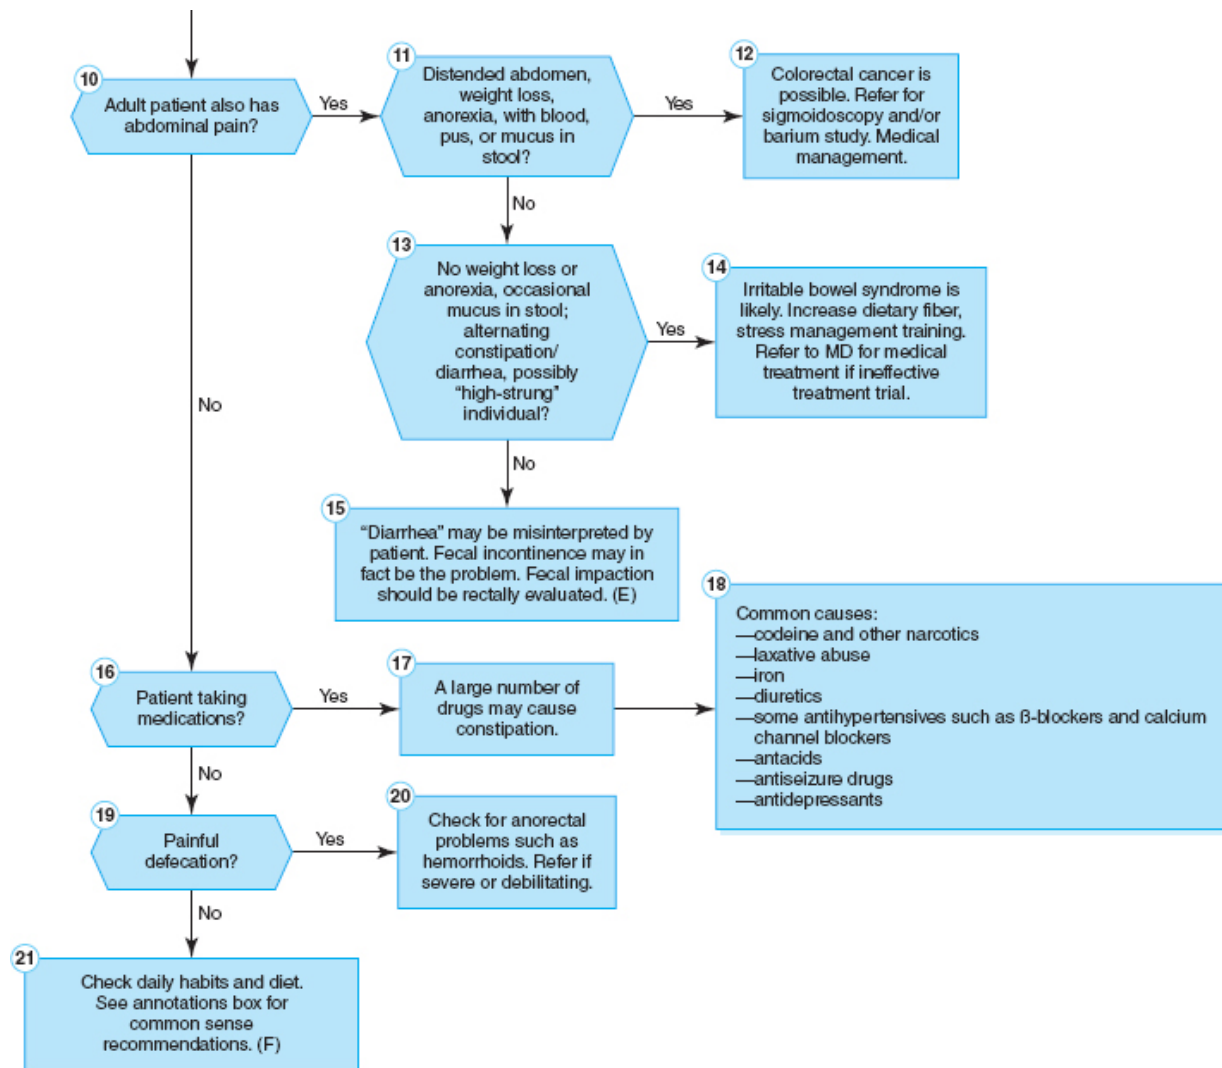

# Algorithm

An algorithm for evaluation and management of constipation is presented in **Figure 32-1**.

#### Annotations

- A. Clarify what the patient means by constipation. Check on exam for fecal impaction, especially in the elderly. If found, digital removal is initial approach; if unsuccessful, refer to MD. Obstipation (passage of hard stools at 3- to 5-day intervals on a chronic basis) and fecal impaction are common in the elderly. Depression and hypothyroidism should also be considered.
- B. A lifelong history of constipation also warrants an investigation for Hirschsprung's disease.
- C. Fecal incontinence in a child usually is due to the child's attempt to avoid defecation urge due to factors listed in the box.
- D. Anal fissures in children are not unusual. They are usually due to rough or aggressive use of toilet paper.
- E. Fecal incontinence may be confused with diarrhea. Distinguishing factors are soiled underwear, small amounts of soiling, patient unaware of leakage.
- F. Common sense recommendations include increasing fluid intake and a healthful diet including foods with high fiber content. Reduction of fats.

# CHAPTER 33

## Diarrhea

### Context

Diarrhea is second only to respiratory infections as a health complaint in the United States.<sup>1</sup> However, the vast majority of patients have a self-limited, familiar problem that does not warrant enough concern to seek the advice of a doctor. Self-treatment with over-the-counter (OTC) medications is used effectively by many patients with acute diarrhea. Diarrhea is more a nuisance, and only when it becomes disruptive or life-threatening are answers sought by the patient or parent. Diarrhea is a concern when it is chronic and/or when it occurs in a frail individual, infants and immunocompromised patients in particular.

Diarrhea is considered acute when it lasts less than two weeks; it is considered chronic when it lasts more than two weeks. Common culprits with acute diarrhea are infections, lactose (and other deficiencies), and medications. Less commonly, but more important, diarrhea may represent part of a syndrome with gastrointestinal (GI) disease such as inflammatory bowel disease, dysentery, irritable bowel syndrome, or cancer. One helpful distinguishing factor is whether blood is present in the stool.

### General Strategy

# History

Determine the following according to **Exhibit 33-1**:

- Determine whether diarrhea is acute (<2 weeks), chronic (>2 weeks), or recurrent.
- Determine whether there are associated signs of infection (i.e., fever, abdominal pain, vomiting) and whether any family members or friends have similar symptoms (viral gastroenteritis likely). (See **Table 33-1**.)
- Determine the volume and consistency of the stool (large-volume, watery stool suggests small bowel problem; small-volume stool indicates colon problem).
- Determine whether the diarrhea is bloody (consider inflammatory bowel disease, dysentery, and cancer).
- Determine any recent ingestion of medications; in particular, antibiotics or magnesium-containing antacids (a side effect with some antibiotics is overgrowth of *Clostridium difficile*).
- Determine whether there is a history of lactose intolerance (more common in patients with Mediterranean and African ancestry, in the elderly, and after acute gastroenteritis transiently).
- Determine whether diarrhea persists if the patient fasts (if present after fasting, secretory diarrhea is likely).
- Determine whether the patient has traveled to a foreign country (*Escherichia coli* or parasitic infection).

## Evaluation

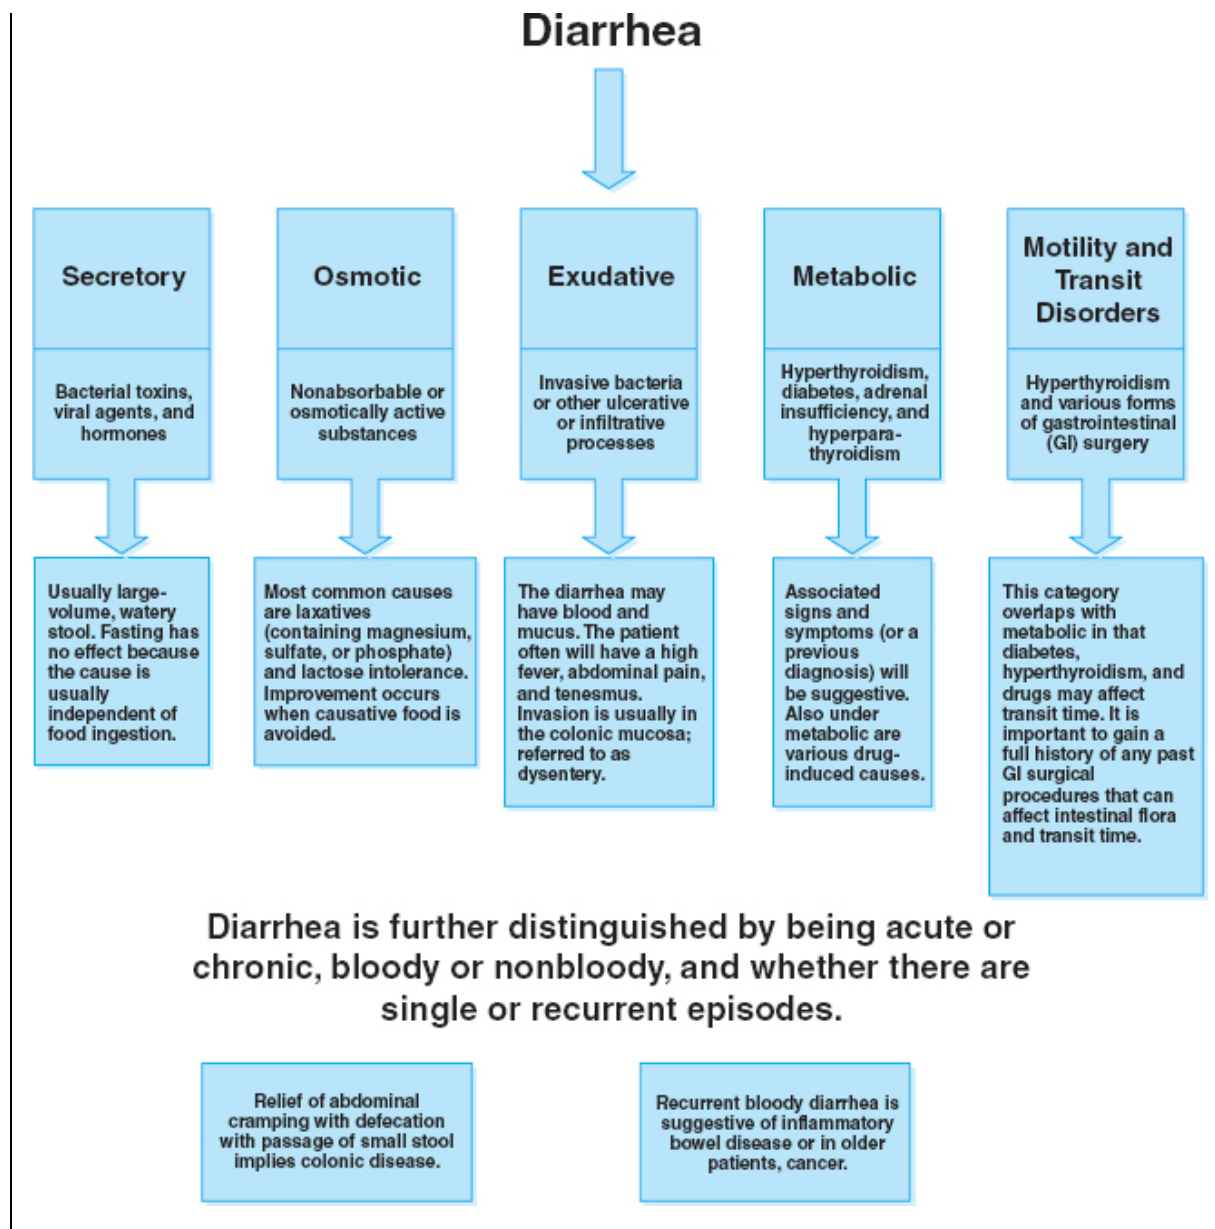

If chronic, check patient for electrolyte loss with lab testing and have stool evaluated for blood, mucus, fecal leukocytes

(enteroinvasive bacteria), undigested food (pancreatic or small-bowel disease), and ova or cysts (parasites).

## Management

- If diarrhea is in an infant, recommend electrolyte substitution drink, avoidance of milk, and cold unfiltered juices. If not effective after two days, refer to pediatrician.

### **Exhibit 33-1 Diarrhea**

- For adults, recommend Imodium or other OTC medication coupled with elimination of milk products and cold, unfiltered juices to determine effectiveness. If ineffective, refer to medical doctor for further work-up such as with proctosigmoidoscopy.

## Relevant Anatomy and Physiology

Motility of the GI tract is dependent on an intact and functioning autonomic nervous system, appropriate digestive tract flora, an appropriate transit time, and an appropriate diet. Additionally, the osmotic balance is important in maintaining a proper fluid ratio in the stool. Two general causes of diarrhea are osmotic imbalance and secretory stimulus. Osmotic diarrhea occurs when material is nonabsorbable, acting as a fluid magnet. Examples include lactose, sorbitol, mannitol, and magnesium-containing antacids. Secretory diarrhea is due to irritation of the intestinal wall by bacterial toxins and viruses. Exudative diarrhea indicates mucosal ulceration, exudation, and bleeding. A common cause is direct bacterial invasion by organisms such as shigella and salmonella. Parasites, most commonly *Entamoeba histolytica*, also should be considered.

Table 33-1 Some Causes of Gastroenteritis	
Onset and Type	Summary Information
Minutes to 2 hours	
Monosodium glutamate	Sometimes referred to as Chinese restaurant syndrome, there is some debate as to whether this condition exists. If

	it does, it may cause a burning sensation in the abdomen, head, neck, or extremities, and may cause chest pain.
Fish toxins	<p>There are a number of sources for fish toxins, including scombrototoxin, shellfish toxin, puffer fish toxin, and ciguatoxin (for which symptoms may take up to 24 hours to appear). Source of toxin and some symptoms for each follow:</p> <ul style="list-style-type: none"> <li>• Scombrototoxin: tuna, mahi-mahi, mackerel, skipjack, or bonito; symptoms include those of a histamine reaction with flushing headache and dizziness; may require hospitalization</li> <li>• Shellfish toxin: found in mussels, clams, oysters, and scallops; neurologic symptoms such as paresthesias, dizziness, and occasionally paralysis</li> <li>• Puffer fish toxin: puffer fish; symptoms, including paresthesias, are common</li> <li>• Ciguatoxin: barracuda, red snapper, grouper, and amberjack; symptoms include paresthesias, painful teeth, visual disturbances, arthralgias, itching, and a metallic taste in the mouth</li> </ul>
Heavy metals	Usually due to a carbonated or acidic beverage, causing a metallic taste and vomiting without fever. If possible, drink should be tested for specific metal.
Mushrooms	Found with mushrooms that have not been processed commercially. May develop into encephalopathy with an altered mental state and visual disturbances. Also, hepatitis may result. Mushrooms should be tested for specific toxin such as muscarine or psilocybin.
<b>2 hours ≥ 8 hours</b>	
<i>Staphylococcus aureus</i>	Caused by ham, poultry, cream-filled pastries, and mixed salads; the predominant sign is vomiting without fever. Usually lasts less than 24 hours. Organism may be isolated from food.
<i>Bacillus cereus</i>	There is an emetic and a diarrhea form. Both are caused by fried rice or macaroni-and-cheese mixes. The enteric form is characterized by vomiting with no fever and lasts less than 24 hours, whereas the diarrhea form is characterized more by diarrhea and abdominal cramps with no fever and lasting less than 2 days. Organism may be isolated from food.
<i>Clostridium perfringens</i>	Caused by meat or poultry, it is characterized by vomiting with no fever and lasts less than 24 hours. Organisms may

	be isolated from food and/or stool.
<b>12 hours to days</b>	
Enterotoxigenic	
<i>Escherichia coli</i>	Rarely reported, thereby difficult to identify vehicle. Characterized by abdominal cramps and watery diarrhea that may last up to one week. Organism can be isolated in stool. Also test for enterotoxin production.
<i>Vibrio cholerae</i>	Rare in the U.S. Characterized by abdominal cramps and watery diarrhea that may last up to one week. Organisms may be isolated from food and/or stool.
Invasive <i>E. coli</i>	No clear vehicle for organism. Characterized by a prolonged course of fever, diarrhea, and/or dysentery. Organism may be isolated from stool. Test also for enteroinvasiveness (e.g., increase in fecal leukocytes).
<i>Shigella</i>	Found with fish or mixed salads. Characterized by a prolonged course of fever, diarrhea, and/or dysentery. Culture organisms in stool or food.
<i>Salmonella</i>	Found after ingestion of meat, poultry, dairy products, eggs, and various salads such as macaroni or potato. Characterized by a prolonged course of fever, diarrhea, and/or dysentery. Culture organisms in stool or food.
<i>Vibrio parahaemolyticus</i>	Found after ingestion of seafood. Characterized by a prolonged course of fever, diarrhea, and/or dysentery. Culture organisms in stool or food.
<i>Campylobacter</i>	Found after ingestion of poultry, meat, or unpasteurized milk. Characterized by a prolonged course of fever, diarrhea, and/or dysentery. Culture organisms in stool or food.
<i>Clostridium botulinum</i>	Serious problem due to cranial nerve palsies, paralysis, and ventilatory failure. Diarrhea also found. Found after ingesting contaminated house-canned foods. Botulinum toxin may be found in food, stool, or serum. Hospitalization is required.

Insufficient time for absorption of nutrients may be caused by intestinal bypass operation, gastric surgery, hyperthyroidism, and vagotomy. These may speed up transit time. Generally, diarrhea that is due to involvement of the small intestine or the proximal colon will be more profuse, watery, and usually nonbloody. With large amounts of fluid loss, electrolytes are also lost, causing particular concern in the young and the elderly. Because of interference in digestion and absorption, the stool may contain undigested food or be greasy and foul smelling. When the pathology is in the distal colon or rectum the defecation reflex is activated, often releasing frequent, small volumes of stool that often are accompanied by flatulence. The stool is not usually foul smelling, but it may contain mucus or blood.

## Evaluation

## History

Usually a well-elicited history will quickly pinpoint the general cause of acute diarrhea (**Table 33-2**). More specific delineation requires laboratory evaluation of the stool; this is rarely indicated, however, unless the diarrhea is chronic or recurrent. From a historical perspective, determination of an offending substance or organism is gained by the distinction of the amount of stool, the presence of blood or mucus, and a detailed ingestion inventory.

Combinations of findings suggest a cause. For example, if the patient has large amounts of diarrhea (high fluid content) that is unrelieved by fasting, it is likely that the patient has a secretory diarrhea most commonly caused by bacterial toxins, viruses, laxative abuse, and hormones. Toxin-mediated diarrhea is usually due to small-bowel irritation. Bacterial and viral etiologies will usually have

accompanying symptoms such as fever, abdominal pain, vomiting, and other symptoms. Hormonal causes are often linked to cancers. This type is rare in the chiropractic office. Laxative abuse may not be elicited on the history, but laboratory testing may uncover a surreptitious cause.

Infectious diarrhea is primarily due to colonic mucosal invasion referred to as dysentery (tenesmus, fever, abdominal pain, and bloody stools). This type of diarrhea is also characterized by early-morning rushes of diarrhea. The stool is often soft and contains mucus.

With acute diarrhea it is important to determine whether other individuals have similar symptoms (i.e., diarrhea, vomiting, or abdominal pain). Food poisoning is likely when the same food was eaten. When the diarrhea is not associated with same-food eating, but occurs in the same family or daycare facility, a viral cause is likely. Traveler's diarrhea is common, with reports of incidents affecting from 10% to 50% of those traveling abroad depending upon location, particularly in underdeveloped countries. Approximately 70% of cases are due to enterotoxigenic *Escherichia coli* (*E. coli*). Other causes include *Shigella*, *Salmonella*, and *Giardia*. Prophylaxis is often attempted. The primary recommendations are large doses of Pepto-Bismol (2 oz. 4 times a day (qid) for 2 to 3 weeks). Antibiotic prophylaxis occasionally may help, such as use of tetracycline (doxycycline); however, resistance has developed and has made this a less effective approach. Also, side effects include photosensitivity and candida vaginitis, among others.

It is always important to obtain a complete drug history, including prescription and nonprescription drugs. Many drugs can cause diarrhea. The primary drugs are magnesium-containing antacids, antibiotics,  $\beta$ -blockers, digitalis, methyldopa, alcohol, phenothiazine, and high doses of pain medications (unless a sedative). Laxative abuse should be suspected when other historical clues are

negative or in the unlikely event the patient volunteers the information. Some patients may be unaware of the abuse and feel that it is necessary for “normal” bowel movements (see [Chapter 32](#)). Antibiotics can also allow overgrowth of *C. difficile*, which then produces irritating toxins. The timing of drug ingestion is often helpful, for example, if the diarrhea began after the initiation of a drug regimen. With antibiotics, however, there is often a delayed response.

**Table 33-2** History Questions for Diarrhea

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Is the diarrhea of recent onset?	Viral gastroenteritis, foreign travel (parasites), drug reaction or side effect.	<p>Did others in your family or did your friends have similar symptoms?</p> <p>Have you just returned from a trip to another country or back from a camping trip?</p> <p>Do you take magnesium containing antacids, laxatives, antibiotics, <math>\beta</math>-blockers, digitalis, or high doses of pain medication?</p>	<p>Viral gastroenteritis is likely.</p> <p>Parasitic infection, or “traveler’s diarrhea.”</p> <p>All may cause diarrhea.</p>
Do you have recurrent bouts of diarrhea?	Irritable bowel disease, inflammatory bowel disease, lactose intolerance.	<p>Do you have alternating bouts of constipation and diarrhea, especially in the morning?</p> <p>Do you have recurrent bouts of bloody diarrhea often associated with stress?</p> <p>Have you noticed an association with dairy products and have associated complaints of bloating and gas?</p> <p>Ask CAGE questions for alcoholism.</p> <p>Do you have any diagnosed conditions?</p>	<p>Irritable bowel syndrome likely.</p> <p>Ulcerative colitis is possible, especially with an onset in the 20s or 30s.</p> <p>Lactose intolerance likely.</p> <p>Alcohol-related.</p> <p>Diabetes, hyperthyroidism, cancer.</p>

When a patient has a complaint of chronic diarrhea, the separation of bloody from nonbloody types is an important first step. Bloody diarrhea that is constant or recurrent is highly indicative of inflammatory bowel disease. The historical distinction between ulcerative colitis (UC) and Crohn’s disease is not always clear.<sup>2</sup> Both often begin at a young age (<30 years of age). It is more likely, because of the small-bowel involvement usually found with Crohn’s disease, that there will be associated weight loss and,

because of the obstruction, perianal fistulas. Patients with Crohn's disease usually have more persistent symptoms and are more likely to have a fever. Bloody diarrhea is possible but less common than with UC. UC is more likely to present with bloody diarrhea. Stressful life events tend to activate the process.<sup>3</sup> Abdominal pain is more common with Crohn's disease than with UC. The final determination is made with barium studies and colonoscopy.

Patients who complain of early-morning constipation (marble-sized stool) and subsequent diarrhea that is recurrent are likely to have irritable bowel syndrome (IBS). It is important, though, that as many other clues be obtained as possible prior to jumping to this conclusion. These patients often have difficulty with specific foods that they can identify for the doctor. The stool is nonbloody, but it may have mucus. If there are associated hemorrhoids, the stool may be blood-tinged.

Other clues may suggest less common causes such as venereal-related diarrhea and diarrhea secondary to other diseases:

- Patients with known diabetes or complaints of numbness/tingling in the extremities, frequent vaginal yeast infections, or orthostatic hypotension should be evaluated for diabetic autonomic involvement.
- Patients with a history of hyperthyroidism or having complaints of heat intolerance, exophthalmos, or fine hand tremors should be evaluated for the secondary effects of hyperthyroidism on increased metabolism.
- Patients involved in unprotected sex, in particular anal sex, should be evaluated for possible venereal disease with diarrhea as part of the symptom complex. Also these patients are at higher risk for acquired immunodeficiency syndrome (AIDS).
- Foul-smelling, light-colored stool that floats is suggestive of pancreatic disease, small-bowel disease,

or post-cholecystectomy.

- A cause of malabsorption with associated diarrhea, found primarily in Caucasians (especially those of European descent), is celiac sprue. Also called nontropical sprue and gluten-sensitive enteropathy, celiac sprue involves an allergic response to gliadin, part of gluten that is found in wheat, rice, barley, and, to a lesser degree, oats. It is unknown whether this antibody (IgA antigliadin and antiendomysial) response is preexisting or acquired. Apparently a combination of factors, including environmental, genetic, and immunologic elements, contributes to the development of celiac sprue. Symptoms may appear at any age, with the first appearance possible when an infant is introduced to cereals in the diet. A remission from childhood onset is not uncommon during the twenties. Symptoms include diarrhea, steatorrhea, weight loss, and the outcome of nutrient deficiencies, primarily anemia. Suspicion is high when symptoms are eliminated through avoidance of gluten-containing foods. Confirmatory diagnosis requires a small intestine biopsy. Celiac sprue is also associated with insulin-dependent diabetes and dermatitis herpetiformis. Approximately 90% of patients will respond to gluten restriction in their diet. The remainder should avoid soy, lactose, and/or include fat restriction. If ineffective, other medical approaches may be considered, including corticosteroids.

## **Examination**

The majority of important indicators are historical. With acute diarrhea, an abdominal examination should be performed to determine acute inflammatory processes. A

rectal examination should be performed in patients with chronic diarrhea.

Laboratory testing to determine the cause of diarrhea includes both serologic testing and stool sample testing. Serologic testing should be performed based on the suspected cause; however, it may include any or all of the following:

- For general inflammation, ESR (erythrocyte sedimentation rate) and/or CRP (C-reactive protein)
- For anemia, infection, and some cancers, CBC (complete blood count)
- TSH (thyroid stimulating hormone) to check for thyroid dysfunction as a cause

For detecting and distinguishing inflammatory bowel disease, the following single tests or combined tests in panels may be ordered:

- pANCA (perinuclear antineutrophil cytoplasmic antibody) for UC; found in about 50% of patients (only 5% to 20% of patients with Crohn's disease).
- ASCA (*Saccharomyces cerevisiae* antibodies), IgG and IgA. For Crohn's disease found in about 40% to 50% of patients. For UC, this test is not very definitive, with ASCA IgG found in only about 20% and with ASCA IgA found in less than 1%.
- Antiglycan antibodies. Elevated in 75% of patients with Crohn's versus only 5% of patients with UC.
- Anti-CBir1 (*Clostridium* species antibodies). For Crohn's, found in about 50% of patients.
- Anti-Omp C (*Escherichia coli* antibodies). For rapidly progressing Crohn's disease.
- Anti-I-2 (*Pseudomonas fluorescens* antibodies)

For the evaluation/detection of celiac disease, the following tests have been utilized:

- IgA class of anti-tissue transglutaminase antibody (anti-tTG): Anti-tTG, IgA is the most *sensitive* and *specific* blood test for celiac disease; however, it may be negative in children under age 3 years who have celiac disease. For this group, deamidated gliadin peptide (DGP) antibodies, IgA, called the Anti-DGP test, may prove useful.
- Anti-gliadin antibodies (AGA), IgG and IgA classes
- Quantitative immunoglobulin A (IgA)

Other tests that are either new or used less often for celiac disease include:

- Anti-endomysial antibodies (EMA), IgA class
- Anti-reticulin antibodies (ARA), IgA class
- Anti-actin (F-actin), IgA class Stool testing is important to find the underlying cause.

Stool samples are tested for blood and for polymorphonuclear leukocytes (PMNs) (e.g., Calprotectin and Lactoferrin).

Fecal PMNs are highly suggestive of an enteroinvasive bacterial cause such as *Campylobacter*, *Shigella*, or enteroinvasive *E. coli*.<sup>4</sup> When fecal PMNs are found, the laboratory should be instructed to culture the stool in an effort to identify the causative organism. Given that the isolation rate of bacteria in stool cultures is under 3% with acute diarrhea, it is unnecessary and expensive to order stool culture in those patients. When giardiasis is suspected, the laboratory should be instructed to look for cysts.

Patients with chronic diarrhea should be screened historically for identifiable causes prior to resorting to laboratory evaluation.

- If medications appear to be the culprit, discontinue if OTC or refer the patient back to the prescribing physician.
- If the patient has a diagnosis of diabetes, hyperthyroidism, pancreatic disease, or other conditions that may cause diarrhea, refer the patient to the primary provider without further laboratory testing.
- If the patient is suspected of having lactose intolerance, recommend a lactose-free diet or an OTC lactase product prior to further laboratory testing.

When a patient is suspected of having an inflammatory bowel disorder, refer to a physician for GI imaging studies or proctosigmoidoscopy. If the patient is suspected of having a metabolic disorder, order laboratory tests specific to the disorder (i.e., serum glucose for diabetes, supersensitive thyroid stimulating hormone [TSH] for thyroid disorders). If maldigestion is evident in the history (i.e., weight loss, vitamin deficiency, and osmotic diarrhea), quantification of fecal fat should be ordered; fatty acids suggest malabsorption.

## Management

Antibiotic treatment is needed only in selected cases. In those patients who are immunosuppressed, antibiotics may protect against complications of a bacterial-caused diarrhea. Most acute diarrhea resolves in two days and therefore does not need antibiotic management. Viral and bacterial toxin-mediated diarrhea is not responsive to antibiotics. Antibiotic therapy is recommended for shigellosis and for any patient with severe enteroinvasive diarrhea.<sup>5</sup> Infections with parasites such as *Giardia* and *E. histolytica* often require metronidazole (Flagyl).

The OTC drug approach to diarrhea is often effective. However, it is important to remember that diarrhea is often the body's attempt to rid itself of infectious agents. Using these agents too early in the course may be counterproductive and may prolong the infection. There are generally three types of medications available:<sup>6</sup>

1. Antimotility drugs—Loperamide (Imodium) is the most common type and quite effective (codeine is an effective prescription drug).
2. Antisecretory drugs—Bismuth subsalicylate (Pepto-Bismol) reduces diarrhea through prostaglandin inhibition (aspirin has some effect).
3. Absorbents—Kaopectate (mainly clay and pectin from apples/citrus fruits) bulks up the stool.

**Table 33-3** lists common medications and their side effects. The primary goal of treatment is to maintain proper glucose and electrolytes. Sports drinks are not appropriate because the fluid must be hypo-osmolar. For infants, several OTC drinks are available, such as Pedialyte. A simple home concoction is a mixture of ½ tsp salt, 1 tsp baking soda, 8 tsp sugar, and 8 oz of orange juice diluted in water to produce 1 L of liquid.<sup>7</sup>

**Table 33-3** Antidiarrheal Medications

Drug Class	Examples	General Mechanism	Interactions/Side Effects
Bismuth	Pepto-Bismol	Hydrolyzed to salicylate which inhibits inflammatory prostaglandins. Used as an antidiarrheal both prophylactic and treatment. Also for temporary relief of indigestion.	May cause temporary darkening of stool, a metallic taste in the mouth, a bluish gum line, and possible bleeding tendencies.
Kaolin-Pectin	Kaopectate Kaospan Kolain w/Pectin	Kaolin as an aluminum silicate may have adsorbent and demulcent actions. Pectin may help to consolidate stool. Used for mild to moderate diarrhea.	May cause mild constipation.
Loperamide	Imodium Maalox antidiarrheal Pepto Diarrhea Control	Synthetic piperidine derivative that inhibits GI peristaltic activity. OTC medication used in the treatment of acute diarrhea or chronic diarrhea associated with inflammatory bowel disease.	Toxic megacolon with overuse, may cause drowsiness, CNS depression, dizziness, bloating, constipation, or abdominal pain.

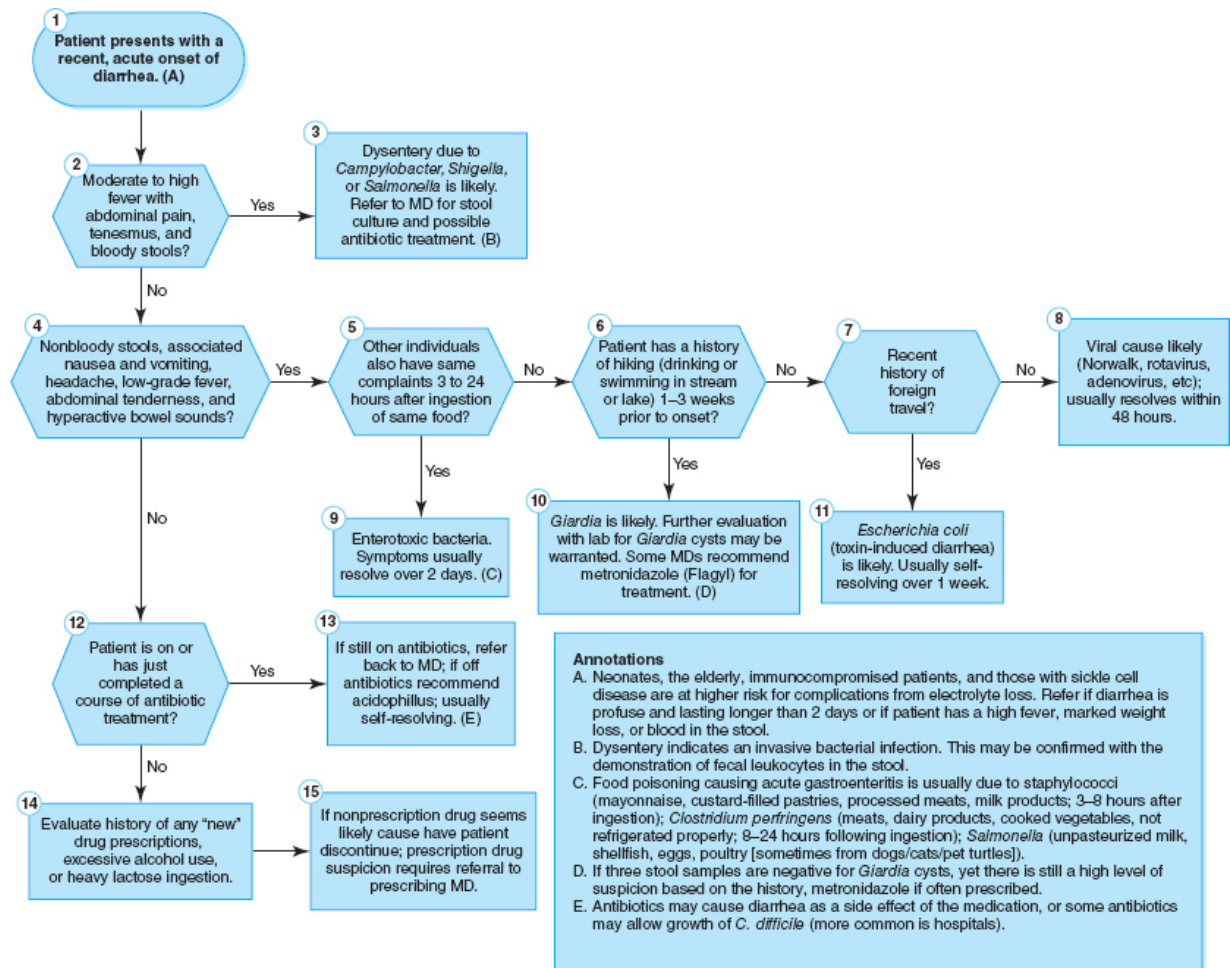

Persons traveling to foreign countries should pack an antidiarrheal compound and, if concerned, ask their physicians about newer antibacterial agents such as Xifaxan (rifaximin).<sup>8</sup>

A common problem for senior patients is *C. difficile*. This is the result of antibiotic treatment that allows the overgrowth of *C. difficile* due to the destruction of much of the normal flora of the digestive tract. Difficult to treat and with recurrence high, this form of infection kills 14,000 Americans each year. A novel approach is now being used for recalcitrant cases. It involves taking a sample of stool from a healthy individual and through a process of preparation, giving this to a patient with *C. difficile*. It is referred to as a fecal transplant and has shown some success warranting its consideration.<sup>9,10</sup>

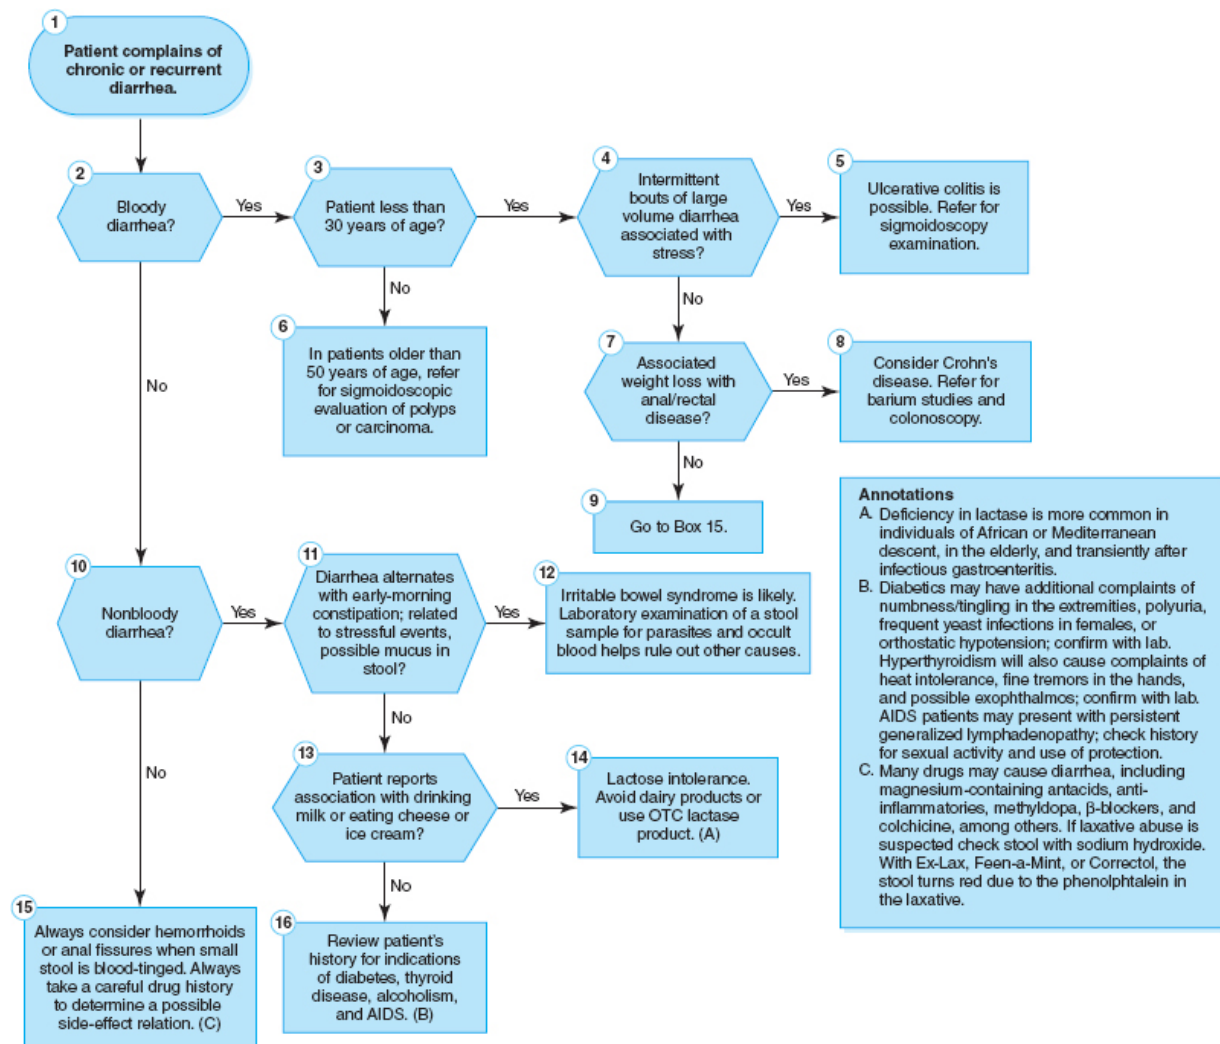

For prophylaxis, commercially available probiotics generally contain combinations of strains or species, generally from two to eight. Most contain lactic acid-producing *Bifidobacterium* or *Lactobacillus* species and strains. The available evidence for probiotics to support many of the commercial claims is not strong. What is available are some studies indicating some success in managing prevention of antibiotic-associated diarrhea in adults, acute infectious diarrhea, and prevention of necrotizing enterocolitis in premature infants.<sup>11</sup>

## Algorithms

Algorithms for evaluation and management of acute and chronic diarrhea are presented in **Figures 33-1** and **33-2**.

## Genitourinary Complaints

## CHAPTER 34

# Urinary Incontinence and Voiding Dysfunction

### Context

Although 10 million individuals in the United States have urinary incontinence, it often remains a secret to loved ones and the patients' doctors.<sup>1</sup> It is estimated that in the elderly, 15% to 30% who live at home have urinary incontinence. This percentage increases in the acute-care setting to one-third, and up to one-half of all the elderly in extended-care facilities are incontinent.<sup>2</sup>

Because of the associated embarrassment, the patient rarely volunteers information about incontinence if it is not a chief complaint. It is important, especially in the elderly and in women over age 40 years, to question the patient about loss of bladder control. It is unfortunate that many women consider incontinence as "normal."

For the chiropractor, it is important to realize that a full evaluation involves examination of the genital and perianal regions in both males and females. This scenario may not be a comfortable one for the chiropractor if his or her training is not extensive for this area of investigation. Historical clues, though, can narrow down the diagnosis to the type of incontinence (or whether there is incontinence) and facilitate proper referral. For those who perform a thorough examination, it is important to realize that a

complete evaluation for some types of incontinence requires ultrasound and/or urodynamic studies. These fall within the domain of the urologist.

## General Strategy

# History

## Determine the following:

- Whether the patient has signs of irritative bladder (urgency, increased frequency, nocturia, dysuria) or obstructive bladder (decreased stream, dribbling, hesitancy, or intermittent stream) dysfunction
- Whether the patient has any known diseases such as Parkinson's disease, diabetes, multiple sclerosis, or others, including other urinary tract diseases (see **Table 34-1**)
- What, when, and how much fluid the patient drinks (large intake of diuretic fluids such as coffee, tea, colas, alcohol, or large amounts of water [especially before bed] may cause nocturia)
- Whether the patient is taking any over-the-counter or prescription medications that may influence micturition (loop diuretics,  $\alpha$ -adrenergic blockers, calcium channel blockers, cold capsules or nasal decongestants, haloperidol, or others)
- Whether there are positions in which the incontinence is most likely to occur (stress incontinence usually occurs while standing [unless patient laughs], nycturia occurs while recumbent)
- Whether coughing, sneezing, laughing, exercising, or jumping causes loss of small amounts of urine

- (common with stress incontinence)
- Whether the patient's mental state or mobility is a factor
- Whether there is a history of past surgeries or radiation therapy

## Examination

- Determine whether the patient has any signs of neurologic dysfunction; test for perianal reflex and lower extremity reflexes.
- Evaluate the perianal area for signs of fistulas or prolapse.

**Table 34-1** Some Urinary Tract Diseases\*

<b>Type</b>	<b>Summary Information</b>
<b>Kidney</b>	
<b>Polycystic kidney disease</b>	A bilateral autosomal dominant disease where numerous fluid-filled cysts are formed (from obstructed tubules) causing the kidneys to be enlarged in size and weight (as much as 20 times heavier). Impairment of renal function leads to early renal failure at around 30–40 years of age. Other congenital disorders, including cystic renal dysplasia, generally affect only one kidney.

# Glomerulopathies

## **Acute Glomerulonephritis:**

Usually secondary to streptococcal infection, occurring 1-2 weeks after antibodies form antigen-antibody complexes that activate complement resulting in inflammation. Rare in the United States. Clinically presents as nephritic syndrome with proteinuria and hematuria, with resulting edema and hypertension. Usually resolves, with 1%-2% having acute renal failure and in <10% of cases, chronic glomerulonephritis.

## **Crescentic**

**Glomerulonephritis:** A rare condition occurring after focal necrosis of the glomerular capillaries as in Goodpasture's syndrome, which is an autoimmune disease forming antibodies to the basement membrane both in the kidneys and lungs (collage type IV). May also be caused by Wegener's granulomatosis, polyarteritis nodosa, or poststreptococcal glomerulonephritis. Capillary loops are blocked, leading to glomerular filtration failure. Survival requires dialysis or renal transplantation.

**Membranous Nephropathy:** An immune disorder causing thickening of the glomerular basement membrane, leading to nephrotic syndrome. Idiopathic in 85% of cases. Known causes include hepatitis B virus or *Treponema pallidum*. Proteinuria is found for years, which progresses in about 40% of patients with eventual need of dialysis or renal transplantation.

**Lipoid Nephrosis** (minimal change disease or nil disease): A

disease of unknown etiology that leads to nephritic syndrome (most common in children). Responds to corticosteroid treatment.

**Chronic Proliferative**

**Glomerulonephritis:** Immune-mediated disorders (e.g., Berger's disease—IgA nephropathy) and with autoimmune disorders, most commonly systemic lupus erythematosus (SLE). Leads to either nephritic or nephrotic disorder with variable results, including possible hematuria and proteinuria with or without symptoms. Some are responsive to corticosteroid treatment.

**End-stage Nephropathy:** For many immune-mediated glomerulonephropathies, progression to hyalinization of glomeruli leads to shrunken kidneys and end-stage kidney disease.

**Diabetic Nephropathy:**

Diabetes causes a number of changes in the kidneys, including diffuse glomerulosclerosis (thickening of the basement membrane), arteriolar hyalinization and thickening, and papillary necrosis. Membrane permeability leads to proteinuria and chronic renal insufficiency. Diabetic kidneys are also prone to infection.

## Pyelonephritis

Infection of the kidneys may be conveyed through the blood or retrograde through the ureters (most common). In children, 30%–50% may be due to vesicoureteral reflux or congenital abnormalities. Females are far more affected than males. Usually bacterial (e.g., *E. coli*, *Proteus*, *Klebsiella*, *Pseudomonas*) and rarely

	<p>parasitic, yeast, or protozoal. Onset is often acute, with fever, flank pain with radiation into the groin, nausea, and vomiting. There is kidney tenderness upon palpation and a positive kidney punch sign. Symptoms of a lower UTI occur in about 33% of patients. Lab findings include leukocytosis, pyuria, and bacteria cultured from urine. Treatment is with antibiotics specific to the organism.</p>
<b>Renal cell carcinoma</b>	<p>The most common kidney neoplasm. Males are affected twice as often as females. There may be a higher risk for smokers to develop renal cell carcinoma. Only 10% of patients are symptomatic, with flank pain, hematuria, and a palpable mass. Fifty percent are discovered incidentally on computed tomography. Nonspecific clinical complaints are more common, including weight loss, fever, or hypertension. Paraneoplastic findings occur in about 20% of patients. Surgical excision results in a 5-year survival of 40%.</p>
<b>Wilms' tumor</b>	<p>Also called a nephroblastoma, it is the most common solid tumor of infants and young children. May be associated with a syndrome that includes aniridia (lack of iris), general malformations, and mental retardation. The tumor, composed of immature cells, is present at birth but is not apparent until 2-4 years of age, usually detected as an abdominal mass by the parent or doctor. The tumor is quite malignant but responds well to chemotherapy and/or surgery, with an 85% cure rate.</p>

# Bladder

## Cystitis

Infection of the bladder is via a number of different organisms including bacterial (e.g., *E. coli*, *Proteus*, *Klebsiella*, *Pseudomonas*) and yeast (e.g., candida). Females are far more often affected than males. The onset of symptoms is acute, with common irritative complaints of urgency, frequent urination of small amounts of urine (including nocturia), and burning upon urination. Other complaints include suprapubic pain/tenderness and low back pain. Laboratory evaluation reveals gross hematuria with bacterial cystitis. Pyuria and culture of midstream catch reveals causative organisms. Common to recur in many patients, especially those with diabetes, benign prostatic hypertrophy, and those with calculi. Drinking cranberry juice may be preventive.

## Carcinoma

Occurring in the elderly, urinary bladder carcinoma is three times more common in males than females. The primary risk factor is smoking, directly proportional to the amount of smoking during a lifetime. An unusual cause is *S. haematobium*, a parasite in Egypt. Symptoms usually occur early with dysuria, lower abdominal pain, and hematuria. Diagnosis is confirmed with cystoscopy with histologic examination of biopsied specimen. Response to surgery, chemotherapy, and immunotherapy such as *bacillus Calmette-Guerin* (BCG) is 98% for

	local tumors that have not metastasized; those that have are usually deadly.
<b>Male Genital (for females, see <a href="#">Table 55-4 in Chapter 55</a>)</b>	
<b>Cryptorchidism</b>	Undescended testicles are usually due to the inguinal canal being obliterated. Descent usually occurs by the time of birth with only a few (3%–4%) having retractile testes where the cremasteric muscle may pull them through the inguinal canal. Only 1% after the first year of life have undescended testicles. Surgical repositioning is an effective treatment. However, some complications include atrophy and hypospermatogenesis, leading in later life to infertility. Also, cryptorchid testes are more likely to develop carcinoma (10-fold greater risk). Early correction reduces this risk.
<b>Testicular cancer</b>	Accounting for only 1% of neoplasms in males, these germ cell tumors occur around ages 30–40 years. There are various types, including seminomas, teratomas, embryonal carcinomas, endodermal sinus tumor, and choriocarcinoma. Metastasis is through the periaortic lymph nodes in the abdomen, potentially spreading to the liver, lungs, and brain. Diagnosis is usually first made with the detection of a scrotal mass. Radio-immunoassay for $\alpha$ -fetoprotein and $\beta$ -human chorionic gonadotropin are the lab markers for tumor. Chemotherapy is quite successful, with a 90% cure rate.

\*Not covered in “Selected Causes” section.

- Perform or refer for a prostate examination on men; a vaginal examination on women.
- Perform a urinalysis on all patients in an attempt to determine renal function or indicators of urinary tract infection (UTI).
- Refer for urodynamic testing by a urologist if incontinence is severe.

## Management

- For patients with prostate hypertrophy, manage with behavioral training and some dietary recommendations; if ineffective, refer for medication or possible surgery.
- For patients with stress incontinence, prescription of exercises and behavioral training may be effective; if not, refer for medication or, in rare cases, surgery.
- For patients with diabetes mellitus, comanage with the medical doctor.

## Relevant Anatomy and Physiology

Bladder control is an intricate balance among several neural systems. The tension within the bladder that is generated by filling must be balanced by restriction of outflow at the bladder neck. The primary innervation of the body of the bladder is parasympathetic (pudendal nerve S2-S4).

Therefore, parasympathetic stimulation facilitates urination by causing contraction of the body of the bladder (detrusor muscle) and urinary sphincter relaxation. Sympathetic innervation is via the hypogastric nerve plexus with nerve cell bodies at T11-L2.  $\beta$ -adrenergic (sympathetic)

stimulation causes detrusor muscle relaxation during filling.  $\alpha$ -Adrenergic (sympathetic) stimulation at the bladder neck (which acts as an internal urethral sphincter) acts to prevent urination.

The micturition center is located in the pons and acts to inhibit urination. Cortical override occurs through connections from the frontal lobe, corpus callosum, and cingulate gyrus, which generally inhibit the pontine micturition center.

Various forms of dysfunction can affect this intricate balance. Involuntary contractions of the detrusor muscle may occur as a result of irritation or neurologic disease. This hyperreflexia is referred to as detrusor instability, or an unstable bladder. A different type of dysfunction occurs when the force of contraction of the bladder is too weak to expel all the urine, leading to residual retention and subsequent irritation or infection. This condition also may occur with any bladder outlet obstruction, such as prostatic hypertrophy or urethral stricture, when the ability to overcome this added resistance from obstruction is exceeded. When there is pelvic floor weakness and secondarily hypermobility of the urethra, an unequal pressure is created. Maneuvers that increase intra-abdominal pressure cause bladder pressure to exceed urethral sphincter resistance, and urine is lost.

Urinary incontinence has been divided into several major types,<sup>3</sup> as follows:

- Urge incontinence—A sudden, uncontrollable urge to void is created by bladder irritation or neurologic dysfunction with urge incontinence. The most common cause is benign prostatic hypertrophy or urinary tract infection.
- Stress incontinence—Stress incontinence occurs when actions such as laughing, coughing, sneezing, or jumping cause loss of a small amount of urine. The

most common cause is pelvic floor weakness in women.

- Mixed incontinence—This is a combination of urge and stress incontinence, often occurring in the elderly. Also, two-thirds of men with prostatic hypertrophy have obstruction and detrusor hyperactivity.
- Overflow incontinence—Overflow incontinence occurs when an overdistended bladder exceeds the resistance of the urethral sphincter, and urine is lost. This is often due to detrusor weakness and/or outflow obstruction.
- Total incontinence—Total incontinence is the loss of urine at all times regardless of body position. Rarely would it be seen undiagnosed in the chiropractic setting. It is usually due to serious neurologic or structural abnormalities.

## Evaluation

## History

The distinction between irritative and obstructive symptoms may give valuable clues to an underlying etiology. For example, if the patient complains of dysuria, urgency, increased frequency, and nocturia, an irritative cause is likely. Further investigation with urinalysis for a UTI is essential. For patients complaining of a decreased stream, hesitancy, dribbling, and a sense of incomplete emptying, an obstructive problem is likely. With men the most common problem is prostate hypertrophy, warranting a digital rectal examination.

For obstructive symptoms in males, the standard questionnaire in use is the American Urological Association (AUA) Symptom Index for Evaluation of Benign Prostate Hyperplasia.<sup>4</sup> It consists of seven questions with the

possibility of the following responses for each: not at all, less than 1 time in 5, less than half the time, about half, more than half, and almost always. The questions all begin with “over the past month” and continue with:

- How often have you had a sensation of not emptying your bladder completely after you finished urinating?
- How often have you had to urinate again less than two hours after you had finished urinating?
- How often have you found you stopped and started again several times when you urinated?
- How often have you found it difficult to postpone urination?
- How often have you had a weak urinary stream?
- How often have you had to push or strain to begin urination?
- How many times do you most typically get up to urinate from the time you went to bed at night until you got up in the morning?

Each question can result in 0 to 5 points with a total score from 0 to 35 possible. Patients scoring 0 to 7 are considered mildly symptomatic, 8 to 19 moderately symptomatic, and 20 to 35 severely symptomatic.

With a complaint of incontinence, the timing of incontinence onset with regard to childbirth, surgery, radiation therapy, low back pain, or medication ingestion often will provide valuable clues. Important clues to differentiation among the various types of incontinence are the amount of fluid lost and the position or circumstances surrounding the loss. Patients who have problems only with increased abdominal pressure from laughing, sneezing, coughing, or jarring and subsequently void small amounts are likely to have stress incontinence. If patients are unable to stop voiding in midstream, stress incontinence is suggested. Patients who have a sense of uncontrollable urge

without regard to body position are likely to have urge incontinence. A large amount of fluid loss associated with a large fluid intake is highly suggestive of diabetes, although some nondiabetic patients believe that an intake of more than eight glasses of water a day is necessary for optimal health.

If the patient complains mainly of nocturia it is critical to determine when the patient goes to bed, how often he or she actually gets up at night, how much is voided, and what his or her fluid intake is prior to going to bed. Patients who report voiding large amounts of fluid after one to two hours of recumbency are more likely to have nycturia. This reflects a shift in fluid from a lower extremity interstitial site to intravascular incorporation assisted by recumbency. This is seen with patients having right-sided heart failure, liver disease, or chronic venous insufficiency. Nocturia is often the continuation of a daily voiding problem caused by diabetes or renal failure.

If the patient is elderly, it is important to remember that there is a natural tendency to void most fluid after 9 p.m. In younger patients, most fluid is voided prior to 9 p.m. In addition, the bladder capacity is reduced in the elderly.<sup>5</sup> If patients ingest water or beverages with xanthine, such as coffee, tea, and sodas, they will likely have to void more often.

Male patients who complain of irritative bladder symptoms that appear to be evidence for a UTI may have an aseptic inflammation of the prostate, referred to as prostatosis. Approximately one-third of male patients who appear to have a UTI do not respond to antibiotic therapy. The belief is that some stimulus for inflammation causes a protracted course lasting approximately nine months to one year. During this time, male patients are likely to seek second and third opinions without any satisfactory answer or solution. If the patient is responsive to an elimination approach, he may have prostatosis. Elimination or

avoidance of alcohol, spicy foods, citrus drinks, and caffeine will usually cause a dramatic decrease in symptoms and in some cases resolve the problem. Reassurance that this is a self-resolving condition is important psychological counseling as the patient may become very frustrated.

## **Examination**

General examination findings that might suggest an underlying cause for incontinence are lower extremity edema, mental status abnormalities, decreased reflexes, or sensory abnormalities. An elderly patient's ability to ambulate should be evaluated as an indicator of the ability to reach the bathroom when needed.

Specific focus is on the genital/rectal area. As mentioned previously, this may be uncomfortable for the chiropractor and especially the patient. If performed in the chiropractic setting, it is important to have a same-sex (as the patient) witness (if opposite sex doctor). The examination begins with an examination of the urethra in an effort to detect possible signs of infection. Rectal examination is used to determine prostate status in men and possible fecal impaction in both men and women. A pelvic examination in women may reveal a cystocele or a prolapse and the estrogen status (atrophic vaginitis). A urethrocele may be evident by bulging of the urethra with coughing. Another similar approach (for women) is to insert a cotton-tipped swab into the urethra and watch for movement of more than 30° from the horizontal with coughing or straining. This indicates a hypermobile urethra, which is associated with stress incontinence.

If the patient is cooperative, the doctor may watch the patient void (especially helpful in men) to determine the degree of hesitancy, the amount of stream, and the consistency of flow. With women it may be helpful to have

the patient cough with a full bladder to determine whether there is any leaking. If there is immediate leaking, stress incontinence is likely. If there is a delay of a few seconds, detrusor instability is more likely. The bladder should be palpated in an effort to determine distention, although this may be difficult in many patients because of obesity or muscularity.

Neurologic status should also be checked, including rectal sphincter tone, by stroking the perianal area, looking for an anal “wink” that indicates an intact S2-S4 spinal cord level.

An essential in-office evaluation of urine is important to detect signs of UTI, renal dysfunction, or possible bladder cancer. A laboratory finding of greater than five white blood cells per high-power field is suggestive of a UTI, especially when accompanied with bacteriuria. A culture should be ordered. Glucosuria, proteinuria, or yeast suggests diabetes. Hematuria may indicate bladder cancer if associated with suprapubic pain. Total and free prostate-specific antigen (PSA) should be included for males with suspicion of prostate cancer.

Special testing may be performed in a urologic setting. Urodynamic studies combine uroflowmetry and cystometry and/or videofluoroscopy. These studies are briefly listed as follows:

- Uroflowmeter—measures the urine flow in millimeters per second and is used in combination with postvoid residual (PVR) urine volume to differentiate between obstruction and weak detrusor tone.
- Cystoscopy—allows a direct visualization of the bladder and is used to determine any obstruction to outflow.
- Cystometry—used to measure capacity and compliance, assess bladder sensation, and determine any voluntary or involuntary detrusor contractions.
- Ultrasonography—used to measure PVR urine volume.

PVR urine volume is often used to differentiate among the various types of incontinence. If the PVR volume is greater than 100 mL, impaired detrusor contraction is suspected. If the PVR volume is greater than 300 mL, overflow incontinence is likely. If the PVR volume is under 100 mL, stress or urgency incontinence is likely. If the uroflowmeter measurement is normal and the PVR volume is normal, obstruction is unlikely.

## **Management**

Conservative nondrug, nonsurgical options may be helpful in patients with detrusor instability or stress incontinence. The basis of these behavioral approaches is bladder training for detrusor instability and Kegel (pelvic floor) exercises for stress incontinence. Additional approaches include biofeedback training, electrical stimulation, and vaginal cones. Conservative approaches require a compliant and highly motivated patient. The success rate with these conservative approaches is rather good when both cure rate and improved rate are combined. For urge incontinence, one study<sup>6</sup> indicated a “success” rate of 87% (12% cured; 75% improved). For stress incontinence the success rate with pelvic floor exercises was also 87% (12% cured; 75% improved); with bladder training, the success rate was 70% (16% cured; 54% improved).

## **Bladder Training**

Bladder training sets timed intervals for voiding. The patient is instructed to postpone voiding until the scheduled time. Starting with one-hour intervals during the day, the patient is asked to increase the time interval gradually (over days) by 15 to 30 minutes. Over weeks, the patient should set a

goal of 2½- to 3-hour intervals. In supporting this attempt, it is important to have the patient keep a diary. Another important factor is to have the patient time his or her drinking habits. Avoidance of intake of large amounts of water, coffee or tea, or carbonated drinks may help. A variation on this technique is timed voiding. With timed voiding the patient sets a schedule that fits his or her natural schedule instead of rigid timed intervals.

## **Pelvic Floor Exercises**

Although women with stress incontinence traditionally use Kegel exercises, they also may be helpful with urge incontinence and for men with incontinence after prostate surgery. The purpose of the exercises is to strengthen the pubococcygeus muscle and increase control over the periurethral and pelvic muscles. One reason for failure (other than noncompliance) is improper performance. In essence, the patient makes the mistake of performing a Valsalva maneuver. It is crucial to explain clearly and give written instructions on the performance of these exercises (or direct patient to Help for Incontinent People [HIP]). The patient must understand that the contractions are localized without concomitant contraction of the abdominal, gluteal, or thigh muscles. A good beginning exercise is to ask the patient to stop voiding in midstream. This can be accomplished only with the proper muscle recruitment. With the same focus, the patient should perform the exercise off the toilet and hold the contraction for approximately 10 seconds. The exercises should be performed religiously and often as many as 100 times per day. An adjunctive approach is to use vaginal cones for females. The cone is inserted and the patient attempts to hold it in place by contracting the pelvic floor muscles. This is performed twice a day for 15

minutes using multiple repetitions lasting for 20 to 30 seconds each.

## **Augmented Voiding**

For residual urine, it may be helpful to have the patient strain at the end of voiding or to have the patient press suprapubically in an attempt to add pressure to the bladder (Credé's maneuver). This technique also may be helpful with urge incontinence.

## **Other Options**

Both biofeedback and electrical stimulation have been used for incontinence. Pelvic floor electrical stimulation (PFES) has been used for half a century as a treatment approach to stress incontinence. PFES stimulates pudendal nerve afferents, activating pudendal and hypogastric nerve efferents and resulting in contraction of smooth and striated periurethral muscles and the striated pelvic floor muscles. Researchers in a recent randomized controlled trial assigned women to one of three groups: an eight-week behavioral training program, behavioral training plus PFES, or reading a self-help booklet.<sup>7</sup>

There was significant improvement in those treated with behavioral training (69%) or behavioral training plus PFES (72%), but no significant difference between the two groups. Those using the self-help booklet also had improvement (52%).

Two devices have been approved for use as a mechanical block to urine flow. One is a short balloon-catheter device that, after insertion into the urethra, is inflated to block urine flow. The other is a shield device for women that cups over the vaginal area.

For the elderly it is important to focus on mobility issues. The proximity of bathroom facilities and the ease of arising from bed play important roles in preventing bed-wetting. A semirecumbent position, a walking device, rail support at the toilet, and the location of the bed may all assist in decreasing the time it takes to reach the bathroom, avoiding “accidents.” Recommendation for protective pads or adult diapers may be needed.

When patients are unresponsive to conservative management or the incontinence is socially disabling, it is important to refer for medical approaches to care. The primary focus with medication is to select drugs that are specific to the cause. In other words, drugs that are helpful for one problem may have no effect or even aggravate incontinence due to another cause. For detrusor instability or hyperactivity, drugs that have anticholinergic effects are used. These block bladder contractions and therefore may be contraindicated in patients with obstructive problems. Anticholinergics may also cause dry mouth, mental confusion, or constipation. The two classes of drugs that are used include tricyclic antidepressants (may cause orthostatic hypotension in the elderly) and propantheline. A number of new medications that are muscarinic receptor antagonists are used to manage detrusor instability (overactive bladder). One of these is VESIcare (solifenacin).

**Table 34-2** lists these commonly used medications.

For stress incontinence, the rationale is to access medically the  $\alpha$ -adrenergic control of the bladder neck and proximal urethra. An  $\alpha$ -adrenergic agonist such as phenylpropanolamine hydrochloride is often used. Oral and topical estrogens are also used. Topical estrogen is particularly useful for women with atrophic vaginitis because it reduces the incidence of infection and dysuria.

Surgical options include retropubic suspension and needle suspension for stress incontinence. For women with intrinsic sphincter deficiency, bulking with Teflon or

collagen, a pubovaginal sling, and an artificial urinary sphincter replacement are options. It is extremely important that prior to these approaches a conservative approach with or without medication be attempted first. Also a thorough urodynamic evaluation preoperatively is important for input in decision-making regarding the best procedure.

Although it is often assumed that the primary cause of bladder outlet obstruction with prostate hypertrophy is mechanical blockage, a dynamic component based on increased sympathetic tone is probably the primary cause in many males. As a dynamic cause, the degree of obstruction and resulting symptoms vary based on external factors such as exposure to cold, overfilling of the bladder, anticholinergic medication (common ingredient in decongestants), and resulting reflexes that affect urethral tension and stress. Symptoms may then vary and often improve during periods of less stress or during warm weather. The medical approach to this sympathetic effect is to use sympathetic blockade as a strategy. The most common medications are alpha-1 adrenergic blockers.<sup>8</sup>

Although not always a cause of voiding dysfunction, it is important to mention prostate cancer. Prostate cancer is quite common in older males. The ethnic risk is more with African Americans and less with Asians. Factors that have been identified include a genetic predisposition and potentially some dietary factors. A high-fat diet increases the risk of prostate cancer.<sup>9</sup> Possible protective factors such as vitamins C, D, and E, beta-carotene, cadmium, and zinc are still being studied at this time.<sup>10</sup>

**Table 34-2** Medications for Incontinence and Prostate Hypertrophy

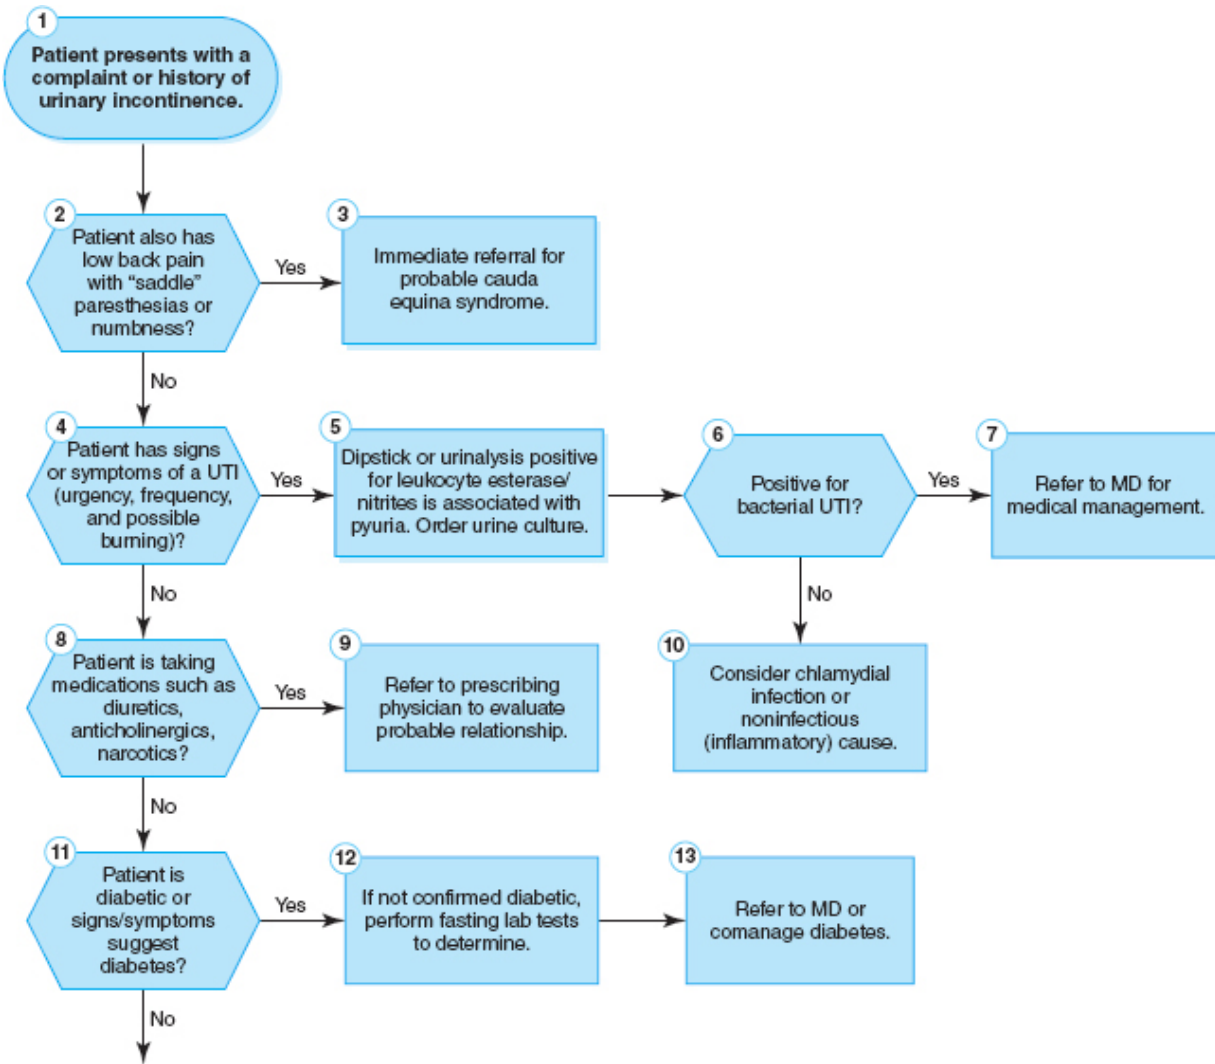

Drug Class	Examples	General Mechanism	Interactions/Side Effects
<b>Prostate Hypertrophy</b>			
5-Reductase inhibitors	Dutasteride	Blocks the conversion of testosterone to 5 alpha DHT (responsible for prostate hypertrophy). Inhibits both type 1 and 2 5-alpha reductase inhibitors.	Gynecomastia, ejaculation dysfunction, impotence, decreased libido.
	Avodart		
	Finasteride	A 5-reductase inhibitor of the enzyme necessary for conversion of testosterone into DHT. Used in the management of benign prostatic hypertrophy and male pattern baldness.	Decreased libido, impotence, or decreased volume of ejaculation.
	Propecia Proscar		
Alpha-1 blocker	Tamsulosin	Used in the management of prostate hypertrophy, this is an antagonist to alpha 1A adrenoceptors in the prostate.	Orthostatic hypotension, priapism, allergic-type reactions, constipation, and vomiting.
	Flomax		
	Terazosin	An alpha-1-adrenergic blocker used in the management of hypertension in combination with a beta-adrenergic blocker and thiazide diuretic. Also used in the management of benign prostatic hypertrophy.	Weakness, dizziness, headache, weight gain, or syncope.
	Hydrin		
<b>Neurogenic Bladder (Unstable Bladder)</b>			
Muscarinic receptor antagonists	Solifenacin	A muscarinic receptor antagonist used in the management of overactive bladder (detrusor instability).	Dry mouth, constipation, blurred vision.
	VESIcare		
	Oxybutynin Chloride	A synthetic amine used for neurogenic bladder or detrusor instability (unstable bladder). Effects are antispasmodic through inhibition of muscarinic effect of acetylcholine on smooth muscle.	May cause drowsiness, blurred vision, dry mouth, constipation, urinary hesitation, dizziness, weakness, or skin rash.
	Ditropan Ditropan XL		
	Tolterodine	A synthetic amine used for neurogenic bladder or detrusor instability (unstable bladder). Effects are antispasmodic through inhibition of muscarinic effect of acetylcholine on smooth muscle.	Drowsiness, blurred vision, dry mouth, constipation, urinary hesitation, dizziness, weakness, or skin rash.
	Detrol Detrol A		
	Oxybutynin	Antispasmodic, anticholinergic, transdermal medication used to control overactive bladder (now available OTC).	Allergic reactions, dry mouth, dizziness, blurred vision, constipation, headaches.
	Oxytrol		
Other	Fluoxetine	A selective serotonin reuptake inhibitor (SSRI) making more serotonin available in the CNS. Used in the treatment of depression and obsessive-compulsive disorders.	About 15% of patients discontinue use due to nausea, anxiety, diarrhea, insomnia, or headache.
	Prozac		

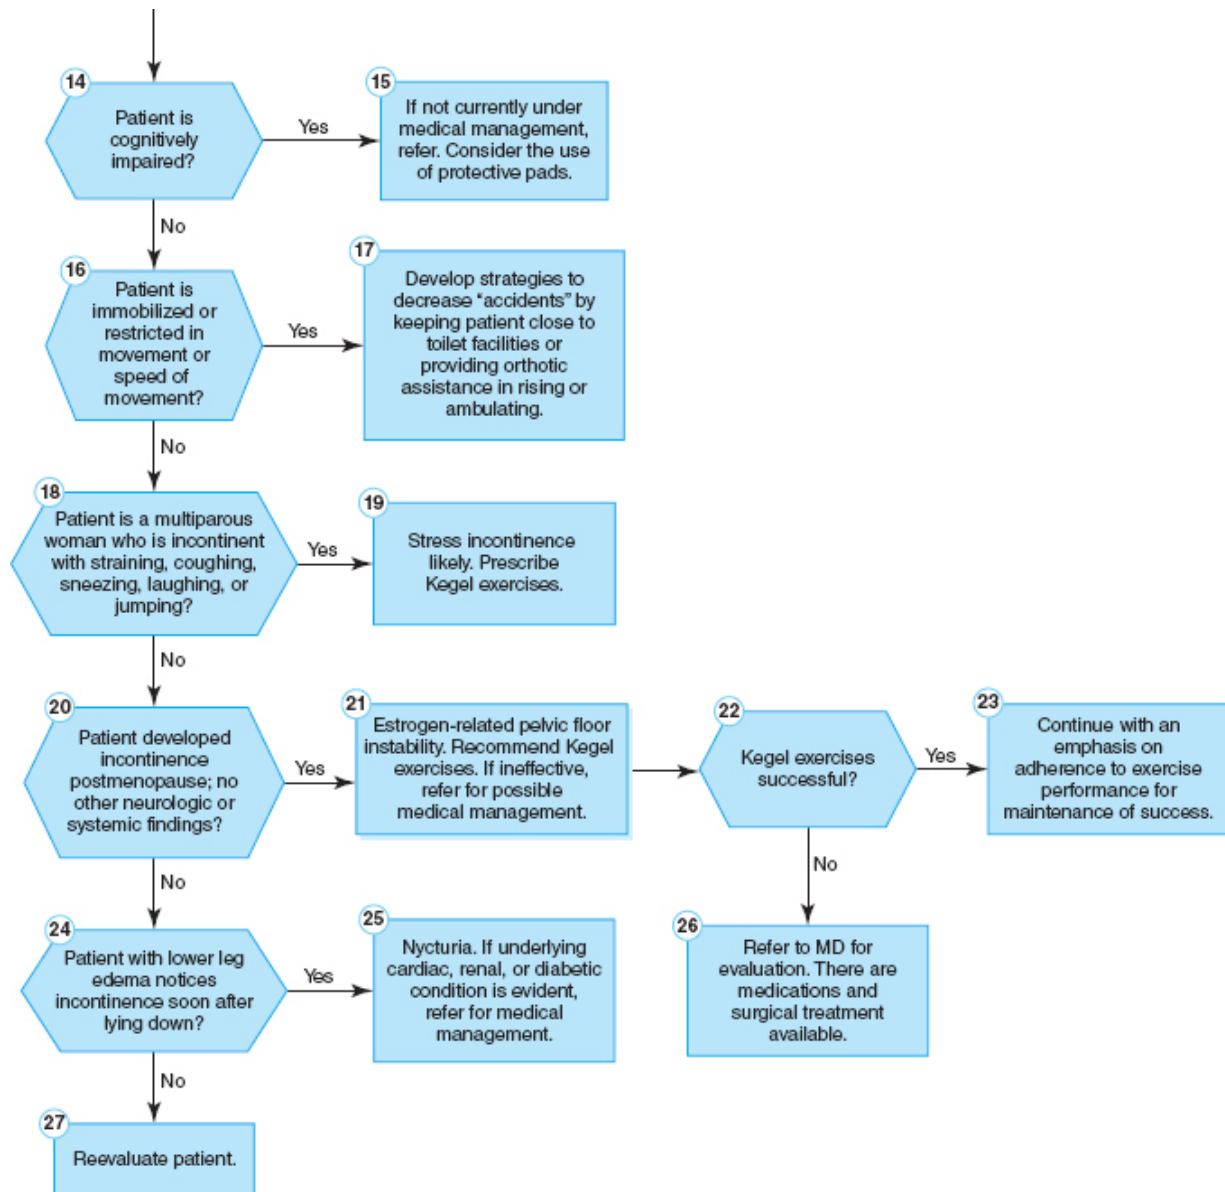

Beginning in their 40s, males with a high familial predisposition and African American males should have an

annual digital rectal examination (DRE) and PSA measurement. For those not at high risk, annual DRE and PSA should begin at age 50 years.

## Algorithm

An algorithm for evaluation and management of urinary incontinence in adults is presented in **Figure 34-1**.

**Figure 34-1** Urinary Incontinence in Adults—Algorithm

# Selected Causes of Voiding Dysfunction or Pain

## Urinary Tract Infection

### Classic Presentation

A female patient presents with complaints of urinary frequency, a sense of urgency, and painful urination (dysuria). Although this is the classic presentation, there are many possibilities, dependent on site of infection and cause. Note: The classic presentation of UTI is not common in the elderly with UTI. Their signs/symptoms are generally behavioral including confusion, memory loss, agitation, hallucinations, or social inappropriateness. Also common are dizziness and falls.

### Cause/Occurrence

The cause differs dependent on age and gender. Boys who have recurrent infection may have an anatomic abnormality such as posterior urethral valves that allow vesicoureteral reflux with subsequent kidney involvement. In most cases of UTI (>95%) the infecting organism is a gram-negative aerobic bacteria. Most often the cause is one of the following: member of *Enterobacteriaceae*, *Pseudomonas aeruginosa*, enterococci, and, in young women, *Staphylococcus saprophyticus*. In addition to a first infection, UTIs are classified into unresolved bacteriuria and bacterial persistence. Unresolved bacteriuria is usually due to patient noncompliance to medication, bacterial resistance, and mixed infection. Bacterial persistence often indicates another site of infection or abnormality including various kidney malformations, infected stones, chronic bacterial prostatitis, and fistulas, among others. Protection from infection includes a low pH and high osmolality, an intact glycosaminoglycan (GAG) protective barrier, full emptying of the bladder (no neurologic or other bladder dysfunction), and estrogen. Risk factors include diabetes, douching, tampon use, catheters, diaphragm use, infrequent voiding, pregnancy, renal failure, and bladder outlet obstruction from various causes.

### Evaluation

The primary confusion in making a diagnosis of urinary tract infection is the overlap with other infections with similar signs and symptoms. The three primary infectious considerations are vaginal infections (e.g., *Gardnerella*, *Candida albicans*, and *Trichomonas*), sexually transmitted diseases that lead to possible pelvic inflammatory disease (e.g., *Chlamydia trachomatis*, *Neisseria gonorrhoeae*), and other sexually transmitted diseases (e.g., Herpes simplex virus). This distinction is important because the organisms are different, and the management approach is different for each category. The primary difference between other local infections and UTI is that STDs and vaginal infections are usually associated with vaginal discharge and vaginal irritation.

Although the relative weighting of risk factors for UTI is not known, there are three risk factors for acute UTI in young women that appear important: recent sexual intercourse, use of spermicide (on condoms or with diaphragms during intercourse), and history of UTI (especially a maternal history of UTI or history of childhood onset of UTI). A combination of symptoms is highly suggestive of a UTI. Dysuria and frequency of urination without vaginal discharge or irritation raise the probability of a UTI to over 90%.<sup>11</sup> Dipstick testing can be used in the chiropractor's office as a quick screen in patients with a high likelihood of a UTI. Dipstick or urinalysis indicators for UTI include nitrites for bacteria and leukocyte esterase. However, these tests do not rule out or confirm a UTI because nitrites may be negative with staph and strep. UTIs and vaginal discharge and bleeding may cause a false positive for leukocyte esterase. A positive result increases that likelihood and should result in a referral for further medical evaluation and possible treatment. However, if the dipstick test is negative, the probability of a UTI is still 23% and should therefore be taken together with presenting symptoms in making the decision for medical referral. For patients with complicating factors such as a history of polycystic renal disease, nephrolithiasis, neurogenic bladder, pregnancy, diabetes, immunosuppression, or recent urinary tract catheterization or instrumented testing, referral for medical evaluation and management is imperative.

The patient is evaluated with a urinalysis. Urinalysis includes a microscopic evaluation of clean-catch urine for bacteria and pyuria (pus in the urine). Pyuria and colony counts greater than 100,000 bacteria/mL of urine are found in most infected patients. In symptomatic patients pyuria and colony counts of 100 to 100,000 bacteria/mL establish infection, most often lower UTI. The urine is cultured if bacteria are found. Generally, the isolation of two or more bacterial species on culture indicates a contaminated specimen. Patients with pyuria without bacteriuria may have chlamydial urethritis, gonococcal urethritis, or gram-positive cocci infection. Gross hematuria strongly suggests cystitis. Men with urethritis and purulent discharge often have *N. gonorrhoeae* infection; men with a whitish mucoid discharge have a nonspecific infection. Yeast infections are most common in diabetics and patients who have had a course of antibiotic treatment. For urethritis in females, see [Chapter 55](#).

## Management

For a conventional UTI, antibiotic treatment with amoxicillin/clavulanate, a cephalosporin, a fluoroquinolone, nitrofurantoin, or trimethoprim/sulfamethoxazole is prescribed. For pyelonephritis, more aggressive therapy including hospitalization with intravenous antibiotics is often recommended. Asymptomatic infections should be treated if there is underlying vesicoureteral reflux, stone, diabetes, or pregnancy or if the patient is an immunosuppressed individual. Prevention may be possible with changes in pH through the use of cranberry juice. A 2008 Cochrane review<sup>12</sup> of the preventive value of cranberries (cranberry juice) concluded that it may reduce the number of symptomatic UTIs over a one-year period especially for women with recurrent UTIs. This was confirmed in a 2013 prospective study.<sup>13</sup>

## **Benign Prostate Hypertrophy**

### **Classic Presentation**

A male patient presents with complaints of decreased force of urine stream, hesitancy, dribbling, and a sense of incomplete bladder emptying.

#### **Cause/Occurrence**

There is a direct relationship between age and benign prostate hypertrophy (BPH). There is histologic evidence of BPH in 50% of men at age 60 years, which increases to 90% by age 80 years.<sup>14</sup> The relationship between glandular enlargement and symptoms is not always present. Symptoms of BPH are usually due to a combination of causes including: (1) enlargement of glandular nodules causing urethral blockage (androgens are primary cause), (2) smooth muscle tone of the posterior capsule and bladder neck ( $\alpha$ -1-adrenergic stimulation), and (3) impaired bladder contractility and detrusor instability (involuntary “spasms” of the bladder). Although BPH increases with age, the symptoms do not necessarily follow this pattern.

### **Evaluation**

A digital prostate examination is required. In an effort to rule out other causes of symptoms or complications of BPH, order a urinalysis to evaluate for UTI or indicators of bladder cancer (hematuria requires an immediate urologic referral). Yearly serum creatinine measurement is recommended to screen for possible involvement of the upper urinary tract.

### **Management**

Patients with mild symptoms may be managed with watchful waiting, with recommendations of decreasing sympathetic stimulation (i.e., decreasing stress, decreased caffeine, etc.) and phytotherapy. Men who smoke more than 35 cigarettes/day and have high alcohol intake are at higher risk.<sup>15</sup> Men who are more physically active have a lower frequency of symptoms.<sup>16</sup> Those with more disruptive symptoms or risk of upper urinary tract involvement may need medical or surgical treatment.

Prostate growth is governed by hormonal influences. Testosterone is converted to 5-alpha-dihydrotestosterone (DHT) in the prostate. This is accomplished through an enzyme 5- $\alpha$ -reductase. The medical approach to reducing DHT is to block the conversion of testosterone to DHT through the use of 5-alpha-reductase inhibitors (e.g., finasteride [Proscar]). In this way the levels of testosterone are not affected.  $\alpha$ -1-adrenergic blocking agents such as terazosin (Hytrin) and doxazosin (Cardura) are often prescribed to reduce smooth muscle tone. Table 34-2 lists common medications and their side effects.

Recently, an association between low 25-OH vitamin D, calcium, and high-density lipoprotein cholesterol and an enlarged prostate has been demonstrated.<sup>17</sup> Studies still need to be conducted on whether correction of these associated low factors will decrease the occurrence of prostatic hypertrophy.

These medical options are being used more frequently in place of transurethral resection of the prostate (TURP). Other surgical options include open prostatectomy, balloon dilation, stents, and newer techniques including laser ablation and microwave hyperthermia. Surgery should be reserved for those who do not respond to conservative or medical management or those with serious complications.

Although initially promising, the clinical value of saw palmetto is being questioned. A study in 2006 by Bent et al.<sup>18</sup> found no symptom or objective measure difference between placebo and saw palmetto using an extract of 160 mg twice per day. A review by Avins and Bent<sup>19</sup> suggests that as larger studies are conducted, the current conflict in report will likely be resolved. It is postulated that saw palmetto reduces levels of DHT. A recommended dose is 320 mg of standardized extract per day. Symptoms may improve within one month.<sup>20</sup>

## **Prostate Cancer**

### **Classic Presentation**

A male patient is usually asymptomatic in the early stages. Later, local growth may cause the patient to present with complaints of decreased force of urine stream, hesitancy, dribbling, and a sense of incomplete bladder emptying. Later presentations with metastasis may include back or pelvic pain.

## Cause/Occurrence

There is a higher incidence of prostate cancer in African American males in the United States and lower rates for Asian males while in Asia. Rates increase for Asian males when they immigrate to the United States, indicating an environmental influence. The development of prostate cancer is related to an interaction of genetic predisposition, dietary factors, and lifestyle. Two genes, RNASEL and MSR1, may increase the risk of prostate cancer in relation to infection.<sup>21</sup> It is now believed that prostatic inflammation, either septic (as in sexually transmitted infection) or aseptic, may progress to proliferative inflammatory atrophy. Loss of  $\pi$ -class glutathione-S-transferase (GSTP1) enzyme caretaker function then allows the development of cells of prostatic intraepithelial neoplasia and prostate cancer cells. The findings from one large study indicate that approximately 42% of cases of prostate cancer are related to inheritance, with the remainder most likely due to environmental factors.<sup>22</sup> Possible dietary relationships include:

- A diet high in animal fats and meats may increase the risk of prostate cancer (especially meats cooked at high temperature or grilled/broiled, which form heterocyclic aromatic amine and polycyclic aromatic hydrocarbon carcinogens).<sup>23</sup>
- Low vegetable intake: High intake of the antioxidant carotenoid lycopene, found in tomatoes, may be associated with a reduced risk of prostate cancer.<sup>24</sup> Also, high intake of cruciferous vegetables containing isothiocyanate sulforaphane may reduce risk of prostate cancer.<sup>25</sup>
- Supplementation with vitamin E and selenium may reduce risk of prostate cancer.
- Although zinc supplementation may be protective at low levels, one study indicated that zinc supplementation above 100 mg/day might increase the risk of prostate cancer.<sup>26</sup>

Adenocarcinoma of the prostate is only second to lung cancer as a cause of cancer-related death in men. Incidence increases with age so that by age 65 years and older, 75% have some prostate cancer.<sup>27</sup>

Most prostate cancers do not progress to metastasis and death. However, those with local disease and high tumor grade tend to progress. Although the incidence does not increase, the risk of fatal prostate cancer increases with smoking, tallness, high calcium intake, and is inversely related to physical activity.<sup>28-30</sup>

## Evaluation

There is still considerable controversy regarding the use of prostate-specific antigens as a screening approach for prostate cancer. Factors including a high false-positive rate, numbers needed to treat, and the effect of obesity on interpretation have made definitive recommendations for threshold levels difficult. Among others, the American College of Preventive Medicine

concluded in 2008<sup>31</sup> that there is insufficient evidence to recommend routine screening with digital rectal examination or PSA. African American men and those with positive family histories cause a higher level of concern, and therefore suggest the use of these screening tools.

For those at high risk (familial predisposition or African Americans), an annual DRE and PSA screen should begin at age 40 years.<sup>32</sup> For men not at high risk, annual screening with DRE and PSA should begin at age 50 years.<sup>32</sup> PSA values in the 4 to 10 ng/mL range have a 25% positive predictive value. PSA values higher than 10 ng/mL have a 67% positive predictive value. Also, the measurement of free and total PSA may help. The proportion of free-to-total PSA is higher for men with BPH and lower in men with prostate cancer. Other available testing includes PSA density, PSA velocity, and PSA age-specific ranges, although their value has not been established. An elevated PSA and an abnormal DRE will usually result in transrectal ultrasound-guided prostate biopsy. Four to six samples are often recommended to increase the yield. The grading system for prostate cancer is the Gleason system. This is divided into five grades based on degree of differentiation. The reality is that the debate continues; the U.S. Preventive Task Force acknowledges that it does save lives for men between around 50 to 65 years of age, but the change in mortality overall does not seem affected. It still is a complex decision to be made with the patient.<sup>33</sup>

## Management

Patients who are over 70 years old or have less than 10 years' life expectancy are usually not treated. Options for those in need of treatment include radical prostatectomy, radiation therapy, or hormonal therapy. As noted above, patients who smoke and have a high calcium intake are at higher risk for fatal cancer. Those who are more physically active, have a high fruit intake, and supplement their diet with zinc and vitamins C and E may have a lower risk for fatal prostate cancer.<sup>34,35</sup>

# CHAPTER 35

## Enuresis

### Context

Nocturnal enuresis is a distressing disorder for parents and children. Approximately 5 to 7 million children in the United States are affected. It is more common in boys than in girls. Girls are more likely to have daytime incontinence, more often associated with bacteriuria. In a large study in Sweden, 2.9% of girls and 3.8% of boy school entrants reported bed-wetting once per week.<sup>1</sup>

Parents are often unaware of the natural history of continence development and expect their child to be continent at a relatively early age. One study indicated that between 30% and 70% of parents punish their children for bed-wetting.<sup>2</sup> Ironically, there is a strong genetic component. Children whose parents both have a history of enuresis as a child have a 77% chance of bed-wetting, 44% chance if only one parent has a positive history, and only 15% chance if neither did.<sup>3</sup>

Parents seeking a nondrug, nonparent-intensive approach to bed-wetting seek a chiropractor's advice. The chiropractor may perform the initial evaluation to determine known causes such as urinary tract infection or diabetes. The nonpathologic, neurodevelopmental type of enuresis may be managed with conservative approaches. When these fail, referral for medication may be warranted.

Enuresis has been defined by the American Psychiatric Association as bed-wetting occurring in a child at age 5 years or above (and mental age of 4 years). The frequency is defined as two or more incontinent occurrences in a month between the ages of 5 and 6 or one or more occurrences after age 6 years in children who do not have an associated physical disorder such as urinary tract infection (UTI), diabetes, or seizures.<sup>4</sup> At age 5 years, approximately 20% of children have enuresis, which decreases to 10% at age 10 years and 1% at age 15 years.<sup>5, 6</sup>

Enuresis is often categorized into primary and secondary causes. Primary causes include both functional and structural causes. Secondary enuresis is defined as the presence of a prior history of continence for more than a six-month period. These patients often have a regression due to a stressful emotional event in the early years of life. Approximately 80% to 90% of childhood enuresis is the primary type.<sup>7, 8</sup>

When not due to a structural cause, enuresis seems to follow a natural spontaneous remission. This natural history must be taken into account when it appears that a child is responding to a specific therapy. Without any specific therapy the natural history indicates that 50% of patients will become continent within four years. The prevalence of enuresis decreases with age at a rate of 10% to 20% per year after age 6.<sup>9</sup>

## General Strategy

## History

- Determine whether the patient fits the criteria for nocturnal enuresis.

- Determine identifiable causes such as a history or indications of diabetes, seizures, or other neuromuscular contributors.
- Determine the family history of enuresis.
- Determine the environmental and social history of the child with regard to changes in living environment, stresses, any psychologic problems, and parental punishment for enuresis.
- Determine any other treatment methods that have been attempted, and the patient/parent compliance.

## **Evaluation**

- Evaluate the neurologic status of the child with emphasis on peripheral sensation and reflexes, genital sensation and perianal reflexes, and a search for any indications of congenital abnormalities such as clubfoot, spina bifida, or other.
- If there are associated complaints of frequent urination or irritation while urinating, obtain a urinalysis.
- Referral for specialized studies such as diagnostic ultrasound or cystourethrograms should be reserved for those patients who have daytime incontinence or signs of frequent UTI.

## **Management**

- If chiropractic management is suggested to the patient, discuss the rationale and literature support and other conservative options, including their advantages and disadvantages.
- If food allergies are the cause of detrusor instability, advise the parents to eliminate dairy products, colas, chocolate, and citrus juices for several weeks to determine the effect.

- The bell-and-pad urine alarm method is probably the most effective approach.
- For those children with persistence and failure of conservative approaches, medical options may be considered; the natural course of enuresis, however, should be discussed with the parents.

## **Relevant Anatomy and Physiology**

Bladder control is an intricate balance among several neural systems. The tension within the bladder that is generated by filling must be balanced by restriction of outflow at the bladder neck. The primary innervation of the body of the bladder is parasympathetic (pudendal nerve S2-4).

Therefore, parasympathetic stimulation facilitates urination by causing contraction of the body of the bladder (detrusor muscle) and urinary sphincter relaxation. Sympathetic innervation is via the hypogastric nerve plexus with nerve cell bodies at T11-L2.  $\beta$ -adrenergic (sympathetic) stimulation causes detrusor muscle relaxation during filling.  $\alpha$ -adrenergic (sympathetic) stimulation in the bladder neck (which acts as an internal urethral sphincter) acts to prevent urination.

The micturition center is located in the pons and acts to inhibit urination. Cortical override occurs through connections from the frontal lobe, corpus callosum, and cingulate gyrus, which generally inhibit the pontine micturition center.

There is a normal micturition maturation that occurs, paralleling changes in bladder capacity and neural development. In the first two years, a child has little control over urination, yet senses when the bladder is full. By the age of 3 years, a child should have some development of

daytime control. By ages 4 and 5 years, the child should be able to control urination in mid-stream with starting and stopping at will. A delay in this normal maturation and a small bladder capacity (less than 50% of normal in 85% of enuretic children) seem to be the primary factors.<sup>3</sup> Another treatment-based theory centers around an abnormal diurnal rhythm of antidiuretic hormone (ADH) secretion.<sup>10</sup>

If there is a decrease or absence during sleep, excessive amounts of unconcentrated urine accumulate.<sup>11</sup> This mechanism may account for enuresis in older children, given that one study found the bladder capacity of these children to be normal.<sup>12</sup>

## Evaluation

## History

First, it is necessary to determine whether the child fits the criteria for enuresis. The child may, in fact, be too young or have infrequent occurrences. When these criteria are met, it is important to screen the child's history via the parent with regard to underlying psychiatric disorders or systemic disorders such as diabetes. If such disorders are not found, performing a review of systems should identify any suspicions with regard to urinary tract infections or diabetes.

Because of the strong familial tendency, it is crucial to identify a family history of enuresis. As mentioned above, the number of relatives (especially parents) with a history of enuresis has an effect on the tendency of a child to have enuresis. Beyond this observation, Ferguson et al.<sup>13</sup> noted that the number of first-order relatives with enuresis correlated with when a child would attain continence. Those with two or more first-order relatives were 1.5 years late in

attaining control, compared with those with no family history.

## Examination

The physical examination is often unrevealing. However, it is important to check genital sensation, perianal reflexes, and peripheral sensation and reflexes. Observation of voiding may be helpful in determining control, caliber of stream, and any associated discomfort.

A host of studies may be performed on the enuretic child, but urine screening tests may help obviate the need for further testing. Measurement for bacteriuria, glucose, blood, casts, and a first-morning urine sample for specific gravity will help disclose whether diabetes, renal disorders, or disorders of urine concentration, respectively, are involved in the patient's enuresis.

Further evaluation using voiding cystourethrograms, renal and pelvic ultrasound, or intravenous pyelograms should be reserved for those with daytime incontinence and associated signs of UTI. These tests are expensive and often are ordered prematurely in cases of primary nocturnal enuresis.

## Management

The reality of primary nocturnal enuresis management is that no treatment has been found to be significantly superior to the natural history on a consistent basis.<sup>14</sup> Most forms of therapy may have an initially high success rate, yet relapse is extremely common. Methods that do work seem to be most effective in older children. Primary care physicians apparently rely more on a pharmacologic approach than a conditioning approach, with as many as

50% of them prescribing medication; 5% prescribe urine-alarm systems.<sup>15</sup>

The role of manipulative therapy has yet to be defined. Few studies have been performed. One or two case studies and two large studies have been published.<sup>16-19</sup> It is difficult to conclude that chiropractic manipulative therapy is effective, given the limitations of these studies. Unfortunately, most studies suffered for lack of longterm follow-up evaluation to determine maintenance of continence or relapse. In generalizing, the two larger studies indicated 15.5% and 25% improvement rates in the treatment groups. Given that the annual remission rate is between 10% and 20% per year, it does not appear that manipulation provides a significant effect over the natural history of the disorder. The one advantage may be that the effect may occur sooner than it would with natural history. Larger studies with longer follow-up periods are required to define more clearly chiropractic manipulation's role in enuresis management. One other difficulty is that the studies that have been performed and the textbooks that recommend specific treatment for enuresis are consistently inconsistent about which spinal levels to address. A side note is that some researchers have attempted to identify a relationship between spina bifida occulta and diurnal enuresis in children. This association seems related only when other clinical findings of neurologic abnormalities are apparent that suggest underlying lipoma or a tethered cord.<sup>20</sup>

It is generally agreed that the most effective therapy is conditioning therapy using a bell-and-pad urine alarm. The alarm system has been studied extensively and is consistently better than medication, desmopressin, and behavioral treatment.<sup>21</sup> Success rates average between 50% and 80% in children over 8 years of age if there is strict compliance for four to six months.<sup>22</sup> Unfortunately, the relapse rate is between 15% and 47%. Noncompliance

occurs in at least 20% of cases. The intention of the alarm approach is to signal the child to awaken through an alarm that is set off by moisture sensors attached to the pajamas. The child is then instructed to finish voiding in the bathroom, change clothes and bedding, and reset the alarm.

It has been suggested that food allergies may play a role in detrusor instability.<sup>23</sup> Unfortunately, the studies have failed to identify specific foods or to use control groups to compare effect. Foods that have been suggested are dairy products, cola, chocolate, and citrus juices.<sup>24</sup> One study attempted to individualize the treatment approach by starting subjects on an oligoantigenic (few foods) diet.<sup>25</sup> When enuresis was improved, introduction of a single food at a time allowed identification of the antigenic food. This study focused on enuretic children with migraine or hyperkinetic behavior. Elimination diets have been proposed by others in the broader group of enuretic children.<sup>26</sup>

When conservative approaches fail, referral for medical management may be warranted. Two approaches are used. One is the administration of a tricyclic antidepressant, imipramine hydrochloride, for two to three months followed by gradual reduction over the following three to four months. The success rate is between 25% and 40% after withdrawal. Some studies have shown less dramatic success.<sup>3, 6, 9</sup> It is believed that the medication lightens sleep and improves voluntary control of the urethral sphincter with an associated increase in bladder capacity. The major concern with imipramine is side effects and—as one review paper suggests—accidental overdose.<sup>27</sup> The main side effects are dry mouth, blurred vision, lethargy and headaches, abdominal pain, mood and sleep disturbances, and in rare cases syncope and cardiac arrhythmias.<sup>28</sup>

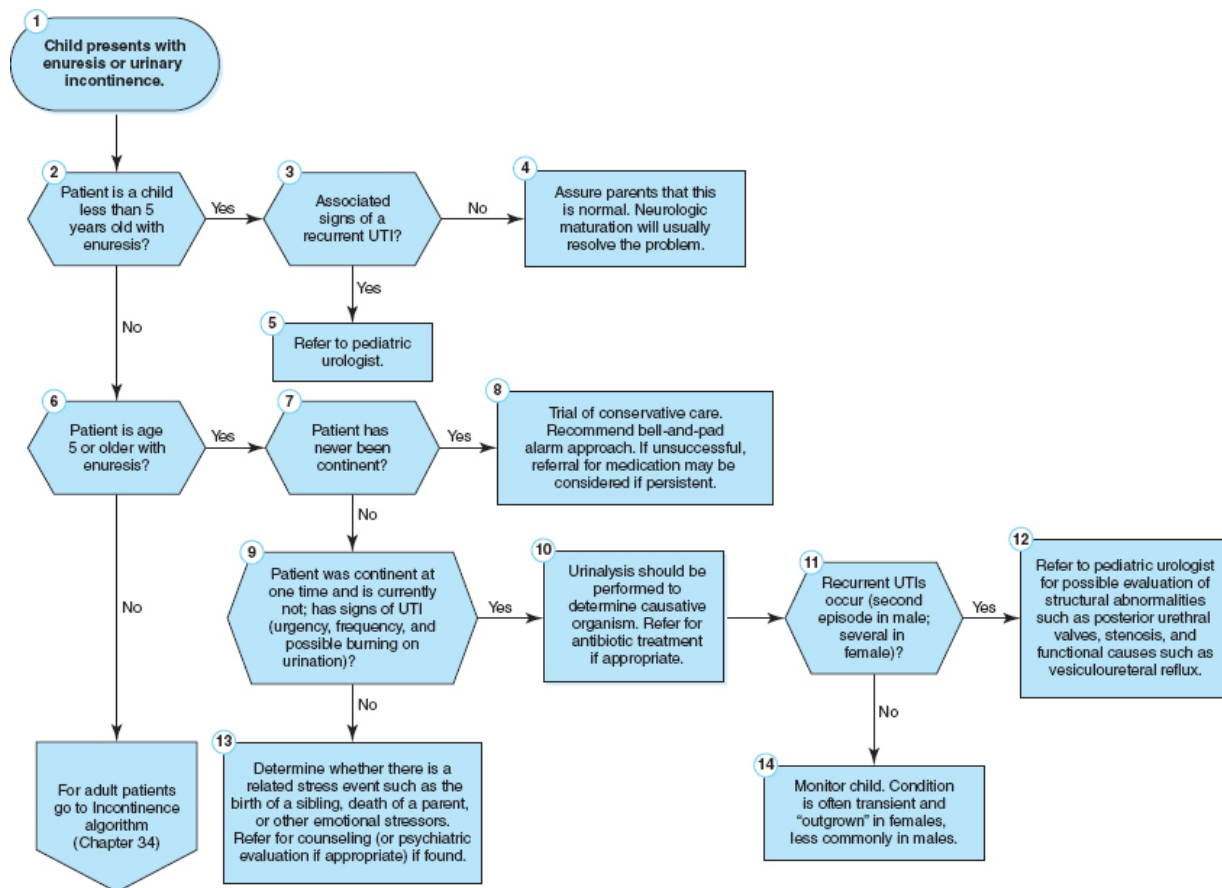

Although intranasal ADH (desmopressin) has been advocated as a viable treatment option for enuresis, studies indicate that the numbers of children who improve are relatively small and that the relapse rate is quite high.<sup>29</sup>

Additionally, the cost is high. When desmopressin is effective, it is usually evident within two weeks. The short-term success is as high as 70%; however, this is decreased to between 17% and 41% with drug withdrawal. Some studies indicate a higher success with older children. Most side effects are related to the portal of delivery. Nasal irritation, epistaxis, and headaches are the most common. Water intoxication may occur rarely and can be prevented with a serum electrolyte measurement taken at one week after therapy is initiated.

## Algorithm

An algorithm for evaluation and management of enuresis in children is presented in **Figure 35-1**.

# CHAPTER 36

## Vaginal Bleeding

### Context

A patient would rarely present to a chiropractor with a chief complaint of vaginal bleeding. However, with directed questioning on a review of systems, a complaint of abnormal bleeding may surface. The chiropractor's role in this scenario is to narrow the list of possibilities to determine whether there is a cause for concern and what that concern may be. Narrowing the list is primarily a historical process; however, some chiropractors trained in pelvic examination may extend the search through physical examination, adding more information to the referral.

### General Strategy

### History

- Determine the patient's staging with regard to her menstrual cycle.
- Determine whether the bleeding appears to be ovulatory or anovulatory.
- Determine whether there are any indicators of thyroid disease.

- Determine whether the patient is taking medications that interfere with menstrual function.
- Determine the patient's use of contraceptives, including an intrauterine device (IUD).
- Determine whether the patient might be pregnant.
- Determine whether the patient has any secondary signs of bleeding loss, such as anemia or iron deficiency.

## **Evaluation**

For those chiropractors who have training and experience, perform a thorough pelvic examination.

## **Management**

Refer the patient to her gynecologist with a letter or phone call explaining relevant findings.

## **Relevant Anatomy and Physiology**

Menarche is not a fully matured occurrence. Maturation of the central nervous system (CNS)-hypothalamic-pituitary axis is the result of a complex triggering of hormonal release that, when not complete, may cause bleeding. The endometrium is the target site for the effect of this hormonal interplay. Phases in the growth and subsequent degeneration of the endometrium are based on hormonal dominance. In the proliferative phase (days 5 to 14 of the cycle), the ovarian follicle secretes estrogen, which stimulates the growth of the endometrium. The secretory

phase (days 15 to 28 of the cycle) is dominated by progesterone, which is released from the corpus luteum. Progesterone stops the development of the endometrium and stimulates differentiation to a secretory epithelium. Both progesterone and estrogen levels drop if conception does not occur by about day 23. This is due to the degeneration of the corpus luteum. The dramatic decrease in progesterone and estrogen triggers the release of follicle-stimulating hormone (FSH). FSH stimulation of ovarian follicle growth causes a concomitant rise in estrogen from the follicle. At the midcycle, a sudden rise in estradiol causes a rise in FSH and a surge of luteinizing hormone (LH), which leads to the formation of the corpus luteum. Without this LH surge, ovulation does not occur.

During adolescence, ovulation does not occur initially. Gonadotropin levels must reach a level high enough to stimulate development of ovarian follicles, which in turn produces estrogen, which in turn leads to the necessary LH surge leading to ovulation. This LH surge may not occur until as late as five years postmenarche.<sup>1</sup> Approximately 75% of abnormal bleeding in the adolescent is due to immaturity of this system.<sup>2</sup>

Dysfunctional bleeding occurs in the perimenopausal (before menopause) woman because of the decreased sensitivity of the ovary to FSH and LH. The resulting decrease in estrogen prevents the LH surge necessary for ovulation. However, similar to the adolescent, there is still enough estrogen being produced to stimulate endometrial growth. Without the balance of progesterone that would normally be produced by the corpus luteum, the endometrium becomes extremely vascular and friable, leading to intermittent sloughing. This type of bleeding is often referred to as estrogen withdrawal bleeding. Estrogen breakthrough bleeding may be due to (1) constant low levels of estrogen, causing portions of the endometrium to degenerate (often seen with low-dose oral contraceptive

use); and (2) high levels of estrogen, which allow the endometrium to become hyperplastic and outgrow its blood supply, leading to degeneration and often profuse bleeding. Another type of hormonal imbalance bleeding is progesterone withdrawal and breakthrough bleeding. This is usually the result of exogenous administration of progesterone.

## Evaluation

Vaginal bleeding is usually due to uterine bleeding. The causes of vaginal bleeding are limited and are usually the result of trauma or atrophic vaginitis found in elderly women. Uterine bleeding should be correlated with the woman's menstrual history in an attempt to place her in a stage of menstrual development. Chronologically, a woman's reproductive system's development may be divided into the following five stages:<sup>3</sup>

- 1.** premenarchal
- 2.** menarche
- 3.** the reproductive years
- 4.** perimenopausal
- 5.** postmenopausal

This categorization is useful in considering the most likely causes in each stage of development. Bleeding in stages 1 and 5 is abnormal and warrants investigation. In premenarchal years, the most common cause is direct trauma and/or sexual abuse. In postmenopausal years, any bleeding that appears to be uterine should be suspected to be cancerous in origin. Irregular bleeding during menarche and perimenopausal stages is often the natural consequence of fluctuations in hormonal balance. However, one-fifth of abnormal bleeding during menarche is due to a

bleeding diathesis. During the reproductive years, the major concerns are that there may be excessive bleeding and there may be bleeding during pregnancy. Alterations in the degree and timing of bleeding related to the menstrual cycle are defined by specific terms as follows:

- polymenorrhea—more frequent than every 20 days
- oligomenorrhea—less often than every 42 days
- menorrhagia—bleeding lasting longer than 8 days
- metrorrhagia—bleeding between periods

The time limits listed above are generalizations and may vary with other text definitions by a few days.

The major differential pivot point is whether bleeding is ovulatory or anovulatory. Ovulatory bleeding is cyclic and is associated with dysmenorrhea and some premenstrual symptoms. In general, the cause is usually a pelvic lesion such as endometriosis, fibroids, an IUD, pelvic inflammatory disease (PID), or pelvic tumors. Anovulatory bleeding is irregular and usually painless; it is often heavy. Endocrine dysfunction or contraceptive use is often the cause. Anovulation often is due to lack of production of LH during the midcycle. The type of bleeding may suggest an underlying cause. If bleeding is bright red with associated clots, a nonmenstrual flow is suggested.

The examination is limited to determination of endocrine causes or a bleeding tendency. An evaluation for thyroid dysfunction is prudent. Pelvic examination should be performed by chiropractors with training in a search for a bleeding source such as tumors. Laboratory evaluation may be helpful in determining whether the patient is anemic.

## **Management**

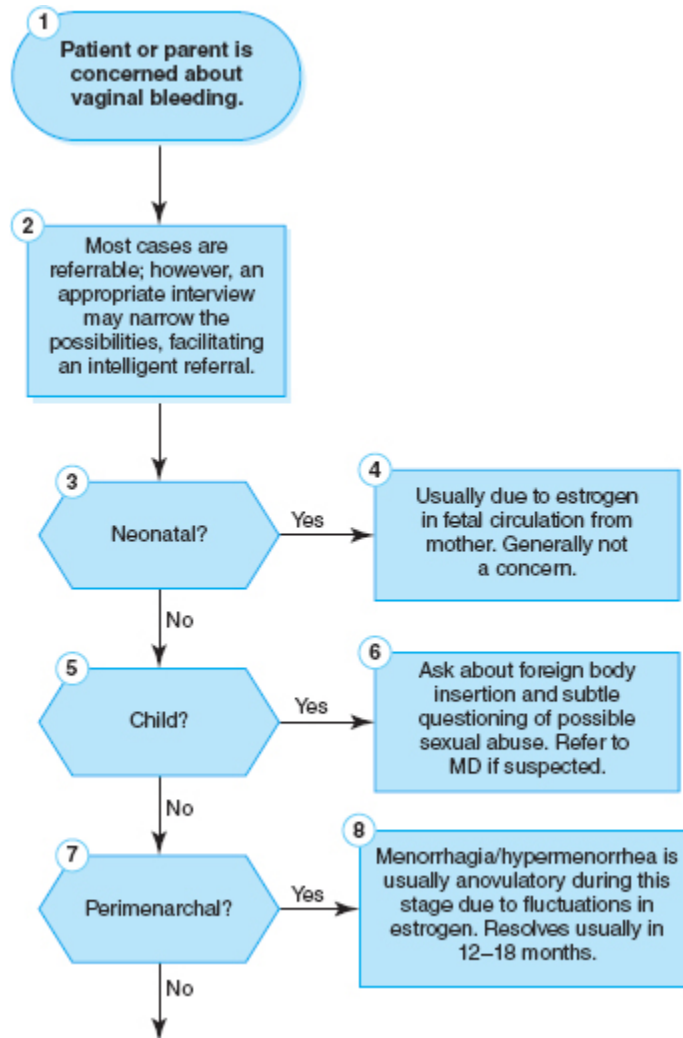

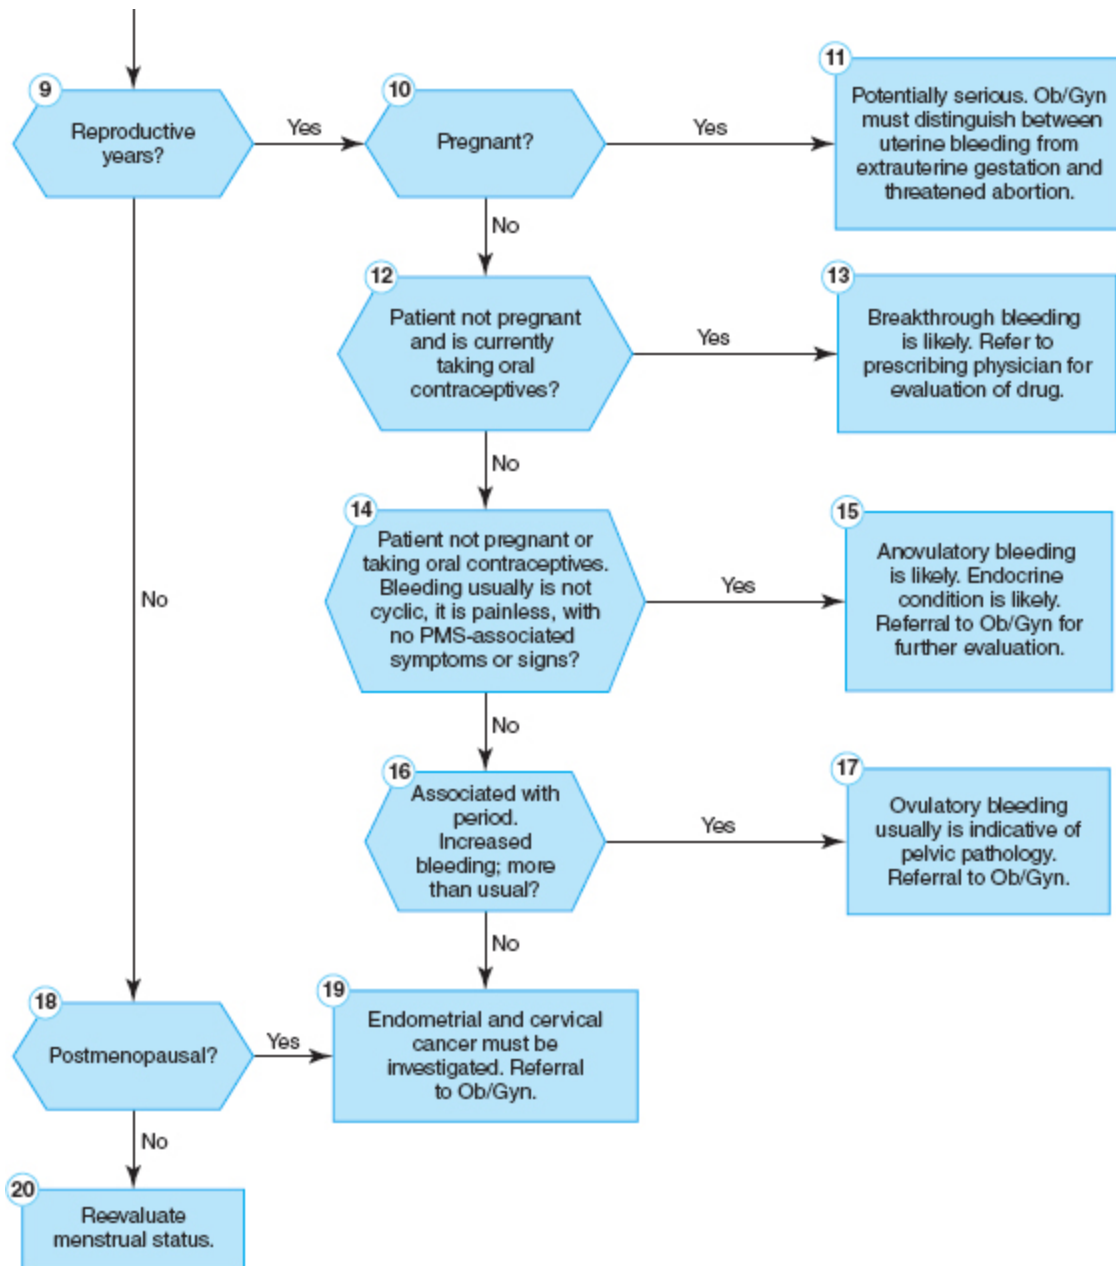

After performing a thorough history and brief examination, the patient should be given an explanation as to the different types of bleeding and what is specifically suggested in her case. Referral should be made with a letter explaining the doctor's rationale or recommendations.

If a structural lesion is not found to be the source of bleeding, an attempt at controlling the bleeding and normalizing the cycle is made. The standard form of treatment is prescription of oral contraceptive pills (OCPs) or nonsteroid anti-inflammatory drugs (NSAIDs). Both OCPs and NSAIDs can reduce bleeding by up to 50% (NSAIDs usually are a little less effective).<sup>4, 5</sup> NSAIDs have a strong vasoconstrictive effect. A side benefit is possible reduction of any associated dysmenorrhea. A small number of women may have an increase in bleeding.

## Algorithm

An algorithm for evaluation and management of vaginal bleeding is presented in **Figure 36-1**.

**Figure 36-1** Vaginal Bleeding—Algorithm

Part VI

# Cardiopulmonary Complaints

# CHAPTER 37

## Syncope/Presyncope

### Context

Syncope is the cause of approximately 3% of emergency department visits and 6% of hospital admissions; however, it generally represents a benign clinical entity in and of itself.<sup>1</sup> In the Framingham study, it was found that about 3% of individuals will have an episode of fainting. Syncope was not associated with an increased risk of stroke, myocardial infarction, or sudden death.<sup>2</sup> In 40% of cases, the cause is not identified and up to 30% of individuals have recurrent episodes. Certainly in the senior population the list of possible causes increases with increasing medication use, atherosclerosis, and dysfunctional neurogenic reflexes.

Although it is not a common primary complaint in the chiropractic setting, syncope is often a secondary concern or is evident on a past history review. Generally, the patient will ignore an infrequent sense of almost fainting (presyncope); however, he or she will be quite concerned with actual fainting if not obviously associated with a stressful, painful, or “sickening” scenario.

The most common cause in younger individuals is vasovagal faint. In the elderly, cardiac dysfunction and carotid sinus hypersensitivity are high on the list of causes.

### General Strategy

# History

- Determine whether the patient has actually fainted or has almost fainted (syncope versus presyncope).
- If the patient did faint, determine whether he or she or a witness can answer questions regarding how long the loss of consciousness (LOC) lasted and whether there were accompanying convulsions or any significant warning symptoms or postfaint signs or symptoms (distinguish between syncope and seizure).
- Determine the frequency of these events.
- Determine the patient's medication history (alcohol, diuretics, vasodilators, antidepressants, sedatives, or sympatholytic drugs).
- Determine whether there was an associated historical trigger such as heat (vasodilation), prolonged standing (pooling effect), sudden pain, emotional stress, tight collar (carotid sinus syndrome), turning the head to one side (carotid sinus syndrome), exercise (hypertrophic subaortic stenosis or vascular pooling), coughing (cough syncope), urinating (micturition syncope), a frightening/nauseating situation (vasovagal), or anxiety (hyperventilation).

# Evaluation

- Test the patient with supine and standing blood pressure measurements (orthostatic hypotension).
- Perform or refer for electrocardiogram (ECG).
- Evaluate the patient with laboratory tests to determine whether anemia or diabetes is present.
- When the diagnosis is not clear, consider referral for tilt-table testing (vasovagal syncope).

# Management

- If triggers are avoidable, give the patient advice regarding a defensive approach.
- Give the patient strategy options for when the sensation of fainting first recurs.
- Refer cases that seem to be medication-related or are unexplained/frequent episodes.

## Relevant Physiology

There are several important cardiovascular reflexes that may be influenced by medications, structural abnormalities, and emotional and environmental factors. There are two broad classifications of receptors that participate in these reflexes based on location and function. First are high pressure receptors. These are found in the walls of arteries, specifically in the carotids and the aortic bodies. The second is a low pressure receptor with two different types. First is the atrial stretch type and second the ventricular type (Bezold-Jarisch reflex). The atrial stretch receptors participate in two reflexes, the atrial stretch reflex and the Bambridge reflex.

Syncope or presyncope is often the result of a pooling effect of either prolonged standing or extreme heat, or the vasodilative effects of many medications. Interference with the normal functioning of cerebral blood pressure may be the result of a dysfunctional neuronal reflex. This occurs in the elderly, those with diabetes, and those with a dysfunctional adrenal gland. With the elderly, a combination of hypersensitivity of the carotid sinus and decreased neuronal conduction may contribute to a decrease in blood pressure upon rising, referred to as orthostatic hypotension. This may be potentiated by certain medications known to

blunt the sympathetic response, such as  $\beta$ -blockers. Also, patients with volume depletion caused by diuretics, vomiting, or diarrhea may develop orthostatic hypotension.

Patients with orthostatic syncope appear to have neurocardiogenic dysfunction due to autonomic dysfunction. They demonstrate  $\beta$ -adrenergic hypersensitivity.<sup>3</sup> Patients who become faint with exercise or fasting may have vasodepressor syncope. This has been shown to occur following a rise in  $\beta$ -endorphin concentration just before syncope. These endogenous opiates have an inhibitory effect on sympathetic tone.<sup>4</sup> Another suggested cause in exercise-induced presyncope or syncope is inappropriate peripheral vasodilation due to ventricular mechanoreceptor stimulation. This was found in patients who had no discernible cardiac structural abnormalities.<sup>5</sup> These two theories obviously may overlap. Another theory to consider is that these individuals have a failure to decrease parasympathetic tone.<sup>6</sup> In addition to syncope, other autonomic nervous system dysfunction signs and symptoms may be related to hypermobility syndromes.<sup>7</sup> Presyncope, palpitations, chest discomfort, fatigue, and heat intolerance appear to be more common in patients with hypermobility. In particular, orthostatic hypotension was found in 78% of patients diagnosed with joint hypermobility syndrome who fulfilled the 1998 Brighton criteria.

Obviously, any decrease in blood supply to the head is a potential syncope cause. Therefore, a consideration of the pulmonary and cardiovascular systems structurally, functionally, and physiologically is needed. Blockage of outflow due to aortic (or subaortic) stenosis will decrease blood supply to the brain. Severe atherosclerosis is also a consideration. Functionally, the heart must pump effectively to maintain cerebral perfusion. Arrhythmias and heart block may result in hypoxia and syncope in some patients. Anemia is rarely a cause of syncope; with severe blood loss or severe anemia due to other causes, however, exertional

syncope may occur. In particular with chronic obstructive pulmonary disease, decreased perfusion or oxygenation may result in a relative cerebral hypoxia.

## Evaluation

## History

The initial focus of the history is to attempt to differentiate between syncope and seizure (**Table 37-1**). This is not as clear-cut as first assumed. One study demonstrated that, when syncope was induced through a combination of hyperventilation, Valsalva maneuver, and orthostasis, myoclonic activity occurred in 90% of those who fainted. Additionally, head turns, automatisms, and righting movements were observed in 79% of patients who fainted.<sup>8</sup> An important clue is the length of LOC. With a simple faint, the patient is often conscious within seconds. This may be extended in some instances, such as with hypoglycemia. When an epileptic seizure is the cause of LOC, the patient is usually unconscious for much longer; when there is convulsive activity, it usually lasts for several minutes. With a simple (vasovagal) faint, most patients have a warning with prodromal symptoms such as nausea, yawning, or belching with accompanying symptoms of lightheadedness, sweatiness, and cold hands. After fainting, the patient with vasovagal syncope is usually able to become functional in a short period of time. Those with seizure-associated LOC take much longer to regain function and often are disoriented after regaining consciousness. In addition, there may be signs of incontinence, extreme tiredness, and general body aching after a seizure episode (postictal). Eyewitnesses often are necessary to document the length of LOC and the associated patient activity during the attack.

**Table 37-1** History Questions for Syncope

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
What position were you in when you fainted?	Recumbent suggests cardiac. Upright suggests vasovagal. Rising suggests orthostatic hypotension.	Were you doing anything just before fainting? How did you feel after fainting?	Twisting/turning head suggests subclavian steal syndrome. Coughing suggests Valsalva response. Urinating suggests micturition syncope.
How did you feel just prior to fainting?	Sweating, lightheadedness, or queasiness suggests vasovagal. Visual, auditory, or olfactory prodrome suggests an aura (seizure). Vision "closing in" or going dark suggests cardiac or orthostatic.	How did you feel after fainting?	Confusion with possible incontinence suggests seizure rather than vasovagal or cardiac syncope.
How quickly did you regain consciousness?	Less than 1 minute suggests vasovagal. Five to 15 minutes is more common with epilepsy.	Were there witnesses?	Try to determine whether there was seizure activity.
Are you taking any medications?	Medications that vasodilate (antihypertensives), deplete fluid (diuretics), or cause nervous system depression (sedatives) are high on the list.	Have you been diagnosed with a condition for which medication was prescribed, but you do not take the medication?	Diabetes. Arrhythmia.
Is this related to exertion?	Cardiopulmonary dysfunction. Extreme exertion with volume depletion or in extreme heat.	Did the fainting occur with exertion or after exertion?	With exertion, cardiopulmonary status should be checked; aortic stenosis, anemia, or pulmonary hypertension. After a strenuous event, rule out dehydration or heat exhaustion, then consider hypertrophic cardiomyopathy.
Were you emotionally stressed?	Most common cause is simple (vasovagal) faint. Anxiety-related hyperventilation.	Were there symptoms prior to fainting?	Nausea, lightheadedness, sweating/clamminess, and cold hands suggest simple faint. Numbness, paresthesias, and cold hands suggest hyperventilation.

A determination of whether the patient was standing, sitting, or lying down at the time of syncope is often revealing. Patients who faint when lying down are almost always suffering from a cardiac condition such as an arrhythmia or heart block. If the patient faints when in an upright position, vasovagal syncope is the most likely cause. This may be precipitated by prolonged standing, causing pooling of blood in the lower half of the body, or by heat, causing vasodilation. If the patient reports the occurrence only when rising from a recumbent position, orthostatic hypotension is most likely the mechanism. The normal sympathetic response from lying to standing causes splanchnic vasoconstriction (mainly venous) to prevent

venous pooling in the abdominal area and increases the force of contraction of the heart. If the sympathetic effect is blocked by some medications or the autonomic nervous system is dysfunctional, this protective response is blunted. The most common drugs involved are those that decrease fluid volume (diuretics), cause vasodilation (many antihypertensives and erectile dysfunction medications), decrease the nervous system response (sedatives and sympatholytics), and antidepressants and antipsychotic medications. Some simple physiologic causes should also be suspected with orthostatic hypotension, such as prolonged recumbency or prolonged standing, the augmenting effects of pregnancy (vascular pooling), and volume depletion from prolonged vomiting or diarrhea and possibly an associated sodium depletion.

The relationship of syncope to exercise may also be an important clue. If fainting occurs with exertion, severe aortic stenosis (particularly in the elderly) or pulmonary hypertension should be suspected. If the syncope is postexertional (particularly in a young man) subaortic hypertrophic cardiomyopathy should be investigated. If the syncope occurs after a prolonged endurance event, many other factors, such as volume depletion and heat exhaustion, must be taken into account.

Exertional syncope in athletes is of particular concern due to the known incidence of sudden death. Syncope in athletes often indicates cardiac structural abnormalities. Athletes have a host of what would appear to be cardiac pathology based on ECG abnormalities including sinus bradycardia, first- or second-degree AV block, increased voltage of R- or S-waves, and incomplete right bundle branch block. It is best to refer to recommendations by the 36th Bethesda Conference to determine the appropriate course of action and athletic participation criteria for athletes with indications of cardiac involvement.<sup>9</sup> Although generally benign, mitral valve prolapse syndrome combined

with a history of syncope and mitral valve regurgitation may indicate an individual at risk for sudden death.<sup>10</sup>

There appear to be a few neurally mediated causes of syncope that are rare but worth mentioning because of strong historical clues. If syncope occurs with coughing, an exaggerated vagal response is likely. If syncope occurs post-urination a similar mechanism may be in effect. This type usually occurs in elderly men at night. If syncope is associated with facial pain provoked by swallowing or yawning, glossopharyngeal syncope is likely, due to a reflex mechanism. If the patient notices that syncope occurs while wearing a tight collar or when turning the head, carotid sinus syndrome is likely.

If the patient appears anxious or volunteers an association of presyncope with anxiousness, ask about associated symptoms such as numbness, paresthesias, and coldness in the extremities. Similar symptoms may occur with hypoglycemia; therefore, it is important to ask about the relation to meals, use of insulin, or use of hypoglycemic medications.

## **Examination**

Initial evaluation involves a search for cardiopulmonary disease through auscultation for carotid bruits, heart murmurs, or indications of congestive heart failure. Often the physical examination is unrevealing in those with a complaint of fainting or near-fainting. Most valuable is a search for orthostatic hypotension. The patient's blood pressure is taken supine and then standing after three minutes. A decrease of greater than 20 mm Hg in the systolic blood pressure or 10 mm Hg in the diastolic blood pressure is suggestive of orthostatic hypotension and warrants an investigation into volume depletion and neuronal dysfunction due to adrenal, medication, or diabetic

causes. Carotid sinus sensitivity is often tested with carotid massage. This is probably not prudent in the chiropractor's office in the event of complications. Many times this potential cause may be suspected from a historical report of tight collar or neck rotational provocation. Laboratory testing may be helpful in detecting an underlying problem with anemia, hyponatremia, diabetes, or more specific testing for endocrine dysfunction. Electrocardiographic evaluation or Holter monitoring may uncover an underlying arrhythmia as the cause, especially in those with a concomitant complaint of palpitations or in patients who faint while lying. In patients who faint after exertion it is important to obtain an echocardiogram to evaluate subaortic hypertrophic cardiomyopathy. If the patient appears to have a history of anxiety-related presyncope or syncope, perform a hyperventilation test whereby the recumbent patient hyperventilates for approximately one minute while the examiner appears to be auscultating the chest. If the patient becomes faint, a suspicion of hyperventilation as the cause is appropriate unless the patient has underlying cardiopulmonary disease.

Recently, upright tilt testing has been increasingly utilized for evaluation of vasovagal syncope. This test incorporates varying degrees of tilt for varying amounts of time to provoke syncope. A comprehensive literature review of upright tilt testing suggests that although isoproterenol is often used to augment the effect, its use is usually unnecessary, adding to cost, complexity, and a higher associated false-positive response. The recommended protocol is passive testing at 60° for 45 to 60 minutes. This approach seems to have a higher overall specificity than other methods.<sup>11</sup>

## Management

Referral is warranted for patients who appear to have any of the following:

- epilepsy
- a cardiac or pulmonary cause
- medication-induced syncope

For patients with orthostatic hypotension unrelated to medication, for patients who have an underlying disease that is managed by a medical doctor, or for patients with vasovagal syncope the following suggestions may be helpful:

- Avoid dehydration, fever, excessive heat, prolonged standing, prolonged recumbency, large meals, skipping meals, alcohol and unnecessary drugs, and quick standing.
- Rise slowly from a lying or sitting posture, maintain adequate fluid and salt intake, maintain physical conditioning, and support the lower extremities with elastic garments if venous insufficiency is a contributing factor.

# CHAPTER 38

## Chest Pain

### Context

Chest pain can be a frightening event. Patients often associate chest pain with the heart and experience enough concern to see a medical physician. The majority of patients with chest pain who present to a chiropractic office setting suspect that their pain is musculoskeletal or know from past diagnoses that their pain is cardiac and are being managed by a medical doctor. However, with some patients, there may be few historical clues or the pain is mild, leaving the patient unaware of an underlying problem of a potentially serious nature. Without a clear history of musculoskeletal cause, the assumption should be cardiac until proven otherwise. Conversely, noncardiac pain may be frighteningly convincing as a cardiac impersonator. The primary role of the chiropractor as a first-contact physician is to differentiate between cardiac (ischemic) pain and noncardiac pain. This is also often the difference between a referable condition and a nonreferable condition. It is crucial, however, that the chiropractor be aware of the important role he or she can play in the long-term comanagement of the patient with angina. The long-term quality of a patient's life and perhaps his or her prognosis may be affected through a lifestyle management approach with emphasis on diet, exercise, and stress management for which the chiropractor can play a supportive role.<sup>1</sup>

In the emergency department, the diagnostic distinction must first be whether or not the patient has acute coronary syndrome (ACS). Acute coronary syndrome represents coronary occlusion and subsequent damage. This is differentiated from stable angina where no damage occurs. There are three primary types of ACS, each representing about one-third of all ACS patients:

1. ST elevation myocardial infarction (STEMI)
2. Non-ST elevation myocardial infarction (NSTEMI)
3. Unstable angina

High-risk patients are usually identified using a version of the Thrombolysis in Myocardial Infarction (TIMI) score.<sup>2</sup> Included are older age (>65 years), use of aspirin without relief, known cardiac disease, ECG abnormalities (ST segment), elevated cardiac biomarkers, and other risk factors (among other

indicators), which are each given a point score and then the total is stratified based on risk. ACS represents only about 5% to 6% of all admissions to emergency departments in Europe and the United States,<sup>3</sup> and only 20% to 25% of admissions to the ED for *chest pain* are caused by ACS.<sup>4</sup>

Recently, clinical prediction approaches have demonstrated the ability to take low-risk patients and through a series of testing, which includes no high-risk factors on admission in the emergency department coupled with testing with serial cardiac troponins and electrocardiography, and exercise tolerance testing (ETT) if indicated, successfully identify 82% of patients as not having cardiac chest pain.<sup>5</sup> In another recent study,<sup>6</sup> only one-third of patients with chest pain and known coronary disease, but with negative ECG, and biomarkers were subsequently found to have adverse cardiac events.

Chest pain that appears to be cardiac may in fact be from another source. Studies indicate that 30% of patients who have catheterization for angina-like pain have no abnormalities angiographically. Of these patients, 50% may have pain due to esophageal disorders. The remainder may have microangiographic involvement not visible on angiography (syndrome X). It is estimated that musculoskeletal causes of chest pain account for approximately 13% to 30% of cases.<sup>7,8</sup>

Recurrent episodes of chest pain are estimated to affect 50% to 90% of patients with noncardiac chest pain.<sup>9</sup> Even though patients are told they do not have cardiac disease, only 30% to 50% feel reassured and as many as 50% remain on cardiac medication and 75% continue seeing a physician.<sup>10</sup>

## General Strategy

## History

- Attempt to distinguish between cardiac and noncardiac pain (**Exhibit 38-1** and **Table 38-1**).
- Use the history to develop a high level of suspicion for cardiac pain—diffuse, substernal pain with radiation into the arm (medial) or jaw, lasting between 10 and 60 minutes (**Table 38-2**).
- In those suspected of having angina, check the history for risk factors, triggers, and other indicators.
- Check the drug history of all patients to determine use of cocaine or other stimulants, and response to nitroglycerin in patients who previously have been diagnosed with angina; some patients do not take their medication properly.

## Evaluation

- Attempt to distinguish among the various causes of noncardiac chest pain—visceral, musculoskeletal, skin, psychogenic, referred, or local.
- Auscultate, obtain a screening electrocardiogram (ECG), and consider a chest radiograph when cardiac causes are suggested.
- With suspicion of musculoskeletal conditions, incorporate a mechanical challenge (stretch, compression, and palpation) in an attempt to reproduce the complaint.

## Management

- Refer cardiac-caused pain for comanagement (input on proper diet and exercise if pain is anginal).
- Manage musculoskeletal causes conservatively based on the tissue involved.

## Relevant Anatomy and Physiology

Cardiac pain is essentially ischemic pain. The degree of ischemia extends from mild, transient decrease of coronary blood flow to life-threatening infarction. Decrease in coronary artery blood flow (CABF) is generally due to vasospasm. Prinzmetal's (variant) angina is also possible as a pure or overlapping cause. CABF is also dependent on the status of the heart and its ability to pump an adequate supply of blood.<sup>11</sup> Specifically, the status of the aortic valve is important. If the aortic valve is stenotic, less blood leaves the heart. This is also true with aortic incompetence, where blood that would normally drain to the coronaries is allowed to return to the left ventricle. This in turn places a high demand on the heart to pump blood from a double source. Over 50% of patients with calcific aortic stenosis and angina have significant coronary artery disease.<sup>12</sup> Hypertrophic obstructive cardiomyopathy (HOCM) is a rare problem that in effect blocks off the aortic exit from the heart, often leading to sudden death. While it is developing it may give a prewarning with chest pain due to ischemia. Through a somewhat similar mechanism, mitral valve prolapse syndrome may cause atypical chest pain because of ischemia. Additionally, anemia may be a factor due to the decreased oxygen-carrying capacity of the blood. Other stimulators are increased sympathetic activity from mechanical or environmental stresses such as anxiety, cold, and exercise.

### **Differentiating between Cardiac Pain and Noncardiac Pain**

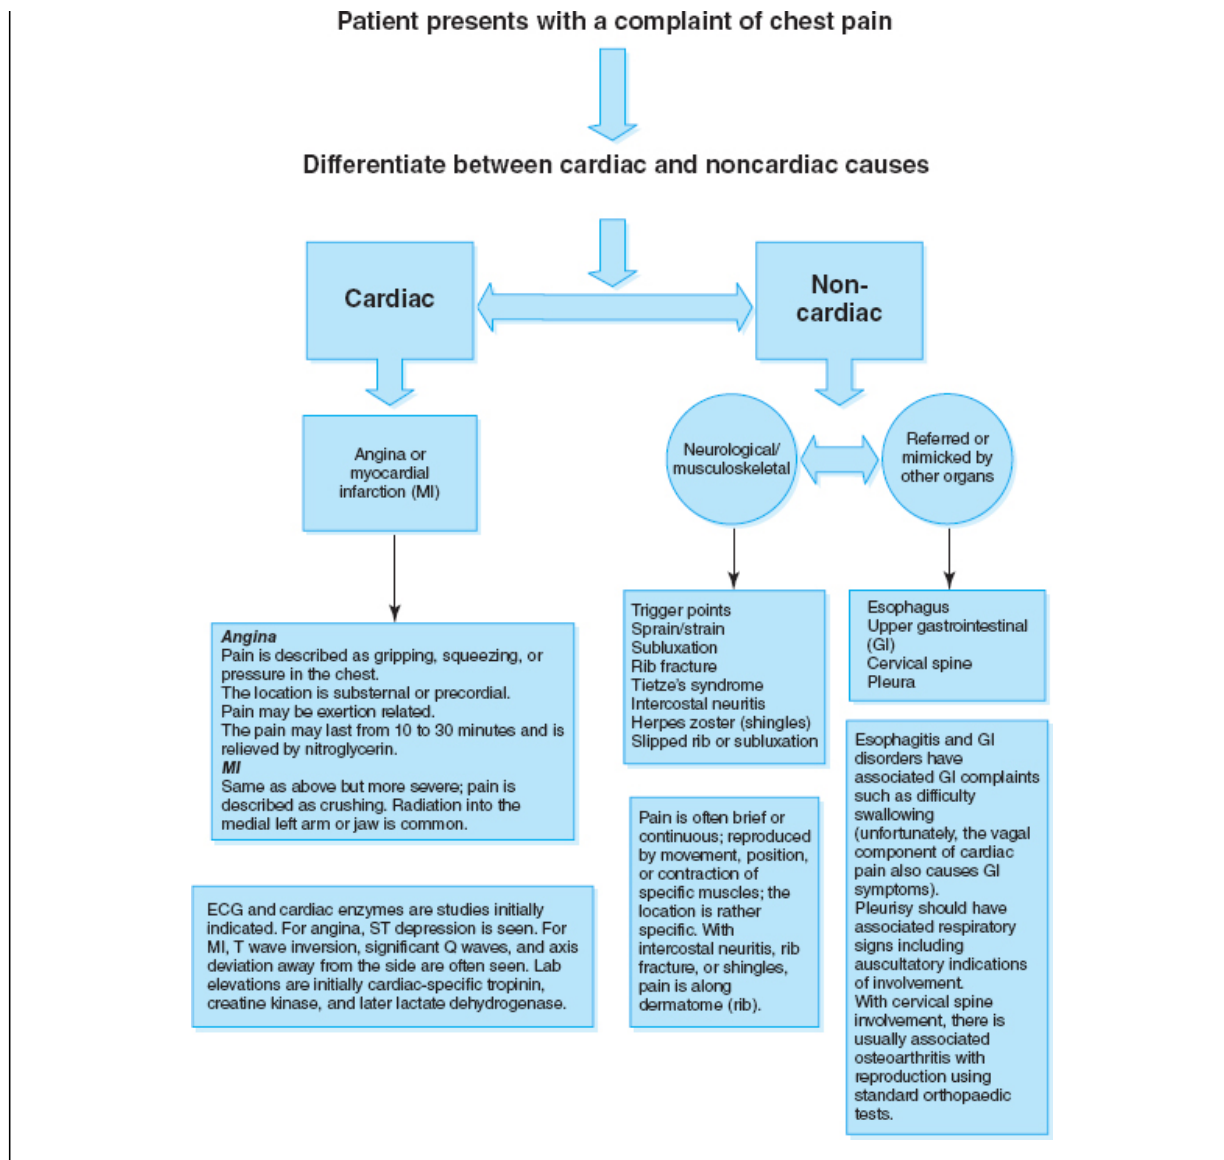

Chest pain is rarely lung pain because the sensitivity of the lungs to pain has been delegated to the endemic vasculature and surrounding pleura. This is why a patient may have bronchogenic carcinoma or other lung processes

such as chronic obstructive pulmonary disease (COPD) without any signal of pain until late in the process.

Pleural pain illustrates an important concept with regard to pulmonary conditions. Processes that affect the pleura such as pleurisy, pneumothorax, pulmonary embolism, and cancer cause pain that is relatively well localized. This is because the parietal pleura is a somatic structure and therefore is innervated by unilateral spinal nerves, making possible localization in vertical and horizontal planes. This also explains why positions such as side bending and lying on the involved side may increase the pain. The pericardium may also react similarly and cause a more localized, left-sided chest pain.

Visceral chest pain is often central, reflecting the embryologic arrangement of most thoracic and abdominal organs. As organs migrate during development, the brain does not receive their forwarding address. As originally midline structures, these organs have a bilateral innervation not capable of providing localizing information. Therefore, a painful stimulus of an organ is not perceived as being on the right or the left. Confounding this natural neural bias is the fact that there is an overlap of sensory innervation to organs that are geographically related (see **Figure 38-1**). For example, the upper two-thirds of the esophagus, the lungs, trachea, bronchi, and heart are innervated by thoracic spinal cord segments T1 through T4 or T5. Overlap continues, with the lower third of the esophagus, stomach, duodenum, liver, gallbladder, pancreas, and part of the small intestine all being innervated by the segments from T5 through T10. Therefore, pathology in one structure is difficult to localize from others when interpreted by the brain at the conscious level. Visceral afferent receptors primarily serve the goal of gathering information about function in an effort to maintain homeostasis. Therefore, information about distention and blood supply governs responses that help maintain normal functioning of these systems. The same pain-producing stimuli for somatic structures apparently do not elicit pain in deep visceral structures. Pain in somatic structures is a stimulus for survival, avoiding the external, potential risk of damage or death. So, although cutting, burning, stabbing, or pinching of somatic structures causes pain, it is not perceptible when applied to deep organs. Pressure, and in particular ischemia, however, do cause pain (see **Table 38-3**).

<p><b>Exhibit 38-1 Differentiating between Cardiac Pain and Noncardiac Pain</b></p>
---

	pneumothorax, tuberculosis, bronchogenic carcinoma, etc.; pain is sharp	side may aggravate complaint; auscultate/radiograph
Esophageal	May or may not have dysphagia; pain is substernal or radiates to central back	Hot or cold food may trigger pain; manometry/barium x-ray may be necessary
<b>Neuromusculoskeletal</b>		
<b>Nerve</b>		
Herpes zoster	Often unilateral, dermatomal pattern; hypersensitivity followed vesicle formation; burning, sharp pain; recurrent	Hypersensitive to palpation
Intercostal neuritis	Similar to herpes presentation without vesicles; common causes include osteophytes and diabetes	May reproduce on rib separation or compression of intercostal space
<b>Bone</b>		
Rib fracture	Usually history of trauma	Reproduce on compression anterior-to-posterior (if posterolateral); tuning fork, oblique radiographs
<b>Joint</b>		
Costochondral junction	Tietze's syndrome found in older women; higher ribs; unilateral; sharp pain	Direct pressure of junction or between ribs
Costovertebral or costotransverse	May or may not be traumatic; pain radiates along rib	Pressure over affected joint causes radiation
Cervical spine	Referral from	Compression/distraction

	osteophytic involvement; usually in older patients	tests
<b>Muscle</b>		
Sprain	Possible history of overuse or trauma; usually, pectorals, serratus anterior, or intercostals	Stretch, contract, combine
Trigger point	Many causative factors, including visceral referral zone; possible autonomic nervous system changes; no neurologic changes; sternocleidomastoid, pectorals, scalenes, sternalis all possible	Sustained pressure on trigger points
<b>Other</b>		
Anxiety related	Patient may appear anxious or depressed; pain is often over heart and is often either quick/stabbing (seconds) or "heavy"/constant	Psychologic evaluation may be necessary; may be aggravated by deep breathing

**Table 38-2** History Questions for Chest Pain: Cardiac or Noncardiac?

Primary Question	What Are You Thinking?	Secondary Question	What Are You Thinking?
Can you point to where it hurts?	If they can, it is unlikely that there is a cardiac cause.	Were you hit in the chest, back, or side?	Possible rib fracture, especially if worse with deep breathing or lying on the same side.
		Have you had a chest cold or flu?	Pleurisy possible, especially in elderly.
		Is it worse with arm movements; especially overhead or trunk bending?	Muscular cause is more likely; pleurisy is possible with trunk bending.
Is it more diffuse or hard to pinpoint?	Cardiac or esophageal, especially if substernal or precordial. Pressure-type pain often described.	Did it occur after exertion and was it relieved with rest?	Stable angina likely.
		Does it occur at rest?	Unstable or Prinzmetal's (variant) angina.
		Does it radiate down your inner arm or to your jaw?	Angina or pre-myocardial infarction likely.
		Does it radiate along your rib?	Intercostal neuritis, diabetes, shingles (with skin lesions), thoracic osteoarthritis.
		Does it radiate to your back?	Esophageal pathology or aortic aneurysm.
How long does it last?	Distinguish among brief, continuous, or a timed period.	Is it continuous (all the time)?	Cardiac unlikely.
		Does it last less than half an hour?	Cardiac more likely.
		Is it a split-second jab (sharp) pain?	Cardiac unlikely; probably short muscle spasm.
Is it relieved by nitroglycerin?	Angina or esophageal spasm.	How long does it take after taking nitroglycerin?	Should take a few minutes, not seconds to relieve angina.
		Do you have difficulty swallowing at times?	Esophageal spasm possible.
Do you smoke?	Lung cancer.	How long have you smoked?	Years of heavy smoking are usually needed.
Any other associated complaints?	Depression/anxiety, collagen/vascular disorders, osteoarthritis.	Do you find your relationships and hobbies still exciting?	Depression.
		Any past diagnosis of collagen diseases?	Lupus, sarcoidosis.
		Is there any neck pain?	Osteoarthritis.

**Figure 38-1** Segmental overlap in visceral sensory nerve supply. The poor correlation between referred pain and its site of origin necessitates a thorough history and a careful screening of the differential possibilities. Cardiac ischemic pain (A) is transmitted via the upper four to five thoracic spinal segments (as well as cervical levels). Sensory impulses from the lungs and bronchi (B) as well as the esophagus, aorta, and body walls (C), however, share the same spinal segments, making the diagnosis difficult in many cases.

**Table 38-3** Differentiation of Somatic and Visceral Pain Based on General Characteristics

Character	Superficial Somatic	Deep Somatic	Visceral
Neurology	Spinal nerves (unilateral innervation)	Spinal nerves (unilateral innervation)	Visceral affords (bilateral innervation)
Structures	Skin, superficial fasciae, tendon sheaths, periosteum	Muscles, fasciae, tendons, joint capsules, ligaments, periosteum	Hollow organs, parenchymatous organs
Quality	Sharp	Aching, dull	Aching, dull
Localization	Yes (lateralizes)	Fairly good; refers often	Difficult; perceived away from organ site; often central
Main stimuli	Cutting, compression, burning	Cutting, compression, burning ischemia	Distention, inflammation, ischemia
Movement	Pain often increases	Pain often increases	Activity often has no effect

Reproduced with permission from T.A. Souza, *Topics in Clinical Chiropractic*, Vol. 1, No. 1, p. 2, 1994. Aspen Publishers, Inc.

Esophageal causes of chest pain are thought to be due to a dysfunction in visceral sensory perception.<sup>13</sup> Either motility or acid sensitivity may play a role in a hypersensitivity reaction or a lowering of the pain sensitivity

threshold. The motility disorders are represented by the nutcracker esophagus (NCE) and esophageal spasm. NCE is an occurrence of high-amplitude peristaltic contractions. Esophageal spasm is due to simultaneous contractions of the esophagus. Some theorize that these disorders and acid hypersensitivity do not cause chest pain but are markers for a propensity toward a dysfunctional visceral sensory system.<sup>12</sup>

Referred pain from the cervical or thoracic spine is possible. Biliary disorders such as cholelithiasis and cholecystitis also can cause pain in the chest. Finally, any irritation of the pleura and the distention by gas of the hepatic or splenic flexures of the colon may cause chest pain.

## Evaluation

## History

The presentation with cardiac pain is often one of concern. Usually, the severity of the pain and the incapacitation with myocardial infarction will result in an emergency department visit or a 911 call. Therefore, most cardiac pain in an ambulatory setting is anginal. The characteristic attributes of cardiac pain are as follows:

- substernal or precordial in location
- diffuse (patient cannot point to a discrete spot)
- a dull, squeezing, or pressure sensation
- radiation to the medial side of the left arm or to the jaw
- relieved by rest
- pain usually lasts between 10 and 60 minutes
- body position has no obvious effect on improving or increasing the pain (with the possible exception of angina, where many patients are often reluctant to be recumbent)
- ischemic pain is usually relieved by nitroglycerin

Cardiac pain is often the result of coronary artery occlusion caused by atherosclerosis or vasospasm. Given that atherosclerosis is a slowly accumulating process, it is logical to assume cardiac disease in older patients who have chest pain. The classic presentation of an older man with retrosternal pain relieved by 5 to 15 minutes of rest is so characteristic of coronary heart disease (CHD) that the patient has a 94% probability of having at least 75% occlusion of one coronary artery on angiography.<sup>14</sup> The opposite is also true; a young woman with chest pain that is not typical cardiac pain has a less than 1% chance of coronary artery occlusion.

Musculoskeletal and somatic chest pain has a broader range of attributes; however, it often presents as follows:

- localized pain
- pain that is often stabbing or sharp; but deep, dull, aching pain is also possible
- no radiation unless along a rib or between ribs (dermatomal)
- pain is either brief, lasting as little as a few seconds, or continuous
- the pain is made worse by specific body positions that stretch, contract, or compress the involved area
- a history of overuse or trauma may be found

When a history of trauma is given (fall or blow to the chest), a suspicion of rib fracture is high. Rib fractures generally feel worse with deep inspiration, coughing, sneezing, and while lying supine. Rib fractures may be the result of abuse, and eliciting a clear history is often difficult. Instead, the patient may claim an “accident.” It is important to look for other clues of abuse during the examination, such as bruises and scars or radiographically for past fractures.

Overuse may be obvious, such as starting a new exercise or workout routine, or as subtle as doing housework, yard work, or helping someone move furniture. If the pain is sharp and felt unilaterally at the costosternal junction, Tietze’s syndrome should be considered. Other causes include repeated coughing or vomiting.

By focusing on the standard approach to history of a chief complaint questioning, a rather accurate distinction can usually be made between cardiac and noncardiac pain. Further distinction between cardiac and other visceral sources may be more clouded. Substernal pain is also possible with esophageal disorders such as reflux or esophageal spasm.<sup>15</sup> Questions pertaining to swallowing and relationship to meals are often revealing. If swallowing is difficult, it is important to ask about the relationship to hot, cold, solid, and liquid foods. If the pain begins after drinking or eating very hot or cold foods and is associated with difficulty swallowing both solids and liquids, esophageal spasm must be considered a likely possibility. Pain that is worse with recumbency, especially after meals or with wearing a tight belt, is indicative of reflux. Reflux may also be associated with the ingestion of certain foods such as chocolate, fats, caffeine, orange juice, onions, and garlic. It is important to note, however, that patients with cardiac pain often have associated epigastric complaints.

The distinction between superficial and deep pain helps first to distinguish between cardiac and noncardiac pain. It also helps in distinguishing among various noncardiac sources of pain. If the patient complains of a superficial sensation of burning or hypersensitivity along a patch of skin, herpes zoster (shingles) should be suspected. This is confirmed within a few days with the appearance of a vesicular rash roughly following a dermatome (not necessarily the entire dermatome). This same superficial sensation may be the result of irritation from osteophytic impingement of a thoracic nerve root or may be due to diabetes. Another rare possibility is Mondor’s disease. This occurs in women as a superficial thrombophlebitis of the thoracoepigastric vein. The patient feels a tender cordlike swelling beneath the breast.

Chest pain associated with difficulty breathing is common. If there are no indicators of an underlying respiratory infection, several possibilities to consider are the following:<sup>16</sup>

- A sudden onset of chest pain associated with dyspnea and fever suggests a pulmonary embolism, especially in a patient who was immobilized, is taking oral contraceptives, or has antecedent calf pain. Immediate referral is necessary.
- Dyspnea preceding chest pain and associated with lightheadedness, dizziness, or syncope, especially in a younger male athlete, suggests HOCM.<sup>17</sup> Referral for ECG or ultrasound evaluation is necessary.
- Sharp pains localized to the posterior chest that are made worse with respiration, there is no history of trauma, and there are no signs of infection suggest the possibility of spontaneous pneumothorax, especially if the patient is young and tall with a history of an exerting activity such as backpacking or exercise. Chest films are necessary.

A psychogenic cause should be suspected in patients with multiple body complaints that appear unrelated, in patients with a past or current psychiatric diagnosis (especially depression), and in those who appear to have anxiety reactions to stressful situations. It is important not to “excuse” the complaint without a thorough evaluation. Hyperventilation is often found with anxious patients.

## Examination

Cardiac involvement is discovered largely through the history. Signs of cardiac involvement are rarely found when the patient is asymptomatic. These signs, when present, would largely be found on an ECG. Changes in the ST segment may reflect underlying ischemia. Depending on severity, either ST elevation or ST depression may be indicative of an ischemic cardiac problem. Given that a resting ECG can provide information only over a short period of time, a Holter monitor (portable recording unit) is often prescribed in an attempt to match the patient’s symptoms to a recorded ECG abnormality. Further monitoring with a stress ECG should be done through referral and consultation with a cardiologist. Prediction of recurrent coronary artery disease may be possible, as indicated by a recent study.<sup>18</sup> Using several biomarkers, the researchers were able to accurately predict risk of recurrence of CAD. These markers included natriuretic peptide, cystatin C, albuminuria, C-reactive protein, interleukin-6, and fibrinogen.

Indirect implications are generated through auscultatory findings such as murmurs or lung congestion. Hypertension also may be an indirect indicator of systemic atherosclerosis suggesting coronary involvement. Other indicators of atherosclerotic involvement are signs of intermittent claudication in the lower or upper extremities. This is characterized by pain and

weakness/tiredness when exercising the extremity that is promptly relieved by rest.

Musculoskeletal involvement may be exposed, reproducing mechanically the patient's complaint with regard to location and quality. Muscles are challenged through a procedure involving contraction, stretch, and contraction in a stretched position. Palpation is used to localize tenderness and in a search for nodules or referred pain upon palpation of specific trigger points. The most common muscles that can cause chest pain are those that are geographically situated in close proximity: the pectoralis major, pectoralis minor, serratus anterior, and intercostals. Following are positions and contraction patterns that may stretch or contract these structures:

- The pectoralis muscles are stretched by elevation of the arms coupled with horizontal abduction (arms brought behind the back); contraction from this position with the patient attempting to adduct the arms horizontally is sufficiently specific to elicit pain when these muscles are involved.
- The serratus anterior can be stretched with the arm abducted and the trunk passively stretched to the opposite side; contraction is accomplished through either protraction maneuvers such as wall pushups or high arm elevation against resistance.
- The intercostals can be challenged by having the patient seated, arms overhead, while the examiner contacts each rib individually and passively stretches the patient away from and to the involved side in an effort to stretch and compress the area.

Rib involvement is challenged by anterior-to-posterior and transverse pressure to the chest, being careful not to apply direct pressure at the painful area. Additional testing may involve the use of a tuning fork. Using a nonvibrating tuning fork, tenderness is checked in areas along the rib distal to the main site of pain. With this baseline reading, applying the vibrating probe of the tuning fork to the same area may cause a jump reaction due the vibrating fracture area. Radiographs for rib fractures must include oblique views because of the overlap that occurs on regular anterior-to-posterior and lateral views.

Chest films should be reserved for cases of suspected pneumothorax, pleurisy, congestive heart failure, and rib fracture. Following are some guidelines:

- Patients with suspected rib fracture should have a posterior-to-anterior (PA) chest film ordered in search of an associated pneumothorax, and oblique films localized to the area of complaint if fracture is not seen on the PA view.
- Patients with suspected pleurisy should have a PA chest film and a lateral recumbent view ordered in search of an air-fluid level.

- With a posterior chest pain complaint, it is important for the chiropractor not to rely on a collimated thoracic anterior-to-posterior view because significant pathology may be obscured.

## Management

Although cardiac-caused pain should be referred for medical evaluation, comanagement may be helpful when attempting to change the patient's lifestyle, including diet, exercise, and stress management.<sup>19</sup> Noncardiac causes are managed based on the underlying tissue involved. See Selected Causes of Chest Pain, later in this chapter, for more detailed recommendations for listed conditions.

Reduction in cardiovascular risk can save lives and improve the quality of life for those living longer. Recommendations in 2013 have included decreasing cardiovascular risk through reduction in LDLc and blood pressure (BP).<sup>20</sup> A synopsis of these recommendations is based on diet and exercise as follows:

- Consume a diet with emphasis on vegetables, fruits, and whole grains including low-fat dairy products, poultry, fish, legumes and nontropical vegetable oils and nuts; decrease sugars and meats. This can be accomplished without a plan or using the DASH diet, the USDA Food Pattern or the AHA Diet. Reduce percent of calories from saturated fats and trans fat.
- For BP lowering add advice to lower sodium intake, consuming no more than 2,400 mg of sodium/day.
- For both groups, it is recommended to exercise aerobically three to four times per week, 40 minutes per session, involving moderate to vigorous activity.

The following are recent changes to the American Heart Association (AHA) guidelines and proposed recommendations<sup>21</sup> for use of CPR, automated electronic defibrillator (AED) units, and the Heimlich maneuver in emergency situations.<sup>22</sup>

### A. Automated Electronic Defibrillator (AED) Units

1. AED protocols have changed based on research of their usage. Studies have found that patients who receive multiple shocks have a low likelihood of survival and a high incidence of significant brain damage if they do survive. The thought is that this is likely due to long periods of anoxia while AED is processing, analyzing, and checking for need for subsequent shocks.
2. Even when the AED is successful in resetting the electrical output of the heart, the hypoxic heart muscle does *not* get reset, thus resulting in insufficient contractions and potentially further anoxia.

- 3.** Based on these two findings, the following protocol changes have been put in place for AED units:
- a.** When a nonresponsive adult patient is found, 911 should be called immediately via a hard-line phone (infants and children commonly have respiratory causes; thus, CPR is applied first for two minutes (five cycles), then 911 is called).
    - For a single rescuer, the ratio of compressions to ventilations is 30:2 for all patients.
    - For two rescuers, the ratio is 30:2 for adults, and 15:2 for infants and children.
    - Compression rate should be 100 comp/min.
    - Five cycles (30 compressions/2 ventilations) should be completed in two minutes.
  - b.** Continue with compressions while the AED pads are applied and machine is going through the initial processes.
  - c.** Stop compression *only* to allow the application of a pad (if necessary) and when the machine advises you that it is “analyzing.”
  - d.** Once the machine has “analyzed” the patient, it will suggest either a shock will be delivered, or advise you to continue CPR. If the latter, then continue one- or two-responder CPR. If a shock is to be delivered, then continue with step “e.”
  - e.** While the shock is being delivered, change responsibilities for two-person CPR (ventilations to compressions and vice versa).
  - f.** Upon completion of the shock, *immediately* begin delivery of chest compressions (30:2) regardless of what the machine says (“analyzing” for repeat shock).
    - *Do not* be concerned if the patient’s electrical rhythm is restored; the compressions are still helpful in assisting the heart muscle in the pumping of blood.
  - g.** Have the person providing ventilations unplug the pads from the AED unit (leave pads attached to the patient).
  - h.** Provide five cycles of CPR (30:2).
  - i.** Plug AED pads back into the unit; unit will pick up where it left off and analyze the need to apply another shock.
  - j.** Continue to apply compressions until AED unit begins to “analyze.”
  - k.** Repeat steps “d-k” until emergency response personnel arrive.

## **B. Effect of Ventilations**

- 1.** Research has found that chest compressions alone are as good as, if not better than, compressions plus ventilations. The compression of the chest itself helps drive air into and out of the lungs.
- 2.** This research has yet to result in a change of the protocols. However, this is likely to be the next major change.

3. In situations where there is no ventilation mask available (or other barrier):
  - a. Provide compressions only (100/min).
  - b. Ventilation via compressions is improved if airway is maintained; therefore, if there is a second responder, have him/her perform head tilt and chin lift; if a single responder, place shoe or object under neck to improve head tilt.

## C. Cricoid Pressure

1. Studies have recently found that applying AP pressure on the cricoid significantly improves CPR outcomes by minimizing gastric distension and episodes of vomiting. Patients who vomit during CPR have significantly worse outcomes than those who do not.
2. When a second rescuer is present and ventilations are being provided, the second rescuer should apply cricoid pressure by using the thumb and forefinger to capture the cricoid and then press the cricoid cartilage posterior until the point of resistance. This helps collapse the esophagus while maintaining the airway, minimizing gastric distension.

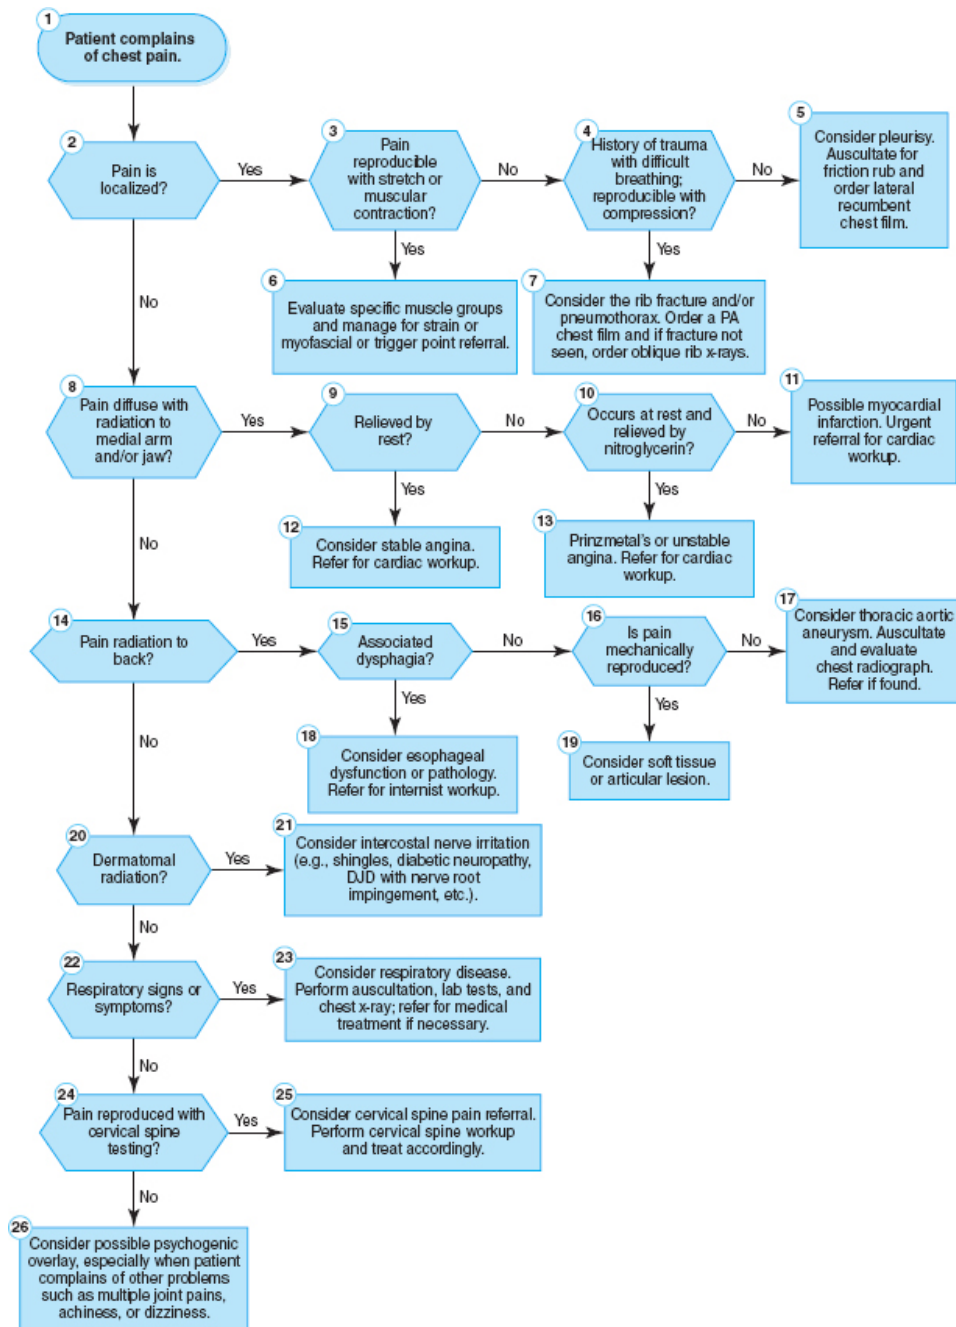

## D. Heimlich Maneuver

1. The abdominal thrust on patients who become unconscious due to choking has been eliminated.
2. Blind sweeps have also been eliminated.
3. Once a patient becomes unconscious during the course of rendering the Heimlich maneuver, the following protocol is followed:
  - a. Perform one cycle of compressions (30).
  - b. Prior to ventilations, check for visible blockage and if found, remove with finger sweep.
  - c. If no object is seen, attempt ventilations (if first ventilation does not work, remember to reposition head; lift/chin tuck to ensure adequate airway).
  - d. Repeat compressions for one cycle.
  - e. Repeat steps “b-e” until emergency personnel arrive.

## Algorithm

An algorithm for initial screening of chest pain is presented in [Figure 38-2](#).

## Selected Causes of Chest Pain\*

### CARDIAC

#### Angina

### Classic Presentation

The patient complains of a squeezing or pressure sensation in the chest. It came on rather suddenly after exertion. The patient said that after resting for several minutes the sensation went away. This was not the first time it had happened. He or she also noticed that there was an aching pain felt down the left inside arm to the fingers.

### Cause

Angina is usually due to atherosclerosis; however, a variant of angina is related to vasospasm that may occur in isolation or with atherosclerosis (Prinzmetal's angina). Patients with Prinzmetal's angina often have an atypical presentation in that they may be women under age 50 years with angina that occurs at night (involves the right coronary artery most often). Another entity is called syndrome X, in which there is no apparent coronary atherosclerosis. It is believed that there are microvascular abnormalities in these patients.<sup>23</sup> The threshold for an angina attack may be decreased by factors such as anemia, valvular disorders (especially aortic stenosis), or conduction problems. Cocaine may also provoke an attack.<sup>24</sup> When atherosclerosis is excessive, angina may occur at rest without provocation (unstable angina). These attacks tend to be longer and may be a portent of impending myocardial infarction.

### Evaluation

The history of a pressure or squeezing pain lasting for several minutes to 30 minutes with possible radiation to the arm or jaw is characteristic of angina. If the pain occurs at rest or without provocation, unstable angina is likely, indicating more occlusion. Given that it is rarely possible to examine a patient during an attack, most findings such as hypertension are indirect indicators of underlying atherosclerosis. Valvular abnormalities such as aortic stenosis in older patients and mitral valve prolapse in younger patients may be found. ECG findings are nonspecific except during the attack, when either ST depression or, with more severe ischemia, ST elevation is found. Provocation with exercise testing includes an ECG. Based on these findings scintigraphic or echocardiographic studies may be added.<sup>25</sup> Ambulatory monitoring with a Holter device may be used, especially if an underlying arrhythmia is suspected. Coronary angiography should be used in selected patients only.

### Management

Nitroglycerin is used for symptomatic management of angina. It decreases contraction of the heart and causes vasodilation. It is usually taken sublingually and takes a minute or two to work. Other medications may be prescribed such as calcium channel blockers. With more fulminant involvement of the coronary arteries, angioplasty or surgery may be suggested to the patient. It is important to advise patients with mild symptoms that supervised lifestyle changes including a healthful diet and exercise may decrease the need for nitroglycerin and, in some patients, reverse the underlying process. It is a comanagement scenario in which the medical doctor, chiropractor, and patient work together.

## Myocardial Infarction

### Classic Presentation

Not all patients with myocardial infarction (MI) are unconscious or in severe pain, although the majority of patients have pain severe enough to warrant a trip to the emergency department or a 911 call. It is possible to have a patient complain about pain that is often preceded by a history of angina. The substernal pain is more severe and often builds up over a few minutes. Nitroglycerin does not help. The pain lasts longer than 30 minutes. Twenty percent of individuals die before reaching the hospital. Approximately 25% of infarctions are silent, apparent only on an ECG.<sup>26</sup>

### Cause

Usually MI is due to coronary thrombus or vasospasm. Blockage of a specific coronary artery causes damage to the area supplied. For example, blockage of the anterior descending branch of the left coronary artery causes infarction of the anterior left ventricle and interventricular septum. The extent of damage is subendocardial with some transmural extension evident in most cases. Extension of infarcted tissue increases after the occlusion and may be diminished by prompt thrombolytic therapy.

### Evaluation

Evaluation is performed in the hospital with a check for associated arrhythmias. There are large variations at presentation with regard to heart rate, adventitious respiratory sounds, and general status of the patient. Laboratory testing performed within the first few hours will reveal an elevation of creatine kinase (CK) that peaks in about 12 to 24 hours. The isoenzyme CK-MB (myocardial band) is specific for the heart. The level of CK elevation correlates to the degree of damage. The new laboratory approach to detecting cardiac damage after an MI is the use of cardiac-specific troponin T (cTnT) and cardiac-specific troponin I (cTnI). cTnI levels are elevated for at least one week following MI (an advantage over creatinine phosphokinase [CPK-MB]), and cTnT levels are elevated from 10 to 14 days following MI. This has led to the use of these tests in place of the older method of measuring lactate dehydrogenase (LDH) isoenzyme levels in patients who present after 48 hours or are assessed after this time. Cardiac troponins are also valuable in detecting small MIs that are not detectable by CPK-MB levels. LDH, especially the isoenzyme 1, may still be elevated five to seven days later. ECG findings involve a sequence of hyperacute T-waves, progressing to ST elevation, to Q-wave development, to T-wave inversion. When found, Q-waves are diagnostic for MI; however, 30% to 50% of patients do not have them.<sup>27</sup> A new approach is the use of myeloperoxidase as an early indicator of risk for myocardial infarction as well as adverse cardiac events in the following one- to two-month period in individuals presenting to an emergency department with chest pain.<sup>28</sup> In this way, it is likely to be a better predictor than measurement of troponin, CPK, or LDH—measures that indicate what has happened but not necessarily what will happen. Another possible predictor of adverse cardiovascular events evaluated in patients with CAD is glutathione peroxidase 1 activity.<sup>29</sup> It has been found that there is an inverse relationship to glutathione peroxidase 1 activity and lowered risk. In other words, the lower the activity level, the higher the risk. For older men, evaluating Lp(a) lipoprotein levels has been shown to be an independent predictor of stroke, death from vascular disease, and, actually, death from any cause in men but not in women.<sup>30</sup>

### Management

It is important for chiropractors to maintain cardiopulmonary resuscitation (CPR) certification (or knowledge). Although rare, it may be necessary to perform CPR in or out of the office. Initial treatment is crucial for survival and to diminish the extent of damage. Thrombolytic therapy must be given within the first one to three hours for best results.<sup>31</sup> This includes streptokinase, tissue plasminogen activator (t-PA), or anistreplase. Post-MI it is important for the chiropractor to work closely with the patient and cardiologist to maintain a program of prevention, including diet and exercise.

## Pericarditis

### Classic Presentation

The patient usually complains of chest pain and difficulty breathing that is worse with lying down; it is better seated. The pain is substernal, often radiating to the neck or shoulder. There may be a history of a preceding respiratory infection, renal failure, or cancer.

### Cause

The pericardium is the double-layered sac covering and stabilizing the heart. Infiltration with infections or other inflammatory processes decrease the available space and movement of the heart. Viral organisms such as Coxsackie virus, Epstein-Barr virus, mumps, varicella, or human immunodeficiency virus (HIV) may be the cause. It can also be associated with hepatitis, tuberculosis, uremia from kidney failure, neoplasms, post-MI, or radiation treatment.<sup>32</sup>

### Evaluation

The presentation may be very similar to that of an acute MI. The characteristic finding is a pericardial friction rub heard on auscultation. ECG findings are similar to those of an MI, including ST elevation or T-wave inversion. A pericardial friction rub is found in 85% of cases and is described as a scratchy, leather-like, or Velcro-like sound.<sup>33</sup> It does wax and wane and may not be constant. Pericardial effusion is a common finding, and when it reaches a critical stage (which may be acute or slowly developing) pericardial tamponade will occur. This is a combination of cardiac output failure, systemic hypotension, and shock. Findings include hypotension, tachycardia, anxiety, muffled heart sounds, and pulsus paradoxus. Jugular vein distension may also be present. If systolic blood pressure decreases more than 10 mm Hg on inspiration or disappears, pericardial tamponade is likely the cause.

### Management

Management is dependent on the underlying cause; however, it should be managed medically. Aspirin or nonsteroid anti-inflammatory drugs (NSAIDs) are given for viral etiologies, antitubercular therapy for tuberculosis, and chemotherapy for neoplastic causes. For pericardial effusion, a pericardial window is created between the ribs to aspirate the fluid and take samples of the pericardial tissue.<sup>34</sup> For known causes, the underlying disease is addressed. In addition, and for idiopathic recurrent cases, a combination of NSAIDs, colchicine, and corticosteroids is used.<sup>35</sup>

## Hypertrophic Cardiomyopathy

### Classic Presentation

The patient may be a young athlete complaining of exercise-induced chest pain and difficulty breathing. More important, there may be a report of postexercise syncope. Unfortunately, the first presentation may be sudden death.

### Cause

Hypertrophic cardiomyopathy (HCM) is a nonfunctional ventricular wall enlargement (not due to increased pressure or volume of blood). This enlargement can involve mainly the interventricular septum, causing an outflow blockage during systole. This diminished outflow leads to ischemia with

syncope as the clearest indicator. HCM may be inherited as an autosomal-dominant trait. HCM is one of the leading causes of sudden death in young athletes.<sup>36</sup> It may also occur in the elderly.

## Evaluation

The evaluation begins as a preventive measure on preparticipation screenings. Although it is still difficult to identify susceptible individuals, a history of chest pain, dyspnea, and/or syncope related to exercise and a family history of HCM or sudden death in a close relative are indicators for further evaluation. The only physical examination finding that is suggestive of HCM is a systolic murmur that is made worse with a Valsalva maneuver; it is improved with squatting. However, this is found only with patients having an outflow tract obstruction, who are the minority. ECG changes usually show ventricular hypertrophy. The echocardiogram is the definitive tool demonstrating asymmetric left ventricular hypertrophy.

## Management

Management depends on the degree of involvement.  $\beta$ -blockers or calcium channel blockers may be used for symptom relief. More severe problems may require excision of part of the enlarged myocardium.

### NONCARDIAC, MUSCULOSKELETAL

#### Muscle Strain

## Classic Presentation

The patient usually will recall a single event or repetitive overuse event. This may include weight lifting or, in many patients, cleaning the house or moving furniture.

## Cause

Exceeding the limits of a muscle's ability to withstand a given load or overstretching the muscle may cause damage to the muscle or tendon.

## Evaluation

Evaluation of muscle injury involves palpation for tender areas and referral zones from these areas, contraction in midrange and in a stretched position, and stretching the muscle passively. The main muscles to consider in the chest are the pectoralis major and minor, the serratus anterior, and the intercostals.

## Management

Myofascial work in the form of trigger point massage and myofascial release techniques are most appropriate. Gradual retraining of the muscle should proceed from isometrics to isotonic and, depending on the need, isokinetics.

#### Rib Fracture

## Classic Presentation

The patient will report either a direct blow to the chest or a fall onto the chest. The most common location of fracture is posterolateral.

## Cause

Direct trauma is needed to break the ribs in adults. In seniors and those with underlying disease processes that result in osteoporosis or lytic processes, minor events may cause a fracture. The rib may be only partially fractured and is referred to as a “cracked” rib. Associated with complete rib fractures is pneumothorax, in which air enters the pleural space.

### Evaluation

The patient has guarded respiration and finds it more difficult to lie supine. Pressure directed anterior-to-posterior or transversely (taking care not to apply pressure directly to the site of involvement) will often cause a sharp increase in pain. Tuning fork application may increase the pain dramatically. It is important to apply a nonvibrating tuning fork first to ascertain a baseline level for tenderness. Applying the vibrating tuning fork should be at a site along the rib away from the suspected fracture site. Radiographs should include a PA chest film and if the rib fracture is not seen, order oblique films of the painful area. The PA chest film is necessary to evaluate for a coexisting pneumothorax. Radiographic evidence of fracture is often subtle and may take two to three weeks for callus formation to uncover the site. With cracked ribs, this may not be apparent.

## Management

Multiple rib fractures are best managed medically. Cracked ribs or small single fractures can be managed conservatively with rest, pain medication, recommendations to avoid sleeping on the back, laughing, coughing, and sneezing. Immobilization with a rib belt or taping is not recommended because of the inhibitory effect it may have on breathing. Gradual stretching should be introduced to avoid contracture and its effect on respiration. Slow, deep breathing should be attempted when possible. Pain is often present for approximately one to two months. In sports, intercostal blocks are often used to allow the player to return to play. This is a medical decision that carries with it possible medicolegal consequences.

### Tietze’s Syndrome

## Classic Presentation

The patient is often a woman over age 50 years who complains of a moderate to severe pain in the upper part of the chest on one side. She points to the second and third costochondral junctions.

## Cause

The cause is unknown. There appears to be an inflammatory reaction at the costochondral and, occasionally, chondrosternal, sternoclavicular, or manubriosternal areas. There may be an overexertion history of prolonged coughing or exertion such as moving furniture. It is bilateral in 30% of cases.<sup>37</sup>

## Evaluation

The area (usually upper chondrocostal junction) is tender, as is the adjacent intercostal area. There is swelling but no associated warmth or erythema.

There are no radiographic findings; however, in the differential diagnosis of rheumatoid conditions, radiographs may be needed. In rare cases, a bone scan may show abnormal uptake at the involved site. Chiropractic evaluation of rib and rib articulation movement is important.

# Management

The condition is benign and self-resolves in about six months. During the symptomatic period, chiropractic mobilization or adjusting may help (or aggravate) the condition. Failure to respond may require medical referral for an anesthetic/corticosteroid injection, which is 90% effective. This condition may be recurrent.

## Costochondritis

### Classic Presentation

The patient is usually young, with a complaint of anterior chest pain that is bilateral and affects the middle ribs close to the sternum.

### Cause

The cause is unknown. This term is also used to describe Tietze's syndrome; however, costochondritis appears to be a distinct entity because of the more common bilateral involvement of multiple rib articulations.<sup>38</sup> Trauma is suspected as the underlying cause. There are no consistent pathologic findings.

### Evaluation

Tenderness without swelling is found at the costal junction of ribs two through five most commonly. A "crowing rooster" position with the patient's cervical spine extended and his or her flexed elbows extended upward behind the body may stretch the involved area and increase pain. Another position that may increase pain is forced horizontal adduction of the shoulder while the patient turns the head to the ipsilateral side. Chiropractic evaluation of the rib and rib articulation are important aspects of the evaluation.

Radiographs are unrevealing and usually unnecessary. Laboratory testing is reserved for those individuals suspected of having an underlying rheumatoid etiology.

# Management

Moist heat and NSAIDs may help in this self-resolving, benign condition. It may be necessary to refer for an anesthetic and/or corticosteroid injection.

## Slipped Rib

### Classic Presentation

The patient complains of a popping or clunking sensation in the lower ribs, usually associated with an exertion maneuver such as a bench press or other lifting maneuver. The patient may report that the rib pops in and out with a specific type of maneuver.

### Cause

Loosening of the lower costal cartilages, often due to direct trauma or constant overcontraction of the chest muscles, allows the rib tip to curl upward. Chest pain may result if this impinges on the superior rib or intercostal nerve.<sup>39</sup>

## Evaluation

Palpation of the involved area is usually unrevealing unless the patient can reproduce the problem with a specific maneuver. Chiropractic evaluation of costovertebral accessory motion may indicate involvement.

## Management

Avoidance of the causative maneuver is important for stabilization. Adjustment of the involved ribs may help the patient temporarily; however, in most cases the condition is recurrent if the patient continues the inciting activity.

## Fibromyalgia

### Classic Presentation

The patient is often a woman (5:1) and complains of an aching, fatigued, and stiff sensation in multiple muscle groups.

### Cause

The cause is unknown. It is believed that there is some relationship to a disturbance in nonrapid eye movement (NREM) sleep.<sup>40</sup> Cold, damp weather, fatigue, a sedentary position or overexertion, mental stress, and poor posture may make it worse.

## Evaluation

The standard evaluation is to find a minimum of 11 of 18 bilateral tender areas designated by the American College of Rheumatology.<sup>41</sup>

## Management

The conservative approach is to use local application of dry heat, mild to moderate exercise, and stress reduction. It may be necessary to refer for Lyrica (pregabalin) or a trial of minidosing of tricyclic antidepressants, which are believed to assist in restoring normal NREM sleep.

## Intercostal Neuritis

### Classic Presentation

The patient complains of pain that is unilateral, extending in a band around the chest.

### Cause

Intercostal neuritis may be idiopathic, or the result of herpes zoster (shingles), diabetes, osteophytic encroachment, or rib subluxation. Herpes zoster is due to a varicella virus infection. The organism's residence is the dorsal root ganglion. During periods of emotional or mechanical stress the organism becomes active.

## Evaluation

In a diabetic patient with poor glycemic control, diabetic neuropathy is likely. For patients with shingles, the pain is followed in three to five days by a vesicular rash along part of the dermatome. Rib subluxation may be determined by palpation of the movement of the rib and at the costotransverse articulation.

### Management

For shingles, avoidance of emotional and mechanical stresses is recommended. When the infection is active, the use of lysine and the avoidance of caffeine may help. For more involved or resistant cases, acyclovir may be prescribed by a medical doctor. Rib subluxations should be adjusted. Patients with suspected osteoarthritic involvement should be adjusted cautiously. Low-force techniques may be more appropriate. Adjusting also may be beneficial for the idiopathic and diabetic cases. Control of the underlying diabetes is the long-term goal.

## NONCARDIAC, VISCERAL

### Pleurisy

## Classic Presentation

The patient presents with sharp pains in the chest that seem related to coughing, sneezing, and positions such as bending to the same side or lying on the involved side. The patient often will have a coexisting or recent history of a respiratory infection.

## Cause

Pleurisy is usually associated with pleural effusion. Effusion is categorized as a transudate or exudate based mainly on the protein content. Transudates are more the result of congestive heart failure or hypoalbuminemia (loss of oncotic pressure). Exudates are usually due to bacterial pneumonia or cancer. Other causes include empyema (direct infection of the pleural space), hemothorax (blood in the pleural space), or chyloform (chyle in the pleural space).

## Evaluation

Physical examination findings (and symptoms) are dependent on the underlying cause and the degree of effusion. A pleural friction rub may be heard. With large effusion there may be a decreased fremitus, dullness to percussion, and an increase or decrease in breath sounds. Chest films may reveal large pleural effusions. Smaller effusions are visible with a lateral recumbent view.

## Management

Small, transudate effusions are often managed conservatively. Larger effusions may require thoracentesis. When cancer is suspected, biopsy is often indicated. Treatment of the underlying condition is the primary feature of management.

### Pulmonary Embolism

## Classic Presentation

A middle-aged male has sudden chest pain after having had pain in his calf. The pain is severe, appearing similar to a myocardial infarction (heart attack).

## Cause

Most often, in the ambulatory population patients develop deep vein thrombophlebitis with subsequent migration to the lungs, causing either embolism or progression to full infarct and death. Approximately 600,000 episodes of pulmonary embolism occur each year in the United States, with approximately one-third resulting in death.<sup>42</sup> It is estimated that 20% to 30% are due to hemodynamic impairment. The remainder may be prevented with elimination of recurrence of embolism.

## Evaluation

Chest pain that is “pleuritic” in nature without dyspnea is a strong indicator of pulmonary embolism; a low-grade fever may be present also, more commonly with infarction. There are several clinical guidelines used to determine the patient who has enough of a clinical profile to warrant special imaging investigation. These include the American Thoracic Society and the European Society of Cardiology. The primary difference is the use of D-dimer testing (degradation products of cross-linked fibrin; nonspecific test for venous thromboembolism). In essence, the path of investigation for patients suspected of a pulmonary embolism includes either helical CT angiography scanning or ventilation perfusion scanning as the initial study. If the perfusion scanning is negative, pulmonary embolism is ruled out. If CT and perfusion testing are negative, further testing would include duplex ultrasonography of the lower legs; however, this is not sensitive, so with a negative test, pulmonary angiography would be used to further evaluate the patient.<sup>43</sup>

## Management

Acute management involves the use of thrombolytic agents such as streptokinase, urokinase, and tPA; then anticoagulant medication is used to prevent further recurrence.

## Esophageal

## Classic Presentation

The patient may complain of substernal chest pain associated with recumbency, dysphagia, and heartburn.

## Cause

Convergence of afferent nerve fibers for both the heart and esophagus may explain why esophageal pain may be a cardiac imitator. There are numerous theories and categories of esophageal dysfunction. Currently there is much disagreement as to the cause and relative importance of these conditions. The three syndromes suggested are an acid-sensitive esophagus including gastroesophageal reflux disease (GERD) (20% of patients), a mechanosensitive esophagus (including motility disorders such as esophageal spasm) (15% of patients), and an irritable esophagus seen as a combination of the other groups (25% of patients).<sup>44</sup> Chest pain of undetermined origin is believed to be due to esophageal disorders in 50% to 60% of patients.<sup>45</sup> Approximately 85% of patients with manometrically demonstrated esophageal abnormalities have a psychiatric abnormality.<sup>46</sup> A connecting hypothesis is that the esophageal disorders may represent a marker for individuals who have a dysfunctional visceral sensory mechanism wherein physiologic or pathophysiologic events may trigger pain, perhaps by lowering the threshold.<sup>47</sup>

## Evaluation

After cardiac diseases have been evaluated and ruled out, evaluation for esophageal disorders is begun, and is varied depending on the suspected underlying dysfunction. Some physicians use a proton-pump medication as an initial test for GERD, looking for relief as a positive test. The most sensitive test for GERD is 24-hour pH monitoring. Further testing may involve using balloon distention, the Bernstein acid perfusion test, or endoscopy. If esophageal motility is the underlying problem, manometry is often indicated.<sup>48</sup>

## Management

Conservative treatment for GERD consists mainly of dietary and positional advice. It would seem logical that patients with motility disorders would improve with the use of smooth muscle relaxants or calcium channel blockers; however, even though often they are objectively improved with manometry, symptoms do not abate. These patients are usually reassured that they have a benign problem and often are given similar advice to that given the GERD patient, including stress relaxation approaches. Patients with an underlying psychiatric problem may benefit from psychiatric counseling or medication.

## CHAPTER 39

# Palpitations

## Context

Although patients may not describe their complaints as palpitations, they may describe an uncomfortable awareness of the heart pounding, fluttering, stopping, skipping a beat, or racing. It is important to note that, although this would logically suggest a structural heart problem, the majority of cases represent physiologic reactions or normal fluctuations perceived as abnormal, or are augmented by psychologic overlay.<sup>1</sup> One study suggests that approximately 16% of outpatients present with a complaint of palpitations.<sup>2</sup> This percentage is likely less in the chiropractic setting. The role of the chiropractor is somewhat limited if an electrocardiogram (ECG) is not available in-office; however, defining the patient's concerns often may reveal an obvious benign cause or suggest the appropriate referral for further evaluation.

There is great variation in an individual's ability to perceive heart rate and rhythm. Common augmenting effects of normal heart activity include a quiet environment (more obvious when going to bed), lying on the left side with the ear against the mattress (sound transmitted through the mattress), and a conduction hearing problem (augments sound in the involved ear). Conditions that cause an increased stroke volume, such as regurgitant murmurs, functional hyperfunction as occurs with anemia,

thyrotoxicosis, and hypertension, may augment the sensation of a palpitation due to cardiac movement. Although it may seem logical that an arrhythmia could be perceived as a palpitation, many patients do not “feel” the arrhythmic occurrence. When patients with palpitations were monitored over 24 hours with an ECG, an arrhythmia was found in a range of 39% to 85% of patients.<sup>3-7</sup> Only about 15% of patients’ arrhythmias correlate with a complaint of palpitations. When not correlated, palpitations are unlikely to be due to cardiac pathology.

## **General Strategy**

### **History**

- Obtain a more defined description of the complaint (heart racing, pounding, stopping, etc.).
- Determine the timing and frequency with relation to exercise, stress, medication intake, and environment (e.g., more in a quiet place versus any other environment).
- Determine whether there are any related symptoms or signs (chest pain, presyncope, syncope, diaphoresis).
- Determine any past evaluation or diagnosis of the complaint and any coexisting diagnoses (i.e., diabetes, hyperthyroidism, coronary artery disease, anemia, depression, panic disorder).

### **Evaluation**

- Evaluate through auscultation, blood pressure measurement, and a 12-lead ECG.

- Laboratory testing should be reserved for patients suspected of having an underlying electrolyte, anemic, hypoglycemic, or endocrine abnormality.

## **Management**

- Referral for further testing should be made with symptomatic patients (chest pain, syncope/presyncope) or asymptomatic patients who are suspected of having an underlying conduction or structural cardiac abnormality.
- The remainder of patients, therefore, will have an identifiable benign problem that can be modified or eliminated, such as by eliminating caffeine use or recreational drug use, or will have no identifiable problem. Psychologic referral may be necessary for some of the remaining patients.

## **Relevant Anatomy and Physiology**

Normal transmission of the pacemaking impulse from the sinoatrial (SA) node to the atrioventricular (AV) node and continuing propagation to the bundle of His and Purkinje fibers is reliant on autonomic nervous system integrity, proper electrolyte balance, proper blood supply, absence of accessory neural pathways, and nonpathologic cardiac structure. Generally, dysfunctional transmission is due to disorders of impulse formation/automaticity, abnormal conduction, re-entry, and “triggered” activity. Cardiac cells have an inherent ability to act as a pacemaker. When this occurs, ectopic generation of impulses is possible, leading to flutter, fibrillation, and re-entry phenomena. Impulse

blockage, often due to organic disease, electrolyte imbalance, or the effects of medication, leads to various degrees of heart block in which impulse propagation from the AV node to the ventricles is prevented.

Re-entry is one of the most common causes of arrhythmias, causing tachycardias, premature beats, and atrial flutter. Re-entry occurs when an impulse is transmitted to a neural fork in the road, which allows travel down one path only. The signal participates in normal activation yet continues to travel in a circuit back to (retrograde transmission) the blocked path. Since blockage is antegrade only, this circle-around-the-back impulse is able to re-enter the original open path and cause restimulation.

## Evaluation

## History

Identify the patient who needs further work-up, such as the following:

- any patient with symptoms such as chest pain or syncope/presyncope
- any patient who has frequent attacks or attacks with exercise
- any patient with known cardiac disease or an immediate family member who died of cardiac disease before age 50 years Also determine the following:
  - any relationship to eating, exercise, or stress/anxiety
  - any relationship to medications or ingestion of stimulants
  - whether the patient has been diagnosed with or has symptoms of metabolic disorders involving diabetes,

hypo- or hyperthyroidism, or depression/anxiety. Patients may describe their concerns many different ways. One study indicated that when patients used the descriptors *racing* or *pounding*, it was unlikely that there was an underlying associated arrhythmia.<sup>8</sup> When patients described the sensation as heart stopping, however, there was a high correlation with an ECG documentation of pre-ventricular premature contractions. A description of an irregular heartbeat or fluttering was often associated with an associated arrhythmia. Neck palpitations or poundings are caused by simultaneous contraction of the atria and ventricles, which leads to reflux into the superior vena cava. This occurs with some forms of supraventricular and ventricular tachycardias. Ventricular tachycardias are more likely to cause symptoms such as syncope; palpitations are not often reported, probably because of the associated small stroke volume.

It is often difficult for the patient to describe palpitations with respect to regularity or rate. As few as one-third of patients were able to do so in a study by Reid.<sup>9</sup> His solution was to have the patient tap out what is felt. Harvey,<sup>10</sup> however, suggests that the examiner simulate different arrhythmias in a sequential manner on the patient's chest. He starts with a quick tap followed by a pause to simulate a premature beat. If this does not represent the patient's sensation, a simulation of bigeminy or trigeminy is attempted. Failure to reproduce the correct simulation sequences requires further simulation of other tachycardias. The first is a simulated sinus tachycardia, similar to what occurs with normal stress. The tapping is gradually accelerated to about 100 beats per minute, keeping the rhythm regular. The examiner describes this to the patient as the sensation he or she might feel in an anxious scenario. If this is not the correct simulation, faster tapping is employed, first with a regular rhythm, then an irregular

rhythm, in an attempt to simulate paroxysmal sinus tachycardia and atrial fibrillation, respectively. There are no studies to indicate the reliability or validity of this approach, yet it would seem to assist in narrowing the myriad possibilities in some patients.

A fruitful avenue of questioning is whether there is overuse of drugs such as alcohol, caffeine, tobacco (smoking or snuff), amphetamines, over-the-counter cold/sinus/allergy medications (ephedrine), or illicit stimulants such as cocaine. Ironically, antiarrhythmic medication can eliminate or facilitate arrhythmias. Facilitation may occur with class I agents, which prolong the Q-T interval, predisposing the patient to ventricular tachycardias. Other cardiac or antihypertensive agents may precipitate bradycardia or tachycardias. It is important to warn patients that sudden withdrawal from these medications may cause arrhythmias and to consult with the prescribing physician before attempting to discontinue medication.

General assumptions may be helpful in discriminating between benign and clinically significant causes of palpitations. Often information by which to make these assumptions is not available at the time of evaluation; however, a well-trained patient may be able to provide these data with any future events.

- If a tachycardia is a possible cause have the patient palpate the pulse during an attack. If the pulse is regular with a rate greater than 160 beats per minute, it is likely to be supraventricular.
- If a tachycardia is a possible cause have the patient perform a Valsalva maneuver or press lightly over the carotid sinus to determine whether it abates an attack. If it does, the cause is likely supraventricular (the patient may report that induced vomiting eliminates the tachycardia, also suggestive of a supraventricular origin).

The relationship to eating may be helpful. If the arrhythmias occur several hours after eating (often late afternoon and early evening) reactive hypoglycemia is possible and can be evaluated via glucose tolerance testing. A similar presentation with diabetic use of insulin occurs at the time of maximum insulin activity. Both types of hypoglycemic responses often are accompanied with sweating and tremors and are often supraventricular in origin. A somewhat similar presentation may occur in the anxious patient, who often complains of difficulty breathing, dizziness, and paresthesias of the hands or face. These are associated with hyperventilation, which may or may not be apparent to the patient.

The relationship to exercise may also be a helpful discriminator with premature ventricular contractions. Palpitations that increase with exercise are likely to be cardiac in origin and require stress testing. Those that decrease with exercise are generally benign. ECG documentation and echocardiography is warranted, however, if the “palpitations” are frequent, to rule out hypertrophic cardiomyopathy and other life-threatening conditions.

When otherwise healthy patients describe palpitations as rare or infrequent and there are no associated symptoms, the patient probably is not in need of further work-up. At this point in the evaluation, the patient may be reassured that it is unlikely that any significant problem exists. Patient monitoring of the problem; keeping a diary of events with the recommendation to return if the frequency of occurrence increases or to seek medical attention if there are any associated symptoms such as chest pain, dizziness, or fainting; and taking the pulse at the time of the next attack are usually sufficient.

## **Examination**

It is unlikely that the patient will have the sensation of palpitations at the time of examination. If palpitations do occur, palpation for heart rate and rhythm and, if possible, an ECG would be helpful discriminators between cardiac and noncardiac causes. Some common findings on ECG are listed in **Table 39-1**. If the heart rate, rhythm, and ECG are normal, a cardiac condition is unlikely. Atrial fibrillation may be suspected if the heart rate is grossly irregular and a pulse deficit or auscultated beat that fails to present peripherally is detected. Examination of the jugular venous pulse is subtle; however, it may provide information regarding dissociation (atrial and ventricular activation are independent of each other). If the atria and ventricle contract simultaneously, blood is refluxed by atrial contraction against a closed tricuspid valve, which results in a large or cannon A-wave at the jugular vein. This may occur with ventricular tachycardia. In patients with a slow heart rate, cannon A-waves may suggest heart block. Large A-waves with each heartbeat occur with retrograde AV, junctional, or ventricular tachycardia. No A-waves are present during atrial fibrillation because of inefficient atrial contraction.

The physician is more often indirectly evaluating cardiovascular function in a patient who is not at the time of presentation symptomatic, in an attempt to identify a potential cause of the patient's complaint. When other systemic problems are suggested by the history, a search for clues to hyperthyroidism, anemia, or sick sinus syndrome should be followed.

<b>Table 39-1</b> Arrhythmias		
<b>Classification/Pathology</b>	<b>ECG Findings</b>	<b>Treatment</b>

# Arrhythmias Originating in the Atrium

## **Sinus Bradycardia:**

Increased parasympathetic (vagal) tone causes heart to beat at < 60 beats per minute. Depolarization originates from sinoatrial node (hence the name sinus).

Slow, but regular rate on rhythm strip.

Not treated if asymptomatic. If patient develops angina, hypotension, heart failure, or other symptoms, treated with: Atropine  
Isoproterenol  
Epinephrine  
(Each of these drugs induces sympathetic predominance.)

## **Sinus Tachycardia:**

Increased sympathetic tone causes heart to race (100-160 beats per minute). Depolarization originates from sinoatrial node.

Rapid but regular rate on rhythm strip.

Not treated if asymptomatic. If treatment is necessary:  
Propranolol  
(It decreases catecholamine-induced firing rate of SA node and slows conduction through AV node.)

## **Multifocal Atrial Tachycardia:**

Depolarization originates from several atrial foci at irregular intervals. Rate is rapid (100-200 beats per minute) and irregular.

P-waves are present, but are morphologically different from one another. P-R interval varies.

Correct precipitating factor(s). Once underlying cause is corrected, may initiate: Verapamil  
Quinidine  
(Both slow conduction velocity of cells that are abnormally pacing.)

<b>Premature Atrial Depolarization:</b> Heart beats prematurely because a focus of atrial cells fires spontaneously before the SA node is ready to fire.	Interruption of regular rhythm by an early P-wave. P-wave may be followed by a normal QRS if the SA node and ventricle have had time to repolarize.	Not treated if asymptomatic. If symptomatic, treated with Class Ia anti-arrhythmics: Quinidine Procainamide Disopyramide
<b>Atrial Flutter:</b> Ectopic focus of atrial cells generates 250-350 impulses per minute. The ventricle responds to every second or third impulse. Both atrial and ventricular rhythm are regular.	Series of 2-4 closely spaced P-waves followed by a normal QRS complex.	1. Control ventricular response by suppressing AV node conduction. Suitable agents are: Digoxin Propranolol Verapamil 2. Convert atrial rhythm to sinus rhythm: IV Procainamide
<b>Atrial Fibrillation:</b> Multiple ectopic foci of atrial cells generate 350-450 impulses per minute. The ventricle responds to an occasional impulse. Both atrial and ventricular rhythm are irregular.	P-waves cannot be discerned. Baseline is irregular with unevenly spaced QRS complexes.	1. If hemodynamically stable, control ventricular response by suppressing AV node: Digoxin Propranolol Verapamil 2. Convert to sinus rhythm: Class Ia anti-arrhythmics IV Procainamide
<b>Arrhythmias Involving the AV Junction</b>		
<b>AV Re-entry:</b> AV node is split into a pathway that conducts toward the ventricle and a pathway that conducts the impulse back to the atrium. Re-entry of the impulse into	Generally normal QRS complexes following normal P-waves. The inverted P-wave (retrograde atrial contraction) is buried in the QRS.	Carotid sinus massage may suppress tachycardia by increasing vagal tone. Alternatively: Verapamil Propranolol Digoxin

the atrium causes the atrium and ventricle to contract simultaneously.	Rate is 150-250/minute.	
<b>Wolff-Parkinson-White:</b> A strip of conducting tissue (other than the AV node) connects the atrium and ventricle. Impulses reaching the ventricle via the AV node circle back to the atrium via the accessory pathway. Alternatively, the circuit may be reversed.	Each P-wave is followed rapidly by a QRS. A "delta wave" leads into the QRS. Rate can exceed 300 beats/minute.	If symptomatic, either slow AV conduction with: Verapamil Propranolol Digoxin or slow accessory pathway conduction: Lidocaine Procainamide
<h2>Arrhythmias Originating in the Ventricle</h2>		
<b>Ventricular Premature Depolarization:</b> Spontaneous depolarization of ectopic focus in the ventricle. Considered benign if fewer than six per minute.	Wide, tall QRS complexes that are not associated with a P-wave. A prominent T-wave often points in the opposite direction as the QRS complex.	Usually not treated if asymptomatic. If treatment is necessary: IV Lidocaine IV Procainamide Long-term suppression may be achieved with: Class I agents
<b>Ventricular Tachycardia:</b> Usually secondary to re-entry circuit. Both AV re-entry and Wolff-Parkinson-White may progress to ventricular tachycardia.	Wide QRS complexes with abnormal S-T segment and T-wave deflections (opposite in direction to QRS). AV dissociation and right bundle branch block are often associated.	Acute treatment involves one of the following: IV Lidocaine IV Procainamide IV Bretylium Oral drugs are used for chronic therapy: Quinidine Procainamide Disopyramide

		Flecainide, Encainide, Tocainide, Mexiletine
<b>Ventricular Fibrillation:</b> Erratic discharge from many ectopic foci in the ventricle. Rate is 350–450 beats/minute. Rhythm is irregular.	Completely erratic. Cannot distinguish normal waves or complexes.	Life-threatening. If cardioversion fails, epinephrine is given prior to defibrillation. If this fails, combine IV Lidocaine and defibrillation. Either additional doses of lidocaine or Bretylium can then be used with defibrillation.

Reproduced with permission from J. Olson, *Clinical Pharmacology Made Ridiculously Simple*, pp. 74–75, © 1994, MedMaster.

Laboratory testing is valuable when a specific suspicion is generated by the history. The following are examples: •  
hypoglycemia—five-hour glucose tolerance testing

- diabetes—serum glucose testing (> 126 mg/dL on two lab tests)
- illicit drug use—drug screen
- thyroid dysfunction—ultrasensitive thyrotropin (ultra-TSH)
- anemia—complete blood count (CBC) or anemia panel
- volume depletion from vomiting, diarrhea, or diuresis—electrolyte panel

When the initial evaluation is unrevealing, it is necessary to evaluate with a Holter monitor. The doctor attempts to correlate any symptom complaints temporally with any abnormal electrophysiologic events. If no correlation is found, the patient's problem presumably is not cardiac. For patients with less frequent yet troublesome events, a cardiac event recorder is given to the patient for a period of one month. The patient is taught to activate the device any time he or she feels symptoms. The information can be transmitted or stored for analysis. Some devices will store

information just prior to activation to catch premature events.

Patients who have historical or physical examination clues of mitral valve prolapse or structural problems often will be referred for echocardiography. Those patients with exertion-induced palpitations are sent for stress testing. Invasive electrodiagnostic studies are rarely needed to diagnose the cause of palpitations; however, patients with suspected anomalous pathways or underlying cardiac structural abnormalities may be candidates.

Atrial fibrillation (AF) is the most common chronic arrhythmia in adults and is associated with an increased risk of stroke and death. More than two million adults in the United States have AF and with the increase in the senior population, this is likely to increase dramatically. Even at the current rate, approximately one in four adults has an overall risk of developing AF. Identifiable risk factors include older age, an increase in systolic blood pressure, diabetes, hypertension, heart failure, valvular disease, obesity, and past myocardial infarction. The association with obesity is higher than previously believed.<sup>11</sup> There have now been studies that demonstrate progressive atrial restructuring and electrical remodeling occurring secondary to obesity.<sup>12</sup> For those with nonrheumatic AF, echocardiographic findings include left atrial enlargement, left ventricular thickness, and decreased ventricular systolic function. A randomized controlled trial<sup>13</sup> in 2013 demonstrated that when patients were put on a weight management program, there were significant reductions in both atrial fibrillation and actual atrial remodeling. One study indicates that there is an associated risk with increased pulse pressure (systolic BP/diastolic BP), which indicates increased aortic stiffness.<sup>14</sup> This risk is beyond that associated with other identifiable factors. Stroke associated with AF is often the result of cardioversion when the heart returns to normal sinus rhythm due to a thrown thrombus.

# Management

If the chiropractor does not have direct access to ECG with medical interpretation or if there is evidence of underlying systemic or cardiovascular disease, referral to a cardiologist is recommended. A number of medications are used in the management of arrhythmias, with some commonly prescribed drugs listed in **Table 39-2**.

The mechanism of action for medications used to treat arrhythmias is generally to slow transmission through sodium and potassium blockade or through smooth muscle relaxation through calcium channel blockers or sympathetic blockers (i.e., beta blockers). These are important for ventricular tachycardias, AF, and supraventricular tachycardia. Examples include:

- Sodium channel blockers—Examples include flecainide (Tambocor), propafenone (Rythmol), quinidine, procainamide, and lidocaine. Avoid Ca and K supplements and grapefruit, and maintain sodium.

- Beta blockers (B1)—Commonly used is Propranolol. Avoid alcohol, calcium, sodium, and licorice supplements.
- Potassium channel blockers—Examples are amiodarone (Cordarone or Pacerone) and sotalol (Betapace). Taken with food due to increased absorption with fat. Avoid St. John's wort, and grapefruit.
- Calcium channel blockers—Example is Cardizem. Avoid Ca supplements, decrease salt intake, limit caffeine, and high-dose vitamin D (2,000 IU).

**Table 39-2 Cardiovascular Medications**

	<b>Triamterene</b> Dyrenium	Blocks action of aldosterone by competing with receptor sites in distal renal tubules. Used as a diuretic. It has direct effects on distal renal tubules to prevent excretion of potassium. Decreases glomerular filtration rate and increases BUN. Used in the management of CHF, and other forms of edema, and as adjunct therapy for hypertension.	May cause hyperkalemia and other electrolyte imbalances, anaphylaxis, some blood dyscrasias, GI disturbances, gout, rash, or hypotension.
	<b>Milrinone</b> Primacor	A new type of drug which is an isotropic/vasodilator inhibitory against cyclic-AMP phosphodiesterase. Increases cardiac output while decreasing pulmonary wedge pressure. Used in the short-term management of CHF.	May cause arrhythmias such as PVCs, supraventricular and ventricular tachycardias, or hypotension.
<b>Anti-thrombotic</b>	<b>Clopidogrel</b> Plavix	An inhibitor of platelet aggregation acting by inhibition of ADP binding to its receptor. Used to prevent atherothrombotic events after recent MI (especially ST-segment elevation-related), stroke, or with peripheral artery disease, acute coronary syndrome.	Bleeding major and minor, abnormal liver function tests, hepatitis, confusion, hallucinations, taste disorders, angioedema, bronchospasm, hypotension and other autonomic nervous system events.

Drug Class	Examples	General Mechanism	Interactions/Side Effects
<b>Anti-arrhythmic</b>			May cause dizziness, headache, syncope, bradycardia, nausea, vomiting, and postural hypotension.
<b>Adrenergic blocker</b>	Bretylium tosylate Bretylol Bretylate	An adrenergic blocker having an effect on ventricular fibrillation and also a peripheral vascular effect which initially leads to postural hypotension. Used specifically for re-entry arrhythmias.	
<b>Calcium channel blocker</b>	Verapamil HCL Calan Covera Isoptin Verelan	A calcium channel blocker that decreases vasoconstriction (especially coronaries) and slow conduction at SA and AV nodes. Used in the management of Prinzmetal (variant) angina and various arrhythmias.	May cause headache, AV block, hypotension, constipation, elevated liver enzymes, or syncope.
<b>Anesthetic</b>	Lidocaine Alestacon Dilocaine L-caine Lidopen Octocaine Nervocaine Xylocaine Xylocard	Acts as both a local anesthetic and also anti-arrhythmic blocking automaticity of His-Purkinje system. Used both for rapid control of ventricular arrhythmias and also as an injectable local anesthetic.	May cause difficulty breathing, anaphylaxis, respiratory depression, numbness, paresthesias, confusion, disorientation, or cardiovascular collapse in rare cases.
<b>Sodium channel blockers</b>	<b>Flecainide</b> Tambacor	A sodium channel blocker used in the treatment of supraventricular tachycardias, AV nodal re-entrant tachycardia, and Wolf-Parkinson-White (WPW) syndrome	Not to be used if there is structural damage such as past MI. Also there is a risk of proarrhythmia.
	<b>Procainamide</b> Procan Procanbid Pronestyl	Used as an anti-arrhythmic especially for atrial fibrillation and flutter. Decreases excitability of myocardium and increases refractory time with possible peripheral vasodilatation effect.	May cause SLE-type syndrome, polyarthralgias, ventricular fibrillation, or agranulocytosis with prolonged use.
	<b>Propafenone</b> Rythmol	A sodium channel blocker used in the treatment of supraventricular tachycardias, ventricular tachycardias, and atrial fibrillation.	May cause SLE-type syndrome, polyarthralgias, ventricular fibrillation, or agranulocytosis with prolonged use.
<b>Potassium channel blockers</b>	<b>Amiodarone</b> Cordarone Pacerone	Prolongs phase 3 of the cardiac action potential. A potassium channel blocker used in the treatment of supraventricular tachycardias, ventricular tachycardias, and atrial fibrillation. Also has beta-blocker-like effects.	May cause blue-grey discoloration of skin, spots on cornea, thyroid dysfunction, and pulmonary fibrosis.
	<b>Sotalol</b> Betapace Betapace AF	Prolongs phase 3 of the cardiac action potential. A potassium channel blocker used in the treatment of supraventricular tachycardias, ventricular tachycardias, and atrial fibrillation. Also has beta-blocker-like effects.	Dizziness, lightheadedness, risk of heart failure, and allergic reactions.
<b>Congestive heart failure (CHF)</b>	<b>Spironolactone</b> Aldactone Novospiroton	Blocks action of aldosterone by competing with receptor sites in distal renal tubules. Used as a diuretic without an effect of hyperglycemia or hyperuricemia. A potassium-sparing diuretic. Used in the management of CHF and other forms of edema, and as adjunct therapy for hypertension.	May cause confusion, lethargy, rapid weight loss, gynecomastia, electrolyte imbalances, elevated BUN, gout, decreased glucose tolerance, or SLE.

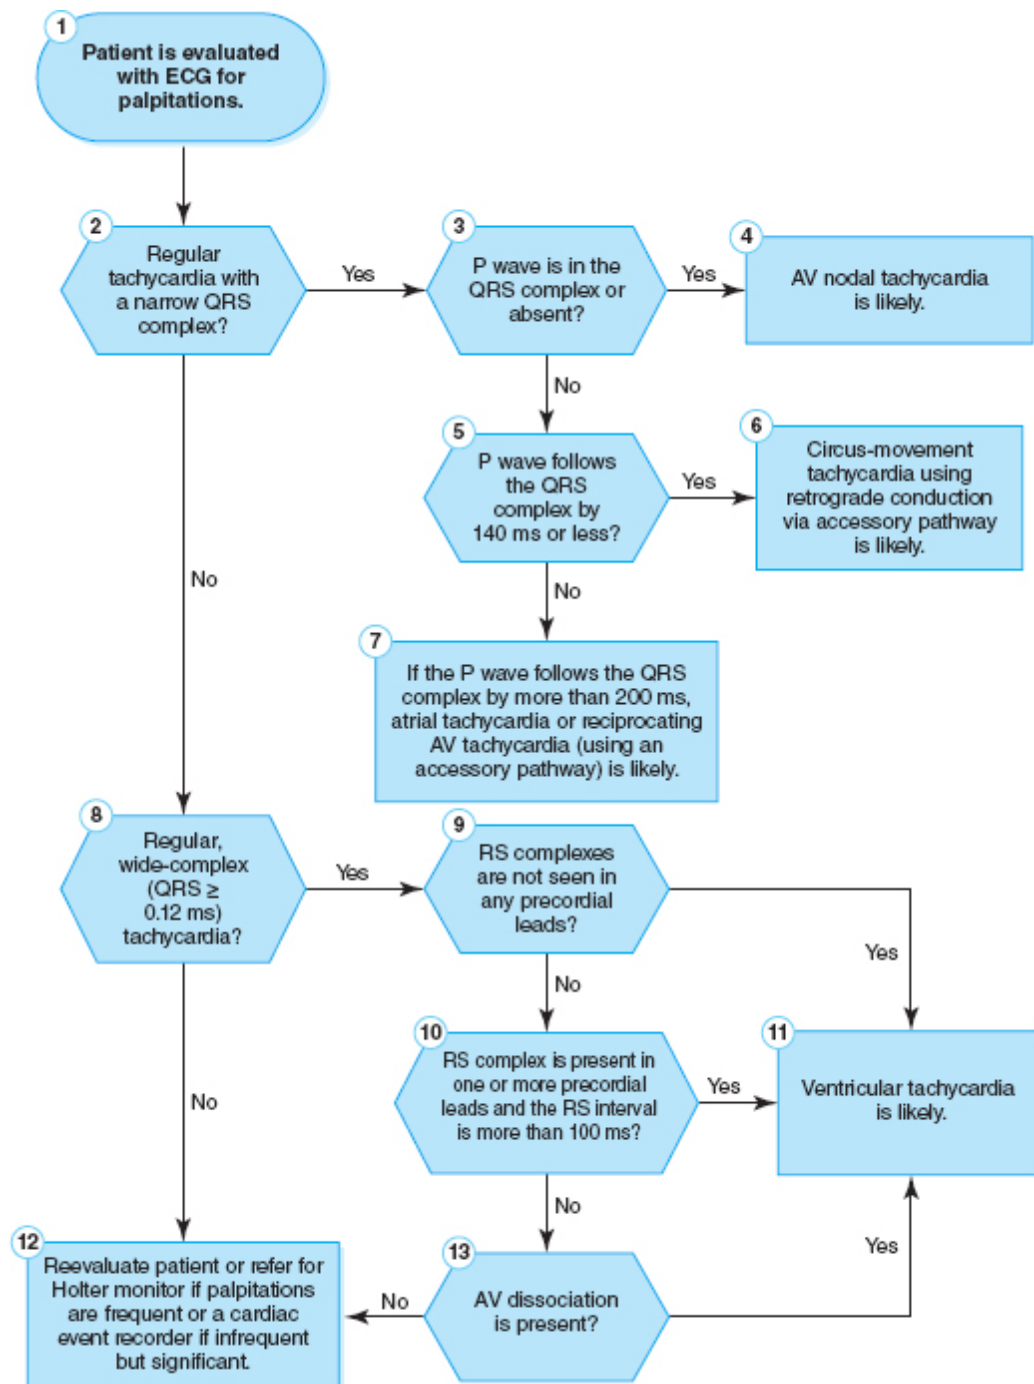

There is a general consensus that medical treatment of arrhythmias is not warranted with the following

asymptomatic presentations: • unsustained supraventricular tachycardia

- unsustained ventricular tachycardia in the absence of structural cardiac disease • Wolff-Parkinson-White syndrome

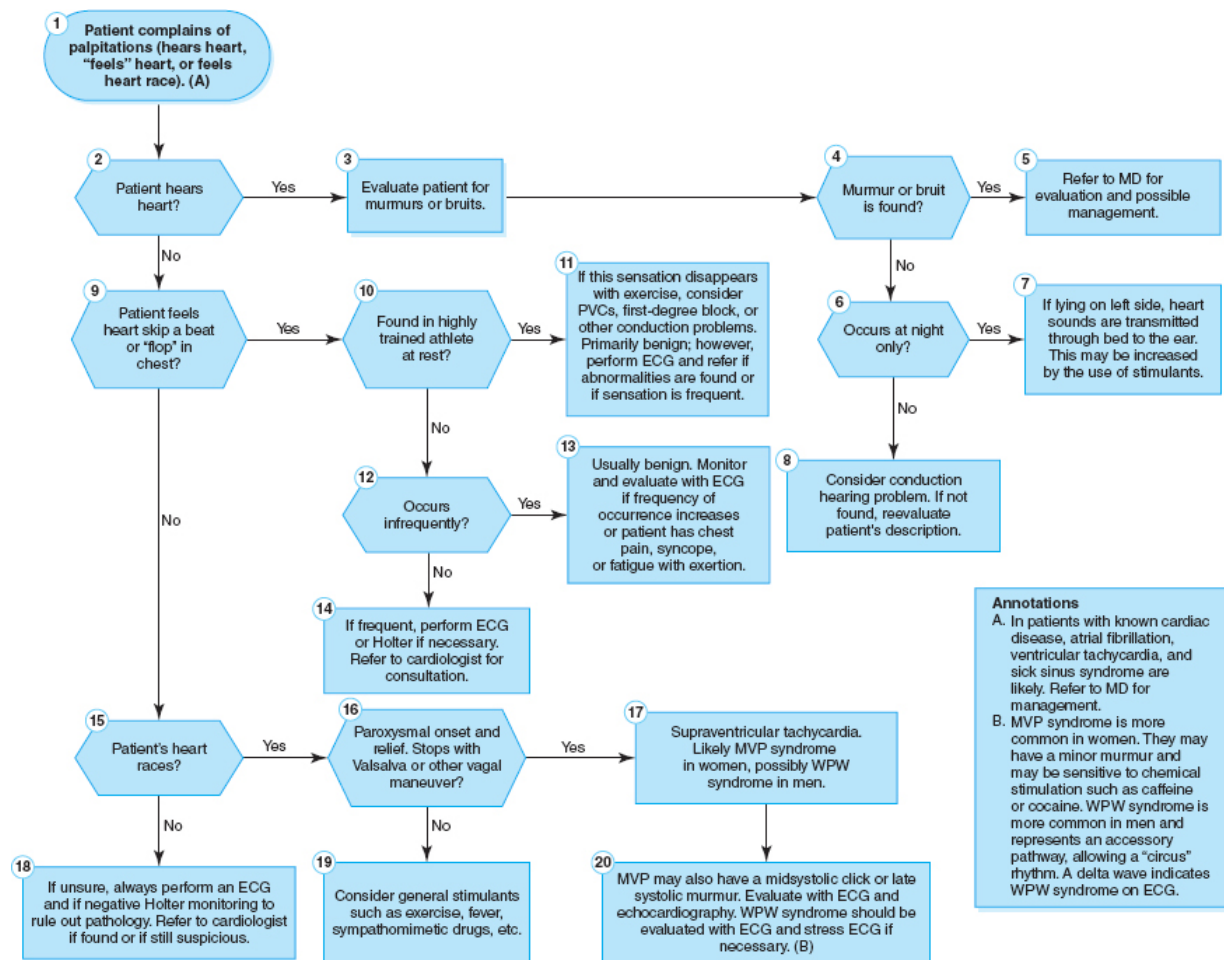

## Algorithms

Algorithms for evaluation of pulse rate, ECG for palpitations, and palpitations in general are presented in **Figures 39-1** and **39-2**.

**Figure 39-1** 12-Lead Resting ECG Evaluation for “Palpitations”—Algorithm

**Figure 39-2** Palpitations—Algorithm

# Possible Causes of Palpitations

## Intra- and Para-Atrioventricular Tachycardia (Narrow QRS Tachycardias)

### Classic Presentation

Patients report a sudden, unprovoked onset of a racing heart. This split-second onset lasts for 15 minutes to several hours and just as suddenly stops. Other symptoms may be lightheadedness, dyspnea, or weakness; syncope is rare. Depending on the cause and length, atypical chest pain may be felt. Patients are often young, with no cardiac pathology. Heart rate is regular and occurs at 160 to 220 beats per minute.

### Cause

There are several names for intra- and para-atrioventricular tachycardia, including supraventricular tachycardia (SVT). The incidence of SVT is about 35 cases per 100,000 per year.<sup>15</sup> Generally, there is no structural heart disease; however, accessory pathways often exist. There are important distinctions between SVT and other tachycardias: • Sinus tachycardia—a progressive onset that is not sudden with normal ECG findings due to sympathetic stimulation or increased cardiac demand.

- Ventricular tachycardia—similar to SVT in that the onset and termination of regular palpitations occurs. However, the patient's initial onset of tachycardia is in the over 50 years age group and in someone with known ischemic heart disease. ECG findings may differentiate by the findings of pathological Q-waves. Ventricular tachycardia is associated with MI and sudden death.
- Atrial fibrillation or flutter—generally the onset is in patients older than 60 years of age with existing heart disease and cardiovascular risk factors. The palpitations are irregular and ECG demonstrates left ventricular or left atrial hypertrophy.
- Paroxysmal SVT—occurs at any age; however, the heart is generally normal with the only ECG finding during asymptomatic periods being pre-excitation.

The most common reason for paroxysmal attacks is re-entry, which ironically can be initiated or abated by a premature atrial contraction (PAC) or a premature ventricular contraction (PVC). This anomalous circuit may involve

the SA, AV, or accessory pathways. Approximately 33% of patients have these accessory bundles in the ventricles. Mainly in men, Wolff-Parkinson-White (WPW) syndrome should be considered. WPW syndrome may also cause atrial fibrillation or flutter. In women, consideration of mitral valve prolapse syndrome is warranted. In the elderly, sick sinus syndrome should be considered, where a “tachy-brady syndrome” is possible.

## Evaluation

It is difficult to catch these often short-lived attacks clinically. ECG evidence is often absent, but WPW syndrome may demonstrate a delta wave or other combination of findings. Mitral valve prolapse (MVP) syndrome usually has no associated findings. Echocardiography for MVP and stress testing for WPW may be necessary.

## Management

Management is largely dependent on the underlying cause. MVP and WPW are often monitored if there are no associated symptoms or findings of underlying cardiac pathology. Sick sinus syndrome or drug-induced paroxysmal tachycardia is managed medically.

### Mitral Valve Prolapse Syndrome

## Classic Presentation

Although MVP may occur at any age and in either sex, most commonly the patient is a woman of childbearing years who complains of palpitations, easy fatigability, or dyspnea. On rare occasions chest pain may be felt. The patient is often thin; more than half of patients may have associated chest wall deformities, including scoliosis, straight back (loss of kyphosis), or pectus excavatum.

## Cause

The cause is unknown. However, there is usually one of several features, including redundant mitral valve leaflets, elongated chordae tendineae, an enlarged mitral annulus, and an abnormal ventricular wall motion. MVP is associated with other conditions such as Marfan’s syndrome, atrial septal defect, and coronary artery disease. Apparently, MVP patients have decreased parasympathetic and increased  $\alpha$ -adrenergic tone.<sup>16</sup>

## Evaluation

As mentioned above, thoracic cage abnormalities may be evident on observation. The cardiac exam may reveal midsystolic click(s) and a late systolic murmur best heard at the apex. These findings are often intermittent; they are not consistent. Maneuvers that may help reveal clicks are standing (decreased ventricular size), which moves the click and murmur closer to S1, and hand gripping or squatting (increased ventricular size), which moves the click and murmur toward late systole. A combination of M-mode and two-dimensional echocardiography will usually demonstrate abnormal valve movement.

## Management

Patients who are asymptomatic or have infrequent attacks of tachycardias are usually watched, but not medically managed. The only recommendation is prophylactic antibiotics for dental work to avoid the risk of subacute bacterial endocarditis. Those with chest pain are sometimes given  $\beta$ -blockers.

## Wolff-Parkinson-White Syndrome

### Classic Presentation

The WPW syndrome is similar in presentation to MVP, except the patient is more often male. The patient presents with a complaint of palpitations that occur suddenly and without provocation. Twenty percent to 30% of patients have atrial flutter or fibrillation.<sup>1</sup>

### Cause

Anomalous pathways connecting the atria to ventricles (Kent bundles) allow re-entry-based tachycardias.

### Evaluation

The primary diagnostic tool is the ECG, which may demonstrate a delta wave. ECG criteria based on the QRS complex morphology seem to be a more sensitive approach. St. George's and Skeber's methods are the most accurate.

# Management

Given the natural history of WPW syndrome in most patients, ablation of the anomalous pathways is reserved for those with severe disease reflected in symptomatology and ECG criteria. Narrow-wave (antegrade conduction through the node) re-entry WPW syndrome is managed pharmacologically, whereas patients with atrial flutter or fibrillation with RR cycle length are at risk for sudden death and are treated with radiofrequency catheter ablation therapy. This approach is 90% effective with antegrade conduction. Failure of ablation therapy forces surgical correction of the problem.<sup>17</sup>

## **CHAPTER 40**

# **Dyspnea (Difficulty Breathing)**

## **Context**

Difficulty breathing (dyspnea) is usually a chronic complaint in the context of a chiropractic office setting. Patients are more likely to present with “acceptable” nondisabling dyspnea or a past history of paroxysmal dyspnea suggestive of asthma. Acute distressing dyspnea is usually due to a severe asthma attack, anaphylaxis, myocardial infarction, or pulmonary embolism. These patients are in need of emergency medical attention.

Although there are a number of disorders that have dyspnea as one of the complaint symptoms, two-thirds of patients with dyspnea as the main complaint have either a pulmonary or a cardiac disorder.<sup>1</sup> It is important then to differentiate cardiopulmonary disease from other causes in an effort to determine referable disorders from those that are manageable or comanageable.

## **General Strategy**

## **History**

## Determine the following:

- what the patient means when he or she complains of difficulty breathing: painful inspiration, tightness in the chest, unable to catch breath, etc. (**Exhibit 40-1**)
- whether the difficulty is positionally related: worse while lying, lying on the side, or standing
- whether it is related only to exertion, the degree of exertion, and the general fitness level of the patient
- whether there was an antecedent respiratory infection
- whether the patient has a diagnosis or signs of depression
- whether the patient was in a setting that produced anxiety prior to the onset of dyspnea
- whether the patient had any previous calf pain and whether he or she was either immobilized for a long period or is taking birth control pills

## Evaluation

- Auscultate the heart and lungs and listen for any murmurs or adventitial sounds (rales, rhonchi, or wheezes).
- Order a posteroanterior (PA) chest film; if rib fracture is suspected order anteroposterior (AP) and PA rib views, if no fracture is seen but suspected order oblique views of the involved area.
- Perform spirometry, if available, to determine pulmonary function (a simple, yet less accurate, monitoring approach is a peak flow meter).
- Order a general screening lab test to determine whether the red blood cell (RBC)/hematocrit (anemia), blood gas, and glucose (diabetes) levels are normal.

# Management

- Refer the patient if pulmonary embolism, pneumothorax, pulmonary hypertension, pleurisy, infection, or tumor is suspected. (See **Table 40-1**.)
- Possible comanagement conditions include asthma, emphysema, congestive heart failure, and rib fractures or the myofascial/subluxation-related elements of these conditions.
- Manage “cracked” ribs (rest and time), vertebral or rib subluxations (chiropractic manipulation), and myofascial disorders (myofascial-release techniques or massage and stretching).

## **Exhibit 40-1 Clarification of Difficulty Breathing**

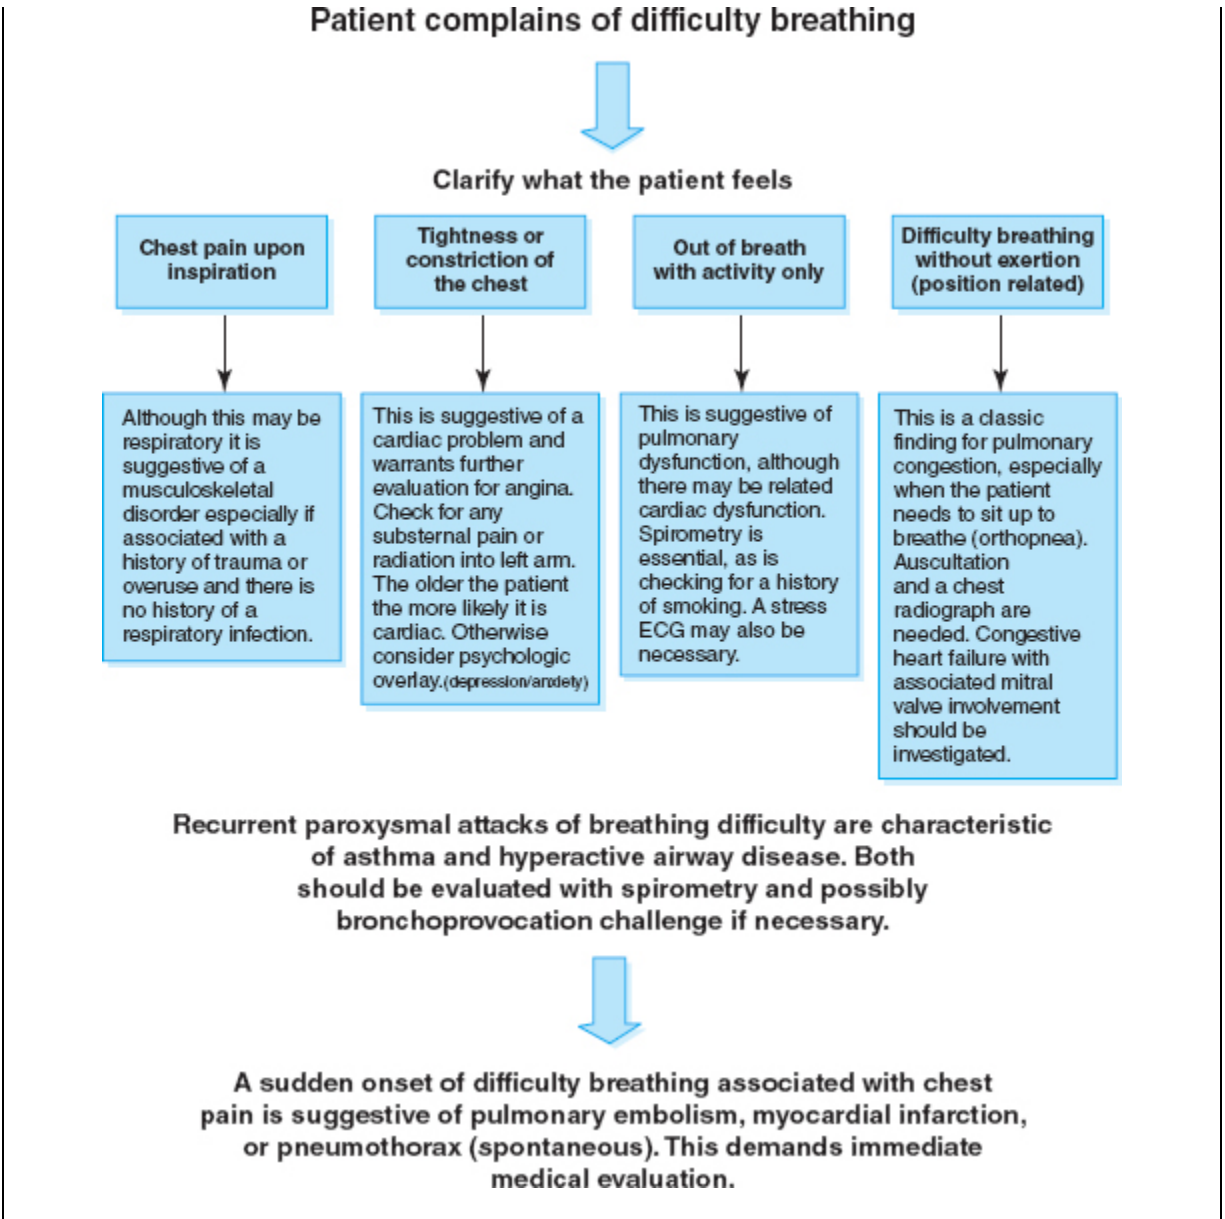

Table 40-1 Pulmonary Disorders*	
Type	Summary Information
	Atelectasis occurs when a portion of the lungs collapses, usually alveolar collapse. There are a number of

# Atelectasis

causes and types, including lack of surfactant in infants, compression atelectasis due to pressure from fluid accumulation in the pleural cavity as is seen with heart failure, tumors, and other causes of pleural effusion. Resorptive atelectasis occurs in the distal bronchi due to an obstructed bronchus. Most often the obstruction is a mucous plug, tumor, or aspirated foreign material. Air in the distal alveoli is resorbed and the alveoli collapse. Atelectasis is usually amenable to treatment if the underlying cause is eliminated.

## Adult-respiratory distress syndrome (ARDS)

ARDS may develop secondary to a number of insults to the body or lungs, including trauma, burns, acute heart failure, pneumonias, toxic fumes, or near-drowning (latent affect). Generally, there is damage to either the pulmonary capillaries or alveolar cells leading to increased permeability and the accumulation of both fluid and blood, with the consequent plasma-derived hyaline clots. Associated disseminated intravascular coagulation (DICS) occurs secondary to shock when intra-alveolar hemorrhages are associated with microthrombi in the pulmonary vasculature. Usually symptoms develop within 24 hours of the causative event. Progression to respiratory failure is rapid with the need for ventilatory support. Mortality is high, with 66% of patients dying within weeks (33% within days).

# Pneumoconiosis

The chronic inhalation of mineral dusts, fumes, and other organic or nonorganic particulate matter may cause a chronic inflammatory process that leads to, among other problems, fibrosis and even cancer. These very small particles are not

cleared by the normal protective clearance with mucus. Entering the alveoli, these small particulates may cause damage through macrophage release of cytokines. There are several varieties, with the most common being coal-workers' lung disease, also known as black lung disease, involving chronic inhalation of carbon and/or silica. Silicosis may also occur in those performing stone cutting and sand blasting. The exposure to silica dust is usually at least 10 to 20 years. There is no treatment for either disease, with symptoms and severity related to the degree of destruction and fibrosis. Chronic exposure to asbestos also may lead to fibrosis, but can also be causative for pleural fibrosis, lung cancer, and mesothelioma. Asbestos exposure was common at one time, specifically with house and building construction, particularly insulation, and also found with car brake lining. Symptoms are restrictive, with dyspnea persisting for years.

## Sarcoidosis

An autoimmune disorder of unknown etiology that affects blacks more often, especially females. Lymph node involvement primarily in the lungs includes predominately CD4+ helper cells (outnumbering CD8-suppressor cells) with a reduction of circulating CD4+ cells. In addition to the mediastinal involvement, lymph nodes in the neck, liver, and salivary and lacrimal glands are also affected in many patients. There is a proliferation of granulomas and effusions that may affect any part of the body. These are unlike fungal granulomas in that they are noncaseating (no necrotic center). About half of patients are asymptomatic when diagnosed after a routine physical examination

	<p>identifies lymphadenopathy. When symptoms develop, they may be generalized, such as low-grade fever, fatigue, and anorexia. The laboratory diagnosis is nonspecific; however, elevated serum levels of angiotensin converting enzyme (ACE) are found in over half of patients. Also, some patients have hypercalcemia. Radiographically, hilar lymph adenopathy may be visible; confirmation is with biopsy of lymph nodes. Approximately 70% of patients recover spontaneously; however, those with symptoms lasting more than 2 years may have a poor prognosis.</p>
<b>Fungal diseases (mycoses)</b>	<p>Fungal infection of the body is primarily related to immunocompromise as would occur with patients with AIDS, diabetes, and long-term corticosteroid use. Also found with lung disorders such as emphysema, bronchiectasis, and tuberculosis, among others that compromise the body's defense mechanisms. Primary fungal disease in the lungs is often geographically related with the most common being coccidioidomycosis (San Joaquin Valley fever); histoplasmosis, mainly in the east and midwest; blastomycosis in North America and Africa; and paracoccidioidomycosis (South American blastomycosis). Symptoms are often nonspecific; however, a combination of low-grade fever, chills, night sweats, anorexia, and malaise coupled with prolonged respiratory symptoms is suggestive. Radiographic findings of diffuse granulomatous lesions are sometimes seen. Diagnosis is through confirmation of the organism in sputum, urine, blood, or bone marrow. Treatment incorporates very potent medications such as</p>

	amphotericin B fluconazole, and itraconazole as first-line treatment with other medications used as adjunctive if primary treatment is ineffective.
<b>Hypersensitivity pneumonitis</b>	Hypersensitivity may be induced by mold and fungi such as on hay or tree barks, in contaminated air-conditioning equipment; also, bird droppings, animal dust, and wood dust may induce hypersensitivity. The allergen causes the formation of antigen-antibody complexes, activating complement-causing symptoms within several hours after exposure. With the chronic type, a cell-mediated reaction occurs, often leading to alveolar granulomas. Common examples are farmer's lung (moldy hay or grain), bagassosis (sugar cane), maple bark disease, mushroom worker's lung, humidifier lung, pigeon-breeder lung, and furrier's lung (animal pelts). With the acute form, avoidance of the antigen is sufficient. With the chronic type, a progressive destructive process may occur leading to the need for lung transplantation.

\*Not covered in the "Selected Causes" section.

- Be advised that management of asthma is controversial, but some practitioners report control with chiropractic manipulation; serious issues are medication changes in those diagnosed with asthma and unavailability of medication in the event of an acute attack with those who have not received medical evaluation and prescription.

## Relevant Anatomy and Physiology

Dyspnea is a conscious sensation and as such is a variable impression based on an individual's comparison to what is considered normal. In other words, although someone may feel an increased workload going up a flight of stairs, he or she would not report this as dyspnea unless it was felt to be an "unexpected" amount of effort. A variety of tissues with different receptors may convey information that is eventually interpreted as dyspnea; however, it is not clear how much each contributes. It does seem clear that respiratory muscle contractions play a predominant role. Some possible factors follow.

Acid-base balance serves as the primary stimulus for ventilation; however, it is not clear how much decrease in oxygen or increase in partial pressure of carbon dioxide ( $P_{CO_2}$ ) contributes to the sensation of dyspnea.<sup>2</sup> The carotid bodies sense pH and oxygen/carbon dioxide levels and stimulate breathing when levels are perceived as unbalanced. However, hypercapnia associated with breath holding can be eliminated as a stimulus for breathing by neuromuscular blockade.<sup>3</sup> This allows discomfort-free breath holding.

Several intrapulmonary receptors play a role. Irritant and C-fiber receptors react to chemical and physical irritants.<sup>4</sup> Slowly adapting pulmonary stretch receptors respond to large increases in lung volume. This afferent information is carried via autonomic pathways. These receptors may be partially blocked by lidocaine or morphine, decreasing some of the severity of dyspnea.<sup>5</sup> However, patients with heart-lung transplantation (denervated lungs) can still sense dyspnea. Also, bilateral vagal block does not totally eliminate the perception of dyspnea.<sup>6</sup>

The key may lie in the sensory receptors of respiratory muscles. Muscle spindles and tendon organs are found mainly in the intercostal muscles. The diaphragm contains mainly tendon organs. These sensory organs are sensitive to

increased muscle work. It appears that acid-base balance and irritant receptor stimulation play a contributory role through stimulation of muscular contraction. The increased muscular effort conveys the sense of dyspnea.<sup>2, 3</sup>

Blockage to inspiration occurs with extrathoracic (upper airway) disorders. Blockages by inflammation acutely with anaphylaxis and subacutely associated with mononucleosis or pertussis are serious causes requiring immediate treatment. Blockage due to foreign body aspiration is also a common serious cause in children and in the immunocompromised. With upper airway obstruction, stridor is often heard if the blockage is not complete. Intrathoracic obstruction has more of an effect on expiratory effort. Blockages from bronchoconstriction, mucosal edema, and mucus production are seen primarily with asthma with some overlapping with other chronic obstructive pulmonary disease (COPD) such as chronic bronchitis and emphysema. When both inspiration and expiration are affected, restrictive lung disorders should be considered. These include intrinsic lung disorders such as pneumonia, fibrotic lung disease, and pulmonary hypertension/edema. Extrathoracic causes of restriction include musculoskeletal disorders such as severe kyphoscoliosis, pectus excavatum, flail chest, and muscular dystrophy. Neurologic depression from central (tumor or stroke) or peripheral (Guillain-Barré, poliomyelitis, or myasthenia gravis) nervous system dysfunction also may cause dyspnea. Myasthenia gravis may simulate cardiac or lung disorders in some patients.<sup>7</sup>

Asthma is certainly one of the most common chronic causes of dyspnea. It is surprising that a 180-degree change in thinking regarding allergic contribution and natural history of asthma has occurred over the last twenty years. Growing evidence, still controversial, suggests that the traditional theory of avoidance of allergens is probably an extrapolation that did not take into account timing of immune response and reactivity. From observations in mice,

it is believed that there are two types of CD4+ T-cells. These may be somewhat reciprocally inhibitory to each other. It is believed that type 1 helper T (Th1) cells are important for cellular defense, producing interleukin-2 and interferon- $\gamma$ . Type 2 helper T (Th2) cells mediate allergic inflammation through the production of cytokines (interleukins-4, 5, 6, 9, and 13). A new “hygiene hypothesis” posits that there is an imbalance between these two cells that is environmentally specific, with timing of exposure as the crucial variable. It is known that newborn infants are more Th2-cell dominant immunologically, and it is hypothesized that the infant needs appropriate exposure to environmental stimulus to create a balance between Th1 and Th2 responses.

Therefore, microbial products may play a crucial role in the maturation of a child’s immune response, resulting in tolerance to other components of environmental exposure, such as pollen and animal dander, due to the balance of Th1 and Th2 responses. As a result of new research, there is a focus on developing a prevention approach timed to the individual’s age (primarily before age 6 years) based on exposure to specific stimulators of Th1 response coupled with knowledge of an individual’s “asthma genes” (inherited tendencies). Added information about the “natural” history of asthma from childhood to adulthood suggests that approximately 25% of children had wheezing that was relapsing or persistent into adulthood, predicted by early age of onset, female gender, airway hyper-responsiveness, sensitization to house mites, and smoking. Yet the damage done at least in reference to lung function did not appear to progress through adulthood.<sup>8</sup>

New evidence suggests the following:<sup>9</sup>

- There is an increase in the Th2 helper-cell response in children with asthma that may be related to the following factors:
  - 1.** widespread use of antibiotics

- 2.** western lifestyle
  - 3.** an urban environment
  - 4.** diet
  - 5.** sensitization to dust mites and cockroaches
- There is an increase in the Th1 helper-cell response in children who do not have asthma that may be related to the following factors:
    - 1.** the presence of older siblings<sup>10</sup>
    - 2.** early exposure to day care (within first six months of life for children without a maternal history of asthma)<sup>11</sup>
    - 3.** tuberculosis, measles, or hepatitis A infection
    - 4.** a rural environment

Further, it has been demonstrated in some studies that exposure to dogs or cats in the first year of life may reduce subsequent risk of reaction to allergens.<sup>12</sup> An association between the development of an IgG response to certain foods (i.e., wheat, rice, soybeans, peanuts, egg whites, cow's milk, meat, oranges, and potatoes) and an increased risk for development of IgE antibodies to inhaled allergens was studied recently. The researchers did find that an increased IgG antibody level to a mixture of wheat-rice or oranges occurred in children who subsequently developed an IgE response to cats, dogs, and/or dust mites.<sup>13</sup> A recent study indicates that there is mast-cell infiltration of airway smooth muscle, which differentiates asthma patients from others with allergic disorders.<sup>14</sup>

There is growing evidence that allergy risk (allergy and extrinsic asthma are related) is in large part related to maternal influence and age of exposure to allergens. One recent study indicates that in children with a hereditary tendency toward atopy, breastfeeding for a minimum of three months protected against it.<sup>15, 16</sup> Interestingly, in those children without atopic heredity, it increased the risk of atopy. Also of interest is that although milk products are

often suspected as being a cause or activator of asthma, the results from a recent study indicate that there was a reduced risk for asthma in preschool children who consumed products with milk fat.<sup>17</sup>

## Evaluation

## History

It is important to distinguish between general fatigue and dyspnea. Of course, these two possibilities may overlap; however, with chronic fatigue, depression, or metabolic/endocrine disorders, the patient will likely feel a more constant, yet nonthreatening, sense of dyspnea unless associated with anxiety or hyperventilation.

A patient's description of what he or she means by difficulty breathing, coupled with the context of when this occurs, is often the compass point needed for directing further evaluation.

- Painful breathing—Patients who feel that breathing is difficult solely because of painful restriction on inspiration are likely to have a somatic problem such as a musculoskeletal cause or pleurisy (parietal pleural irritation). This is differentiated by determining whether there is a history of trauma or respiratory infection, respectively. Rib subluxations are often nontraumatic, whereas rib fractures are usually due to direct chest trauma. If the patient has no history of a respiratory infection or trauma, spontaneous pneumothorax should be considered. This disorder occurs without warning and appears to be more common in young, tall men, often after exertion (although it may occur at rest). This disorder is also a

possibility in those patients with COPD who develop a sudden, sharp, unilateral chest pain that is worse with inspiration. These same patients may have a rib subluxation due to chronic coughing. Relatively recent additions to the literature are reports of diaphragmatic spasm.<sup>18</sup> This condition will present with an abrupt onset of chest pain and dyspnea with no obvious provocation or triggering event. Some patients will report the ability to eliminate the pain and dyspnea with a forced, full expiratory effort.

- Chest tightness—If a patient complains of chest tightness and/or substernal discomfort or pain, angina should be considered as a strong possibility, especially if relieved by rest (or nitroglycerin). Patients who appear depressed or anxious may complain of a similar sensation. Further questioning regarding emotional context is important.
- Dyspnea at night—Difficulty breathing while sleeping suggests congestive heart failure (CHF)/pulmonary hypertension, or asthma. Patients with CHF often are awakened with dyspnea (paroxysmal nocturnal dyspnea) and find they have to prop themselves up with pillows (redistributes blood and decreases visceral compression on the diaphragm). Patients with asthma may have attacks at around 12 AM to 4 AM because of changes in sympathetic activity and cortisol levels.
- Dyspnea with exertion—Difficulty breathing with exertion suggests cardiopulmonary or pulmonary disease (especially asthma or hyperactive airway disease). With CHF or pulmonary hypertension, minor effort is enough to bring on shortness of breath. With asthmatics, dyspnea usually occurs after 10 to 15 minutes of intense exercise and/or after exercise in general. The recovery period with CHF and pulmonary hypertension would generally take longer.

If dyspnea appears to be position-related, a clue to underlying causes may be found. Common terms used and conditions associated with position-related dyspnea include the following:

- Trepopnea—occurs in one lateral position; if lying on the involved side improves breathing a pleural effusion or internal lung disorder is likely because of the increased perfusion created by gravity; if breathing is made worse by lying on the same side, a somatic problem such as rib fracture or pleurisy is more likely.
- Orthopnea—occurs when lying supine; it is usually relieved by sitting up and is characteristic of left ventricular failure and sometimes with COPD or weakness of the respiratory muscles.
- Platypnea—occurs in the standing position, is relieved by lying down; this is suggestive of right-to-left shunt in the heart or pulmonary vascular shunting of venous blood.

A history of prolonged immobilization, use of birth control pills, or prior calf pain suggests the possibility of pulmonary embolism, especially in a patient with a mild fever. A history of prolonged smoking would steer the investigation toward COPD. An associated history of a chronic productive cough suggests chronic bronchitis. If the patient appears to be in respiratory distress, having to lean forward to breathe through pursed lips and using the secondary muscles of respiration (like someone who has just finished a race), emphysema is likely. A history of smoking with a recent history of weight loss warrants a suspicion of lung cancer. It is important to determine prolonged occupational exposure to various dust particulates in an effort to uncover a possible pneumoconiosis such as asbestosis or silicosis.

When dyspnea is gradual and constant, progressive cardiac or pulmonary disease is likely. Other possibilities

include deconditioning and obesity. When dyspnea is characterized by recurrent attacks with resolution into symptom-free periods, asthma is likely. Questioning regarding family history of asthma or allergies and any triggering events or substances (allergens, drugs, or pollutants) is important. Cold and dry environments are more likely to trigger an asthmatic reaction, especially in an athlete. Allergies to pollen, pets, dust mites, foods, clothing, and medications (aspirin or nonsteroid anti-inflammatory drugs [NSAIDs]) are common in asthmatics. Emotional triggering with stressful events is known to occur with asthma.

Most other causes are due to conditions that have enough premonitory signs or symptoms prior to dyspnea that the diagnosis is already made. For example, a patient with Guillain-Barré syndrome will almost always present with an ascending weakness starting in the legs. This usually gives ample time for the diagnosis and preparation for ventilation support. The same is true of polio (associated muscle weakness), myasthenia gravis (weakness of cranial muscle first with repetitive use), and other disorders.

## Examination

Although there are classic examination techniques recommended in the evaluation of pulmonary and cardiac conditions, a review of a large literature base on sensitivity, specificity, and reliability is disappointing. One common examination technique is percussion, used to detect various lung pathologies and in estimating heart size and diaphragmatic excursion.<sup>19</sup> Although factors such as the speed of the stroke of the plexor finger, the speed at which the finger is withdrawn, and the degree of force (light or heavy) are determinants of the sensitivity and accuracy of percussion, it appears that their value has been

overestimated. It is generally believed that percussion travels several centimeters through the body, and the result is a sound whose pitch and quality reflect the density of tissue directly under the percussion. There is poor literature support for this belief. In several studies,<sup>20,21</sup> chest percussion revealed large pleural effusions; however, smaller lesions such as granulomas or deep nodules went undetected.

Traditionally, chest percussion is used to evaluate diaphragmatic excursion. Several difficulties with this approach exist. There is a high interexaminer disagreement,<sup>22</sup> and radiographically, differences between bedside percussion and chest film measurements are as much as 3 cm.<sup>23,24</sup> This means that the difference between rating a patient normal or abnormal with percussion is often not possible.

As long ago as 1899, the accuracy of percussion for delineating cardiac size was challenged. Through comparisons with cardiac weight at autopsy it was discovered that only about half of moderately enlarged hearts and less than one-third of mildly enlarged hearts had been discovered and noted by clinicians. More recent studies indicate a generally good correlation between a displaced left-sided heart border detected by percussion and an enlarged cardiothoracic ratio on a chest radiograph.<sup>25</sup> The only problem is that patient outcome is poorly correlated with this measure. Other factors are more predictive of patient outcome, such as left ventricular end-diastolic volume and left ventricular mass. Percussion was sensitive (0.91) to these two measures, but not specific (0.30).<sup>26</sup>

A chest radiograph is important in the evaluation of cardiac size and the status of the lungs. Following are some classic findings and associated disorders:

- Haziness of vascular markings with an associated cardiomegaly may be evident with CHF.
- Diffuse granulomatous involvement of the lungs may suggest a fungal disorder and, if more apical, tuberculosis.
- Decreased markings suggest emphysema.
- Hyperlucency (no markings) and/or shifting of the trachea suggest pneumothorax.
- Lobar consolidation suggests pneumonia.
- Evidence of an air-fluid line would suggest pleural effusion.
- Perihilar opacities may suggest sarcoidosis or lung cancer.

Pulmonary function testing is essential in patients with a complaint of dyspnea. Peak expiratory flow rate (PEFR) can be measured using a peak flow meter. This is an inexpensive device that measures the patient's ability to expire. It is an acceptable monitoring device; however, it is effort-dependent, and decreases are found with many disorders. Age-, gender-, and height-matched standards are used as optimal comparison values. Spirometry is more sophisticated and may give more specific clues. If the forced expiratory volume in one second ( $FEV_1$ ) or maximum midexpiratory flow rate (FEF 25%–75%) is decreased, COPD is likely. If this response is reversed with a bronchodilator or made worse by a bronchoconstrictor (methacholine challenge), asthma is likely. Measurements of lung volume or diffusing capacity are expensive and should be reserved for the specialist. When a pulmonary embolism is suspected, referral for lung perfusion scanning or digital subtraction angiography is needed.

Laboratory testing is usually unnecessary unless anemia, diabetes, or endocrine disorders are suspected. In children with asthma, it is important to obtain skin-allergy test

results. This may direct the development of an avoidance program if necessary.

## Management

Management of the acutely dyspneic patient is better delegated to medical personnel in an effort to provide any supportive emergency efforts when needed. The patient with a more chronic or mild complaint may be amenable to comanagement. Specific management approaches are discussed under Selected Causes of Dyspnea. Medical management of COPD is often based on an approach to decrease inflammation and stimulate the sympathetic nervous system during acute attacks. These medications are listed in **Table 40-2**. In general, the chiropractic approach may include cervical or thoracic manipulation, myofascial work, stretching, and breathing exercises.

**Table 40-2 Respiratory Medications**

Drug Class	Examples	General Mechanism	Interactions/Side Effects
Allergy Medications			
Antihistamines	Fexofenadine	An antihistamine H1 receptor antagonist used for the management of seasonal allergic rhinitis and chronic urticaria	Headache, nausea, fatigue, dyspepsia, nausea, throat irritation
	Allegra		
	Diphenhydramine HCL	An H1 receptor antagonist used in the treatment of many varied conditions. Has significant anticholinergic effects and seems to prevent reuptake of dopamine. As a result it is used for allergic conditions, partial management of Parkinson's, as a non-narcotic cough suppressant, and as a sleep aid for those with intractable insomnia.	May cause dizziness, drowsiness, tachycardia, thickening of bronchial mucus with associated wheezing, anaphylaxis, dry mouth, and hypersensitivity.
	Allerdryl		
	Banophen		
	Belix		
	Ben-Allergin		
	Benadryl		
	Benahist		
	Benylin		
	Diahist		
	Nordryl		
	Nytol with DPM		
	Valdrene		
	Many others		
	Hydroxyzine	An antihistamine with anticholinergic and sedative properties. Tranquilizing effect mainly due to depression of hypothalamus and brainstem reticular formation. Primarily used to treat allergic reaction and to relieve nasal congestion and other symptoms.	May cause drowsiness, dizziness, headache, urticaria, dyspnea, wheezing, rash, or hypotension.
	Vistaril		
	Atarax		
	Vistacon		
	Vistaject		
	Loratadine	An antihistamine used in the treatment of allergies, hives (urticaria), and other allergic inflammatory conditions. A long-acting selective peripheral H1 receptor blocker (prevents release of histamine).	May cause dry mouth, dizziness, fatigue, changes in salivation, flushing, hypotension, palpitations, tachycardia, arthralgias, myalgias, blurred vision, rash, and photosensitivity.
	Claritin		
	Claritin RediTab		
Steroid	Fluticasone	A synthetic corticosteroid used for the management of nasal symptoms for allergic and nonallergic rhinitis.	Nose bleeds, nasal sores, nasal or oral fungal infection, glaucoma, cataracts.
	Flonase		
	Flovent		
	Cutivate		
COPD Medications			
Epinephrine	Epinephrine	Both synthetic and prepared from animal adrenal glands. Used in the treatment of asthma. Effects are to cause bronchial arterial constriction, bronchodilation (smooth muscle relaxation), and inhibit histamine release. Also used for anaphylactic shock, restoring sinus rhythm, for open-angle glaucoma, and to reduce uterine contractions.	Causes sympathetic effects of nervousness, tremor, palpitations, tachycardia, anorexia, urinary retention, etc. Also may cause pulmonary edema, ventricular fibrillation, or MI.
	Bronkaid Mist		
	Epi E-Z Pen		
	Epinephrine		
	Primatene Mist		
	Bromitin Mist		
	Asthmahaler		
	AsthmaNefrin		
	Epitrate		

<b>Beta-agonists</b>	<b>Salmeterol xinafoate</b>	Similar to albuterol, it is a long-acting beta2 receptor agonist. Effects include reduction of bronchospasm, increased motility of cilia, and decrease in inflammatory mediators such as histamine. Used in the treatment of asthma and hyperactive airway disease. Not used to treat acute bronchospasm.	May cause dizziness, headache, tremor, palpitations, and in rare cases, acute respiratory arrest.
	Serevent		
	<b>Metaproterenol</b>	Beta2 agonist used in the treatment of asthma. Causes bronchodilation without secondary vascular and cardiac effects.	May cause anorexia, tachycardia, nausea, arrhythmias, tremor, hypertension, muscle cramps, convulsions, weakness, hallucinations, or postural hypotension.
	Alupent		
	<b>Albuterol</b>	Beta2 agonist used in the treatment of asthma. Causes bronchodilation without secondary vascular and cardiac effects.	May cause anorexia, tachycardia, nausea, arrhythmias, tremor, hypertension, muscle cramps, convulsions, weakness, hallucinations, or postural hypotension.
	Ventolin Proventil		
	<b>Isoproterenol</b>	Used primarily as a bronchodilator with asthma. A beta1 adrenergic agonist that causes increased expectoration, increased ciliary motility, and bronchodilation with increase in cardiac output and strength. Also used for cardiac stimulation with cardiac arrest, and various arrhythmias.	May cause anorexia, tremors, palpitations, tachycardia, flushing, or ventricular arrhythmias.
	Isuprel Dispose-a-Med		
<b>Xanthines</b>	<b>Theophylline</b>	A xanthine derivative that causes the relaxation of smooth muscle, stimulates the medullary respiratory center, and stimulates myocardium. Used primarily in the management of bronchospasm and prophylactic and acute attacks of asthma. Also may be used for edema associated with CHF.	May cause gastric upset, irritability, anorexia, abdominal pain, dizziness, headache, drug-induced seizures, palpitations, tachycardia, albuminuria, fever, dehydration, and rarely respiratory arrest.
	Bronkodyl		
	Elixophyllin		
	Pulmophylline		
	Slo-Bid		
	Slo-Phyllin		
	Somophyllin		
	Theo-Dur		
	Theospan		
	Uni-Dur		
<b>Leukotriene receptor antagonists</b>	<b>Montelukast</b>	Used as prophylactic treatment of chronic asthma, exercise-induced bronchospasm, and allergic rhinitis.	Sinusitis, nausea, diarrhea, dyspepsia, otitis, viral infection, and laryngitis.
	Singulair		
	<b>Zafirlukast</b>	An oral leukotriene receptor antagonist. Leukotrienes are pro-inflammatory chemicals derived from arachidonic acid. Blocks the binding of leukotriene types D4 (LTD4) and E4 (LTE4). Used in the treatment of asthma; decreasing the inflammatory aspect of asthma.	May cause headache, GI distress, and in older patients an increase in respiratory infection.
	Accolate		
<b>Combination meds</b>	<b>Fluticasone propionate with salmeterol</b>	An inhaled medication for the treatment of asthma and chronic bronchitis. A combination of a long-acting beta-2 agonist (salmeterol) and oral corticosteroid. Not used for acute asthma attacks.	May increase the risk of asthma-related deaths. Dizziness, headache, palpitations, sinus tachycardia, respiratory arrest, long-term steroid use effects.
	Advair		

	Triamcinolone	A corticosteroid with anti-inflammatory and antirheumatic effects. Aerosol version commonly used in the management of asthma.	With injectable type may have Cushing's-like features, growth retardation, hyperglycemia, carbohydrate intolerance, nausea, vomiting, headache, euphoria, muscle weakness, osteoporosis, aseptic necrosis of bone, and delayed wound healing.
	Aristocort		
	Atolone	A spacer is used with the inhaler to prevent possible candida infection of the mouth. With the inhaled version the usual side effects associated with long-term glucocorticoid use are not seen, partially due to the clearance on first pass through the liver.	
	Kenacort		
	Kenalog-E		
	Aristospan		
	Cenocort		
	Triam-Forte		
	Articulose		
	Trilone		
	Tristoject		
Mast cell stabilizer	<b>Cromolyn</b>	A prophylactic medication used in the management of asthma; specifically extrinsic or allergic-related asthma. Stabilizes sensitized mast cells preventing the release of histamine and SRS-A (slow reacting substance of anaphylaxis). May also be used ophthalmologically for allergic ocular disorders.	Side effects mainly due to method of administration. Includes nasal stinging and burning, irritation of throat, nausea, rarely angioedema and bronchospasm.
	Intal		
	Disodium cromoglycate		
	Pivent		
	NasalCrom		
	Gastrocrom		
	Rynacrom		
	Vistacrom		
Anticholinergic	<b>Tiotropium</b>	A once-a-day inhaled anticholinergic specific for muscarinic receptors used in the management of bronchospasm associated with COPD.	Dry mouth, constipation, increased heart rate, blurred vision, glaucoma, urinary difficulty.
	Spiriva		
<b>Smoking Cessation</b>			
Nicotinic receptor agonist	<b>Varenicline</b>	Used in the management of smoking cessation. It is a partial agonist for alpha-1, beta-2 nicotinic acetylcholine receptors.	Nausea, sleep disturbance, constipation, flatulence, and vomiting.
	Chantix		

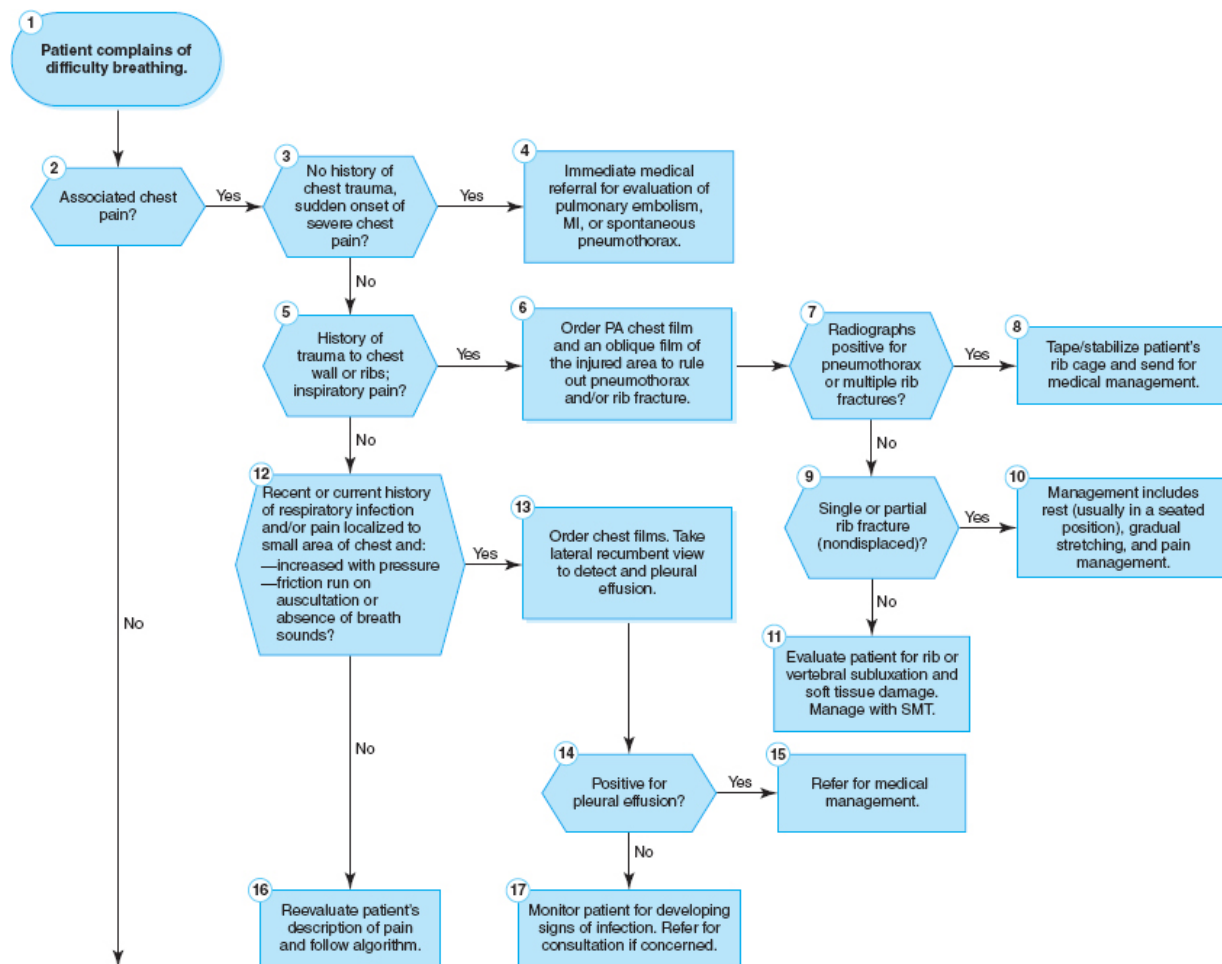

A controversial issue is the management of asthma or asthma-like conditions with chiropractic manipulation. The current literature support is still slim; however, there is a suggestion that there is a possible subjective benefit.<sup>27, 28</sup> More research is needed prior to making claims of consistent success. Like many conditions, there are multifactorial causes, and therefore multiple aspects of management. The approach to many conditions is avoidance of triggers. This is certainly part of chiropractic management as well. In addition, there may be reflex mechanisms that either simulate or worsen an asthma attack. Perhaps these are important aspects that can be addressed through chiropractic manipulation. The major concern with sole management of asthma is the

unavailability of abortive medication in the event of a severe attack. Attacks occur without warning, or with little warning, and the opportunity to get to the chiropractor (or the emergency department if severe) in time may be unrealistic. Therefore, comanagement is a safer approach for the patient. There are, however, many younger patients with either cough-variant asthma or minor episodes, solely related to upper respiratory infections, for whom dyspnea is not the prominent component. Initial management of these cases over several weeks of an actively symptomatic period may be appropriate. If there appears to be no improvement, especially in peak-flow or spirometry measurement, comanagement or referral is suggested.

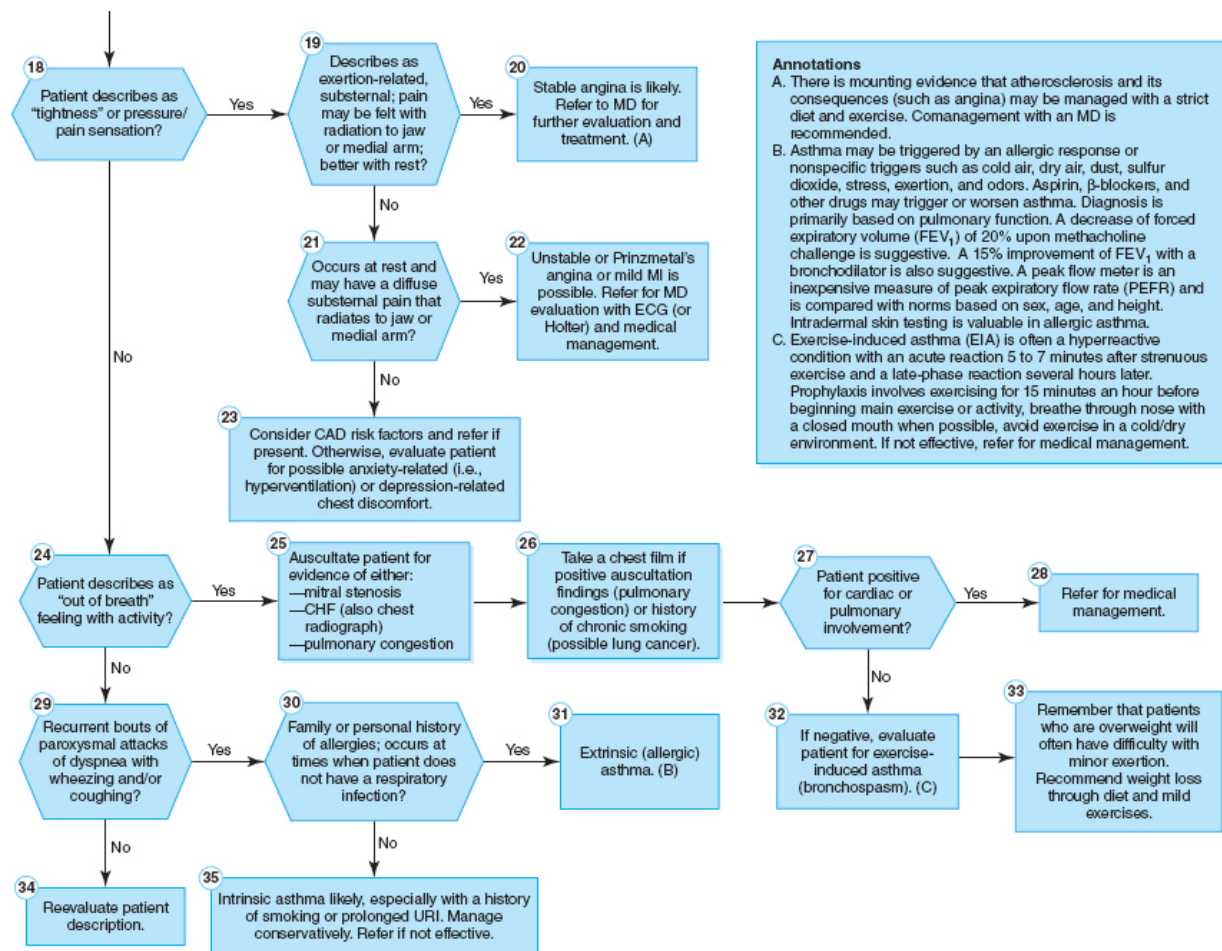

The underlying mechanism with asthma appears to be a chronic inflammatory process. The medical approach is to reduce this underlying inflammation through the use of anti-inflammatory medications (e.g., aerosol corticosteroids) in an effort to decrease this predispositional state. The medical literature also seems to support an earlier resolution in asthma patients. In other words, those treated seemed to recover entirely from their asthma at an earlier age with fewer complications.<sup>29</sup>

## Algorithm

An algorithm for evaluation and management of dyspnea is presented in **Figure 40-1**.

**Figure 40-1** Dyspnea (Difficulty Breathing)—Algorithm

# Selected Causes of Dyspnea\*

## Asthma

### Classic Presentation

The presentation is variable depending on type. In a child with an allergic form of asthma, the presentation will be one of recurrent episodes of wheezing, cough, dyspnea, and a feeling of chest tightness. These attacks may be related to exposure to an environmental allergen or may be aggravated by stress or exercise. The patient may notice attacks occurring in the early morning. In an adult, it is more common to have a patient with similar symptoms; however, the patient will not be aware of allergies. There is often a history of a prolonged respiratory infection, exposure to occupational toxins, and/or a history of smoking.

### Cause/Occurrence

Approximately 17 million individuals in the United States have asthma, according to a forecasted state-specific estimate made by the Centers for Disease Control and Prevention (CDC).<sup>30</sup> The prevalence of self-reported asthma increased 75% from 1980 to 1994 in the United States. Asthma onset occurs by age 6 to 7 years in 80% of patients.<sup>31</sup> During the past 15 to 20 years there has been an increase in both incidence and prevalence of severe asthma.<sup>32, 33</sup> Alarming is the recent finding that among school-aged children in Hartford, Connecticut, 19% had asthma.<sup>34</sup> Given the increase in the number of asthma cases diagnosed each year over the last two decades, theories of cause have been developed. One obvious conclusion is that pollution has increased, which then increases either asthma or the response of asthmatics to the pollution. In a recent study, researchers found evidence of an association between low-level ozone and respiratory symptoms in children with asthma.<sup>35</sup> Other findings were that there was not an association with fine particles as was hypothesized. The level of ozone exposure that would trigger symptoms was lower than levels set as protective standards by the Environmental Protection Agency (EPA). Remission or significant improvement during late teenage years is likely in those with mild asthma. It is believed that those with moderate to severe asthma have an underlying epithelial inflammatory condition and suffer damage to the epithelium and mechanisms of airway defense. The rationale for medical control is to decrease this underlying continuous inflammatory response.

It is believed that asthma is due to an underlying subacute inflammatory disease of the airways. Early-phase response occurs when allergens or irritants cross-link immunoglobulin E (IgE) receptors on mast cells, activating them to release histamine and other inflammatory mediators. A subgroup of helper T-cells helps orchestrate the inflammatory response by secreting cytokines. With the allergic form, there are sensitized mast cells that degranulate releasing histamine, bradykinin, and other factors that lead to acute-phase and late-phase reactions.<sup>29</sup> During an attack, bronchoconstriction, mucus production, mucosal edema, and underlying inflammation join together to cause wheezing with associated dyspnea. In addition to this immediate response, there is often a late response four to six hours later. During this phase, the inflammatory process causes sections of the epithelium and mucociliary transport system to slough off. This leads to the exposure and sensitization of irritant receptors priming the area to be hyperresponsive to normal stimuli. There are many triggers, including cold/dry air (e.g., exercise induced), allergens, dusts and sulfur dioxide fumes, emotional stress, upper respiratory infections, and medications such as aspirin,  $\beta$ -blockers, NSAIDs, and angiotensin-converting enzyme (ACE) inhibitors. In about 25% of patients, the primary complaint is coughing. This is referred to as cough-variant asthma.

## Evaluation

An investigation for historical clues such as family history of allergies (extrinsic asthma), triggers to attacks, and severity of attacks is helpful to establish a high index of suspicion. Auscultation may detect wheezes. Simple pulmonary function testing with a hand-held device such as a peak flow meter may detect a decrease in peak expiratory flow rate when compared with age-, sex-, and height-matched values. Spirometry testing focuses on detecting a decrease in forced expiratory volume in one second (FEV<sub>1</sub>). If there is no decrease, two other functional tests are possible. The first is a provocation test, often with methacholine (a bronchoconstrictor). A hyperresponsive reaction will significantly reduce expiratory measurements (e.g., a decrease of 20% or greater in FEV<sub>1</sub>). The opposite approach is the use of a bronchodilator to measure improvement in pulmonary function (improvement of 15% or greater in FEV<sub>1</sub>).<sup>36</sup> Ancillary tests include laboratory evaluation of sputum to detect Curschmann's spirals, eosinophils, or Charcot-Leyden crystals. Skin testing for allergens is particularly helpful in younger patients with extrinsic asthma. Radioallergosorbent (RAST) testing is usually too expensive and less sensitive than skin allergen testing.

## Management

There are anecdotal reports of success with chiropractic management. Some studies and a literature review provide mixed results but suggest the need for further research.<sup>27, 28, 37, 38</sup> What is consistent between two randomized

studies is that when chiropractic manipulation is used in conjunction with medical management, there is no apparent benefit.<sup>39, 40</sup> However, it is also interesting to note that these two studies incorporated “sham” manipulation phases or groups. Both the sham and true-manipulated groups of patients showed decreases in  $\beta$ -agonist use and symptom severity decreased or quality of life increased. These findings must be interpreted with caution given that patients were always on medication during chiropractic care and therefore direct treatment of asthma with manipulation was not tested. Second, a further research question is created: What aspect of “sham” treatment is “common” with true manipulation and can this be utilized to help reduce symptoms and medication usage? A study<sup>41</sup> on patients who were highly susceptible to hypnosis is perhaps related. There were marked improvements in airway responsiveness and symptoms. In addition, two small osteopathic studies evaluated the effectiveness of using a full array of osteopathic techniques. One study by Guiney et al.<sup>42</sup> incorporated techniques such as rib “raising,” muscle energy for the ribs, and myofascial release. The other study by Bockenbauer et al.<sup>43</sup> utilized traditional techniques such as bilateral ligamentous tension in the occipito-atlantoid and cervicothoracic junctions, “upward displacement” of the first rib, and diaphragmatic release. The studies both attempted to determine if there was an improvement in respiration as measured by a peak flow meter. The strength of the studies was the use of a sham treatment control group. The difficulties with the studies are the small number of patients in each, and the use of peak flow meter measurement instead of the more accurate and standardized forced expiratory volume measured with spirometry. In the Guiney study there were improvements in peak flow measurement. In the Bockenbauer study there was no statistically significant improvement in peak flow measure; however, measurements of upper and lower thoracic forced respiratory excursion, and subjective measure of asthma symptoms both indicated improvement after treatment with osteopathic manipulative techniques. In a study<sup>44</sup> that was unblinded but randomized and controlled, patients who practiced yoga experienced improvements in respiratory function and symptom reduction.

It is important to realize that the chiropractor cannot make recommendations to parents or patients on medication regarding a change in the prescribed use; consultation with the prescribing physician is necessary. If a treatment trial is initiated, it is extremely important to use spirometry or a peak flow meter to measure function when the patient is not symptomatic to establish a comparative baseline. Comanagement or referral is recommended in cases where asthma is moderate to severe or the patient is unresponsive.

Medication is used to abort an attack and manage acute reactions, and another group of medications is used as prophylactics.  $\beta$ -agonist medications such as albuterol (Ventolin) are used during an attack. Newer drugs such as longer acting  $\beta$ -2 agonists (e.g., salmeterol or formoterol) or leukotriene receptor antagonists (e.g., Zafirlukast) have been suggested as “preventive” approaches taken at low dosages daily. The benefits and risks of this approach are still being debated. Anti-inflammatory drugs, such as aerosol corticosteroids, are used to control the underlying inflammation that exists

between attacks. Combination therapy with corticosteroid and beta-2 agonist are now popular (e.g., Advair). A mast cell stabilizer (cromolyn sodium) is used to prevent degranulation and release of histamine and other mediators. The general recommendation from the National Institutes of Health is to use cromolyn sodium and monitor response for several weeks. If unsuccessful, an inhaled corticosteroid at the lowest dose possible using a large-volume spacer (to avoid local oral candidiasis) is recommended.<sup>45</sup>

One recent study<sup>46</sup> indicated that patients with moderate to severe asthma who wrote about their stressful life experiences demonstrated clinically significant improvements in their health status compared to those who did not. The literature is complex and mixed on the contribution of diet to either the development of asthma or the effect of diet on existing asthma. Several themes have developed:

- The consumption of apples and fish may have a protective effect on the development of childhood asthma or allergies.<sup>47</sup>
- The consumption of apple juice from concentrate (not apples) and bananas may protect against wheezing in children.<sup>48</sup>
- Another study found that apples and pears may be protective against asthma.
- Contrary to prior belief, whole milk may protect against current asthma and conversely, soy beverages may increase risk of current asthma.<sup>49</sup>
- Women who have a high intake of tomatoes, carrots, and leafy vegetables have a lower prevalence of asthma.<sup>50</sup>
- There were similar findings in a study on the Mediterranean diet, which appears to be protective for allergic rhinitis and asthma symptoms.<sup>51</sup> The diet studied contained mainly fruits, vegetables, and nuts.

## Emphysema

### Classic Presentation

The patient has a history of smoking and has noticed gradual difficulty breathing. If the emphysema is advanced the patient will appear barrel chested and will demonstrate the use of accessory muscles of respiration, or breathing through pursed lips. When advanced, the patient is often thin and frail.

#### Cause

Destruction of alveolar walls due to the release and deregulation of proteases released from neutrophils and macrophages leads to a decrease in the available cross-sectional area available for gas exchange. The cause appears to be smoking and, in a small percentage of patients, a deficiency in  $\alpha$ -1-antiprotease (an inhibitory enzyme for proteases). As a result of the destruction of the elastin portion of the lung matrix, the natural elastic recoil

response with expiration is lost, forcing the patient to work hard to expel air. The inefficient expiratory effort leads to an increase in residual air in the lungs. The patient is forced to expend 25% of his or her total body energy just for breathing and often will become a respiratory cripple. It is common to find chronic bronchitis and emphysema coexisting in patients.

## **Evaluation**

The patient's appearance is characteristic when presenting in the later stages. This is often referred to as a "pink-puffer" (breathing through pursed lips to create a positive back pressure, opening the airways and making breathing less laborious). The patient in the later stages will have hyperresonant lungs on percussion coupled with diminished breath sounds on auscultation. The chest radiograph will reveal diminished markings in the periphery with associated low and flat hemidiaphragms.

## **Management**

The patient must cease smoking. This may require outside support. In addition, referral to a respiratory therapist is necessary to prevent the cycling of decreased function that leads to the "respiratory cripple." Chiropractic management of associated musculoskeletal complaints would be likely beneficial.

## **Pulmonary Embolism**

### **Classic Presentation**

Although it is unlikely that a patient will present to a chiropractor with an acute attack of pulmonary embolism, the patient would be in distress with chest pain, dyspnea, cough, and diaphoresis.

### **Cause**

Thrombi that develop in the lower extremity, particularly in the calves, travel to the lungs and cause vascular blockage and/or infarction. About one to two out of 1,000 individuals will be diagnosed with a pulmonary embolism in the United States annually.

## **Evaluation**

The difficulty with the presentation of a patient with pulmonary embolism is the wide variation. Typically, chest pain and dyspnea are part of the presentation but cough, hemoptysis, or fainting are less often part of the clinical picture. Risk factors, together with presentation, may be helpful. Several studies have indicated that, although the clinical picture is inaccurate, patients can be categorized as low-, moderate-, and high-risk.<sup>52</sup> High-risk indicators include unexplained hypoxemia ( $\text{SaO}_2 < 95\%$  in a patient who is not a smoker, asthmatic, or has another COPD), hemoptysis, or recent surgery (within last four weeks). Also of concern would be individuals with a shock index  $>1$  (HR/SBP), or those age 50 years and older.

Physical exam findings that may be suggestive are tachycardia, tachypnea, and an accentuated pulmonary component of the second heart sound (S2). Other findings that have been suggested in the past are of little value, such as jugular distention, and S3 or S4 heart sound, or hepatomegaly. D-dimer is a specific fibrin degradation product that indicates the presence of venous thromboembolism. It can be helpful in ruling out a pulmonary embolism; however, there are several different types of assays each with their own sensitivity and specificity. To date, the most sensitive is the Organon-Teknika assay. If still in question, a pulmonary lung perfusion is performed. If equivocal, a compression ultrasonography is the next evaluation, followed by pulmonary angiography if negative or equivocal.

## Management

Antithrombotic therapy with streptokinase, urokinase, or recombinant tissue plasminogen activator (TPA) is used in an acute event. Preventive therapy incorporates anticoagulant therapy with heparin or warfarin.<sup>53</sup>

## Pneumothorax

## Classic Presentation

There are different types of pneumothorax, each with a different patient presentation. The patient with spontaneous pneumothorax (SPT) is often a tall, thin male between 20 and 40 years of age with an acute onset of sharp, unilateral chest pain with dyspnea. It often occurs at rest or when sleeping. Traumatic pneumothorax is often the consequence of rib fracture. The presentation would be one of someone who presents with a blow or a fall to the chest. Pneumothorax can also occur as a consequence to COPD, asthma, cystic fibrosis, or tuberculosis (TB).

## Cause

Pneumothorax is an accumulation of air in the pleural space. With SPT, it appears that subpleural apical blebs rupture spontaneously. Traumatic pneumothorax is usually due to outside air entering the pleural space. This may progress to tension pneumothorax if air is allowed in with each respiration, but on expiration air is trapped (check-valve mechanism).

## **Evaluation**

The patient with SPT may have complaints mild enough to wait several days before being evaluated. The patient may have a family history of SPT or a history of smoking. Unilateral, sharp chest pain without a history of trauma, no recent or current signs of a respiratory infection, and no signs of other pulmonary disease should raise the suspicion of spontaneous pneumothorax. Severe tachycardia and mediastinal or tracheal shift are not likely to occur unless the pneumothorax is massive, as may occur gradually in tension pneumothorax. Also, the signs of decreased fremitus and breath sounds are detectable only in a large pneumothorax. Chest films may reveal a visceral pleural line (especially on expiration). If a film is taken supine, a “deep sulcus” sign may be evident as an unusually radiolucent costophrenic sulcus. If thoracic films are used for chiropractic evaluation, it is important not to collimate out the lungs.

## **Management**

It is important to distinguish SPT from a rib subluxation. Because the pain of SPT is pleuritic, it may be reproducible mechanically. If the patient is found to have a large pneumothorax, he or she is hospitalized and monitored. If the pneumothorax is small (< 15%) the air is often absorbed over time. However, if it is larger, tube thoracotomy is performed.

## **Congestive Heart Failure**

## **Classic Presentation**

The patient complains of bilateral leg edema. He or she has associated complaints of difficulty breathing with exertion or lying fully supine at night (orthopnea).

## **Cause**

Right-sided heart failure may be isolated or more often secondary to left-sided failure, which may be due to mitral valve dysfunction. Pressure increases into the venous system, delaying return to the heart from the lower extremities. Fluid backup results in liver congestion, ascites, and lower leg edema.

Although mortality related to coronary artery disease and stroke has been declining over the last decade, there is an increase in those dying from CHF. In the United States, the total is 4.7 million annually. There appears to be a relationship between a high-sodium diet and an increase in congestive heart failure for those individuals who are overweight.<sup>54</sup>

## Evaluation

The edema is reduced by elevation of the legs. Rales are often apparent on auscultation. Hepatojugular reflux may be evident with the patient lying in a position where the highest level of venous pulsation is evident in the lower half of the neck. Exerting sustained pressure (30 to 60 seconds) in the patient's right upper quadrant may increase the level of pulsation by 1 cm or more when CHF is present. The chest radiograph provides important confirmation of cardiac failure with a demonstration of cardiomegaly, dilation of the upper lobe veins, haziness of vessel outlines, and interstitial edema. Electrocardiography may reveal associated arrhythmias or hypertrophy. Laboratory testing may reveal proteinuria.

## Management

Comanagement is recommended. The standard approach is the use of diuretics for early-stage failure. However, long-term management should include a change to a strict, low-fat diet, with gradual supervised exercise. Recent studies<sup>55, 56</sup> showed marked improved in respiratory function in patients who performed moderate aerobics. Exercising at this level of intensity was both safe and effective even in patients with severe congestive heart failure. A recent Cochrane review<sup>57</sup> evaluated the benefit of hawthorn extract for treating CHF. This systematic review indicates there is significant value in symptomatic control and physiologic outcomes when hawthorn extract is used as an adjunctive treatment for CHF.

# CHAPTER 41

## Cough

### Context

Everyone coughs at some time. Coughing is a natural defense mechanism used to clear the airways. Most individuals accept this as a naturally occurring component to most respiratory infections and assume that it is self-limiting to a week or two. When the cough is persistent, individuals are more likely to seek attention. In a primary care setting, cough is the fifth most common presenting complaint in adults.<sup>1</sup> This accounts for 30 million office visits per year. In children, the numbers may be higher.<sup>2</sup>

As a common complaint, it is not surprising that approximately \$600 million is spent per year in the United States alone on prescription and over-the-counter (OTC) cough medications.<sup>3</sup>

Chiropractors are probably more inadvertently involved in the evaluation of a patient with cough. Most patients would first seek medical consultation with a chronic cough. However, the chiropractor is well positioned to evaluate and diagnose a patient with cough and offer suggestions regarding conservative approaches that may benefit. Patients with chronic cough may also have musculoskeletally related complaints due to the constant strain on the chest and thoracic spine and musculature.

The majority of acute cough is due to viral infection or smoking.<sup>4</sup> Other causes include bacterial pneumonias,

inhaled irritants, allergies, and medications. Chronic cough is most often due to one of a short list of causes.<sup>5, 6</sup> The following is a hierarchical list of these causes:

1. postnasal drip—40% of cases (87% in one study)
2. asthma—25% to 35% of cases (cough is the only presenting complaint in up to 25% of asthmatics)<sup>7</sup>
3. gastroesophageal reflux (GER)—20% of cases
4. chronic bronchitis—5% to 10% of cases
5. bronchiectasis—4% of cases

However, it is important to consider that smoking may be the underlying initiator of many of the above causes. Most important, a history of chronic smoking should raise the concern of bronchogenic carcinoma. Tuberculosis (TB) should also be considered when a low-grade upper respiratory infection (URI) seems to persist or there is known exposure to a TB carrier. Rarer causes of chronic cough are subdiaphragmatic abscess or tumors.

## General Strategy

<b>Acute Cough (&lt; 3 weeks)</b>
-----------------------------------

Determine the following:

- whether the patient has been exposed to any chemicals—occupational or home cleaning solutions
- whether the patient could have aspirated food or liquid—infants, seniors, alcoholics, or sedated individuals
- whether the patient has additional signs of a URI and possible history of exposure to others with similar symptoms—viral infection most common; consider TB also
- whether the patient smokes or is exposed to a smoker

- whether the patient is taking medications that may provoke cough—angiotensin-converting enzyme (ACE) inhibitors, other antihypertensives, and some antiasthmatic medications such as albuterol (Ventolin) or cromolyn (drying of airways)
- response to OTC drugs—often ineffective, yet patient overutilizes
- whether the cough is positionally related—cough that increases with recumbency indicates postnasal drip, pulmonary vascular congestion, or asthma (if at night)
- whether there are any associated complaints such as fainting, incontinence, rib or chest pain, headaches, nausea/vomiting, hernias, or low back pain with radicular symptoms

## **Chronic Cough**

### **Determine the following:**

- whether initial signs of a URI resolved within two weeks, but cough is persistent—possible viral infection, superinfection with bacteria, or TB
- whether the cough is recurrent and appears to be either seasonal or associated with eye itching or stuffy nose—allergies, possible postnasal drip
- whether the patient has to clear the throat often—postnasal drip
- whether the patient is a smoker or is exposed to a smoker—chronic bronchitis
- whether the cough is worse with recumbency and is associated with a tickling in the upper throat—postnasal drip
- whether the cough is worse when recumbent and possibly associated with epigastric discomfort or a

- sour taste in the mouth—GER
- whether the cough is worse with exertion or associated with shortness of breath—cough-variant asthma
- whether there are any associated complaints such as fainting, incontinence, rib or chest pain, headaches

## Evaluation

- Auscultate for wheezes, rales, or other adventitial sounds.
- If TB, congestive heart failure, fungal infection, pleurisy, or lung cancer is suspected, order a chest film.
- Laboratory testing may help differentiate bacterial causes from viral causes.
- Pulmonary function testing is particularly important when asthma or chronic bronchitis is suspected.

## Management

- Depending on underlying cause, hydration and brief OTC medication are all that are needed for acute cough.
- When GER is suspected, changes in the types of food eaten, quantity of food, avoidance of lying down after large meals, and loss of weight will all be of benefit.
- For chronic bronchitis, smoking cessation is most important.
- A short course of manipulative therapy may be applied for uncomplicated asthma; comanagement is suggested.

# Relevant Anatomy and Physiology

Cough receptors are ubiquitous. They are found in the nose, pharynx, larynx, trachea, bronchi, pleura, diaphragm, stomach, esophagus, also in the tympanic membrane and external auditory canal. Within the tracheobronchial tree there are several types of receptors: (1) slowly adapting stretch receptors; (2) rapidly adapting, irritant receptors; (3) pulmonary C-fiber receptors (J receptors); and (4) bronchial C-fibers.<sup>8</sup> The stretch and irritant receptors are myelinated. The rapidly adapting receptors are probably the main group associated with coughing. The C-fiber receptors are sensitive to inflammation and toxins or other noxious substances. Receptors in the external auditory meatus are sensitive to hair or cerumen and may be the cause of cough in some individuals.

The medullary cough center modulates the cough reflex via afferent vagal, glossopharyngeal, trigeminal, and phrenic nerves and efferent vagal, phrenic, and spinal accessory nerves.<sup>9</sup> Coughing is a rather violent act requiring several simultaneous participants. First, inspiration prior to coughing stretches the lungs, taking advantage of an elastic recoil effect. Next, a Valsalva maneuver occurs with closing of the glottis and contraction of the muscles of the abdomen, chest, and diaphragm. This is followed by an expiratory blast occurring with abduction of the glottis. This is then followed by a deep inspiration. During the cough phase, flow rate is as high as 600 L/min at speeds of up to 500 miles/h.<sup>10</sup>

Interference of coughing may be caused by position, weakened musculature, pain, or an overwhelmed mucociliary ladder. The inability to expel foreign material or mucus can result in atelectasis and/or infection. Chronic

smoking is known to inhibit the mucociliary ladder and cause metaplasia of the cells in the smaller bronchioles. Normally, the cells of the smaller airways secrete a clear, nonviscous fluid. Chronic smoking causes these cells to transform into mucus-producing cells called Clara cells. It is much more difficult to clear the smaller airways except through coughing.

Sometimes associated with cough is a tendency toward thoracic flexion. This is an important consideration in older osteoporotic patients who may cause a compression fracture while coughing.

## Evaluation

## History

The history will provide a high level of suspicion in most cases (**Table 41-1**). A search for external irritants should include smoking, exposure to smoke, occupational dust exposure, apparent pet allergies, and smog. Given that the most common cause of acute cough is a viral infection, questioning regarding associated signs of fever, runny or stuffy nose, and lethargy is helpful. In older patients and immunocompromised patients, a concern for the possibility of an underlying pneumonia is warranted.

A drug history, especially in those with a diagnosis of hypertension or asthma, is often revealing. ACE inhibitors are known as potential cough stimulators in some patients.<sup>11</sup> This is believed to be due to either stimulation of C-fibers through an ACE inhibitor effect of accumulation of kinins (i.e., bradykinin) or secondarily through production of a postnasal drip. Unfortunately, the association may not be clearly evident because the reported reaction may occur three to four weeks and as much as one year following

initial usage. ACE inhibitor cough may also be worse in the supine position, probably related to the above-mentioned secondary effect.<sup>12</sup> Other medications include  $\beta$ -blockers (especially nonselective) that may, through a bronchoconstricting effect, irritate an asthmatic or those with hyperresponsive airways.<sup>13</sup> Ironically, asthmatics taking  $\beta$ -agonists such as albuterol or cromolyn sodium (Intal) or corticosteroids may develop a nonproductive cough due to irritation or drying of the bronchial membranes.<sup>14</sup>

**Table 41-1** History Questions for Cough

Primary Question	What Are You Thinking?	Secondary Question	What Are You Thinking?
Algorithm	Consider common causes such as viral or bacterial URI, bronchitis, or pneumonia.	Is there someone you have been in contact with who has similar symptoms? Associated signs of sore throat, low-grade fever, stuffy nose, malaise? Associated signs of high-grade fever, chills, or rigors (shaking, teeth chattering) in addition to above list?	Determine contact's symptoms. Common infection likely. Viral cause likely. Bacterial cause likely. Does the patient have other predisposing conditions such as AIDS, diabetes, chronic obstructive pulmonary disease (COPD)?
Does the cough occur only with or soon after exertion?	Asthma, hyperactive airway disease, and cardiopulmonary causes.	Worse in dry, cold environment?	Asthma and hyperactive airways disease more likely. Look for auscultation findings if cardiopulmonary cause is suspected.
Have you had the cough longer than 3 weeks?	Causes of chronic cough include postnasal drip, COPD, esophageal reflux, and bacterial complication of viral disorder.	Is the cough worse when you are lying down at night? Is the cough productive? Do you smoke?	Consider postnasal drip; if associated with difficulty breathing, orthopnea (cardiopulmonary); with meals, consider esophageal reflux. A productive cough would suggest bacterial infection. COPD; with isolated wheeze consider bronchogenic carcinoma.
Does the cough occur intermittently (off and on)?	Occupational or environmental exposure. Also consider medications such as ACE inhibitors, beta-blockers, and some asthma medications.	Does the cough happen without other signs/symptoms? Does it occur only at work? Does it occur after returning home but before bed?	Probably environmental. Ask about occupational exposure, relationship to eating, etc. May be allergic if patient lives in rural area and works in urban area.

If the cough is present only under stressful circumstances, both cough-variant asthma and psychogenic cough should be considered, especially in the adolescent. If

the cough is provoked by exertion, exercise-induced asthma should be considered.<sup>15</sup>

If the cough appears or is made worse by recumbency, consider the following:

- Chronic cough occurring after lying down after a large meal and/or association with epigastric discomfort is probably GER.
- Recurrent cough occurring while lying flat and improved by support of the body or head at an angle is suggestive of postnasal drip or congestive heart failure (pulmonary vascular congestion).
- If the cough is worse while lying flat and is associated with dyspnea (orthopnea), congestive heart failure is more likely.
- Chronic cough that becomes worse in the middle of the night and is not always position-dependent is likely to be asthma.

The distinction between a productive and a nonproductive cough is helpful. Productive coughs usually imply infection. Nonproductive coughs are often the result of irritation such as with the underlying inflammation of asthma, postnasal drip, and external irritants such as from allergies or smoke. Questions regarding the color and consistency of phlegm are traditionally asked; however, they probably contribute little to the diagnosis. The typical assumption is that yellow or green phlegm is found often with bacterial or viral infections. A clear or mucus-like phlegm is suggestive of allergy or viral infection. Blood in the sputum (hemoptysis) is an indication of erosion or trauma from coughing found with pulmonary infarct, TB, bronchiectasis, and bronchogenic carcinoma.

Patients with a productive cough on the majority of days for three consecutive months occurring over two or more

consecutive years are likely to have chronic bronchitis. This is particularly true in chronic smokers.

## Examination

The primary focus of the examination is observation of the nose and throat and auscultation of the lungs. A cobblestone appearance of the oropharyngeal mucosa or direct visualization of mucoid secretions may be seen with postnasal drip.

Auscultation for wheezes may provide clues to an underlying chronic obstructive pulmonary disease (COPD) such as asthma, chronic bronchitis, or emphysema. A localized wheeze is suggestive of bronchogenic carcinoma in a patient who is a chronic smoker. Always check for a prominent supraclavicular lymph node (sentinel or Virchow's node). Extrathoracic wheezing—stridor—is associated with whooping cough (pertussis) in infants and children. This must be differentiated from blockage by a foreign object. When further testing is requested, supportive historical and/or physical examination findings must be present, as follows:

- Only when suspicion is high for pneumonia, TB fungal infection, or cancer does a chest film need to be ordered.
- When perinasal tenderness, positionally related nose stuffiness, or transillumination of the sinuses is positive, skull radiographs for sinus infection should be considered.
- If asthma is suggested by the history, spirometry testing with a focus on forced expiratory volume should be performed or ordered (peak flow meter evaluation is an inexpensive, but less sensitive measurement tool).

- Laboratory studies are rarely needed. The most common scenarios are with the suspected asthmatic patient in whom skin testing or pulmonary function testing is needed. A search for eosinophilia is not warranted given the nonspecificity of this finding. Sputum evaluation for Charcot-Leyden crystals or Curschmann spirals is rarely performed or needed.

## Management

Conservative management of cough should be pursued in both a generic and specialized approach. The generic approach focuses on environmental factors that are modifiable, including the following:

- Ensure adequate hydration—8 oz of water every waking hour. Use of a humidifier/vaporizer may be helpful, but some asthmatics respond poorly to humidified air. Humidifiers must be thoroughly and properly cleaned to avoid spread of other allergens or infectious agents.
- Avoid smoking or being in a smoke-filled environment.
- Ensure that the house environment is clean. Change or clean furnace filters regularly. Use a vacuum cleaner that does not recycle room air.
- Avoid any potential allergens including grasses, plants, animals, or foods.
- Avoid supine positions; elevate the head of the bed or prop up the head and upper trunk with pillows.
- Consider supplementation with antioxidants such as vitamins A ( $\beta$ -carotene 20,000 IU/day), C (100 mg/waking hour), and E (400 to 800 IU/day).

Specific musculoskeletal approaches may include the following:

- Perform spinal and costovertebral adjusting to allow unrestricted movement while breathing.
- Perform deep trigger point work or myofascial release to the trapezius, serratus anterior, intercostals, pectorals, and midscapular muscles, and cervical spine musculature when the need is determined.
- Educate the patient to breathe through use of the diaphragm, and to breathe through the nose when possible; breathing should be deep and relaxed.

When GER is the cause, avoidance of large, heavy meals and foods such as chocolate, caffeine, alcohol, fat, onions, garlic, and orange juice will usually help. Avoidance of a supine position, especially after eating, is a requisite.

Pharmacologic treatment of cough should be tempered with the knowledge that, initially, cough serves a protective function. Inhibition of this function should be considered in patients only under the following conditions:

- when it interrupts sleep (which is necessary for recovery of an underlying infection)
- when there is the potential of damage, such as in osteoporotic patients or postsurgery
- in those patients with spinal pain and radicular symptoms
- in patients with hernias, stress incontinence, or syncope
- when the cough is incapacitating

Pharmacologic treatment is based on several approaches. Interruption of the cough reflex may occur peripherally, by acting on sensory receptors, or centrally, by acting on the cough center in the medulla and nucleus tractus solitarius. Antitussive (anticough) medications are generally divided into (1) central suppressants, (2) expectorants, (3) mucolytics, and (4) peripheral anesthetics

(benzonatate). The primary prescription suppressant is codeine, a narcotic. Because it is so effective, OTC (nonnarcotic) medications pale in comparison. OTC medications are a confusing array of mixtures with unproven effectiveness. When looking for or recommending an effective OTC antitussive, check for one of two ingredients: dextromethorphan or diphenhydramine. The combination of antihistamines, cough suppressants, and expectorants is probably useless or counterproductive.

Expectorants theoretically stimulate submucosal gland fluid secretion, rendering mucus less viscous and easier to clear. The primary approach to accomplishing this task is proper hydration, orally and via a humidifier. When ineffective, OTCs with guaifenesin (glycerol guaiacolate) or iodinated glycerol are sometimes effective. It is interesting to note that there is no evidence that these medications are any more effective than home remedies such as garlic, horseradish, pepper, or chicken soup. In patients with thicker sputum unresponsive to expectorants (rarely seen in a chiropractic office) a mucolytic agent, N-acetylcysteine, may be prescribed.

The common OTC approach of using cough lozenges is probably no more effective than sucking on candy. However, the psychologic effect of the sensation provided by camphor, menthol, or eucalyptus oil is soothing enough to continue sales.

Preventive measures should be encouraged when an infectious cause of cough is suspected. This includes washing one's hands after sneezing, nose blowing, or coughing. Use disposable tissues rather than handkerchiefs. Coughing into a flexed elbow or sleeve may also prevent direct spread through hand contact with others.

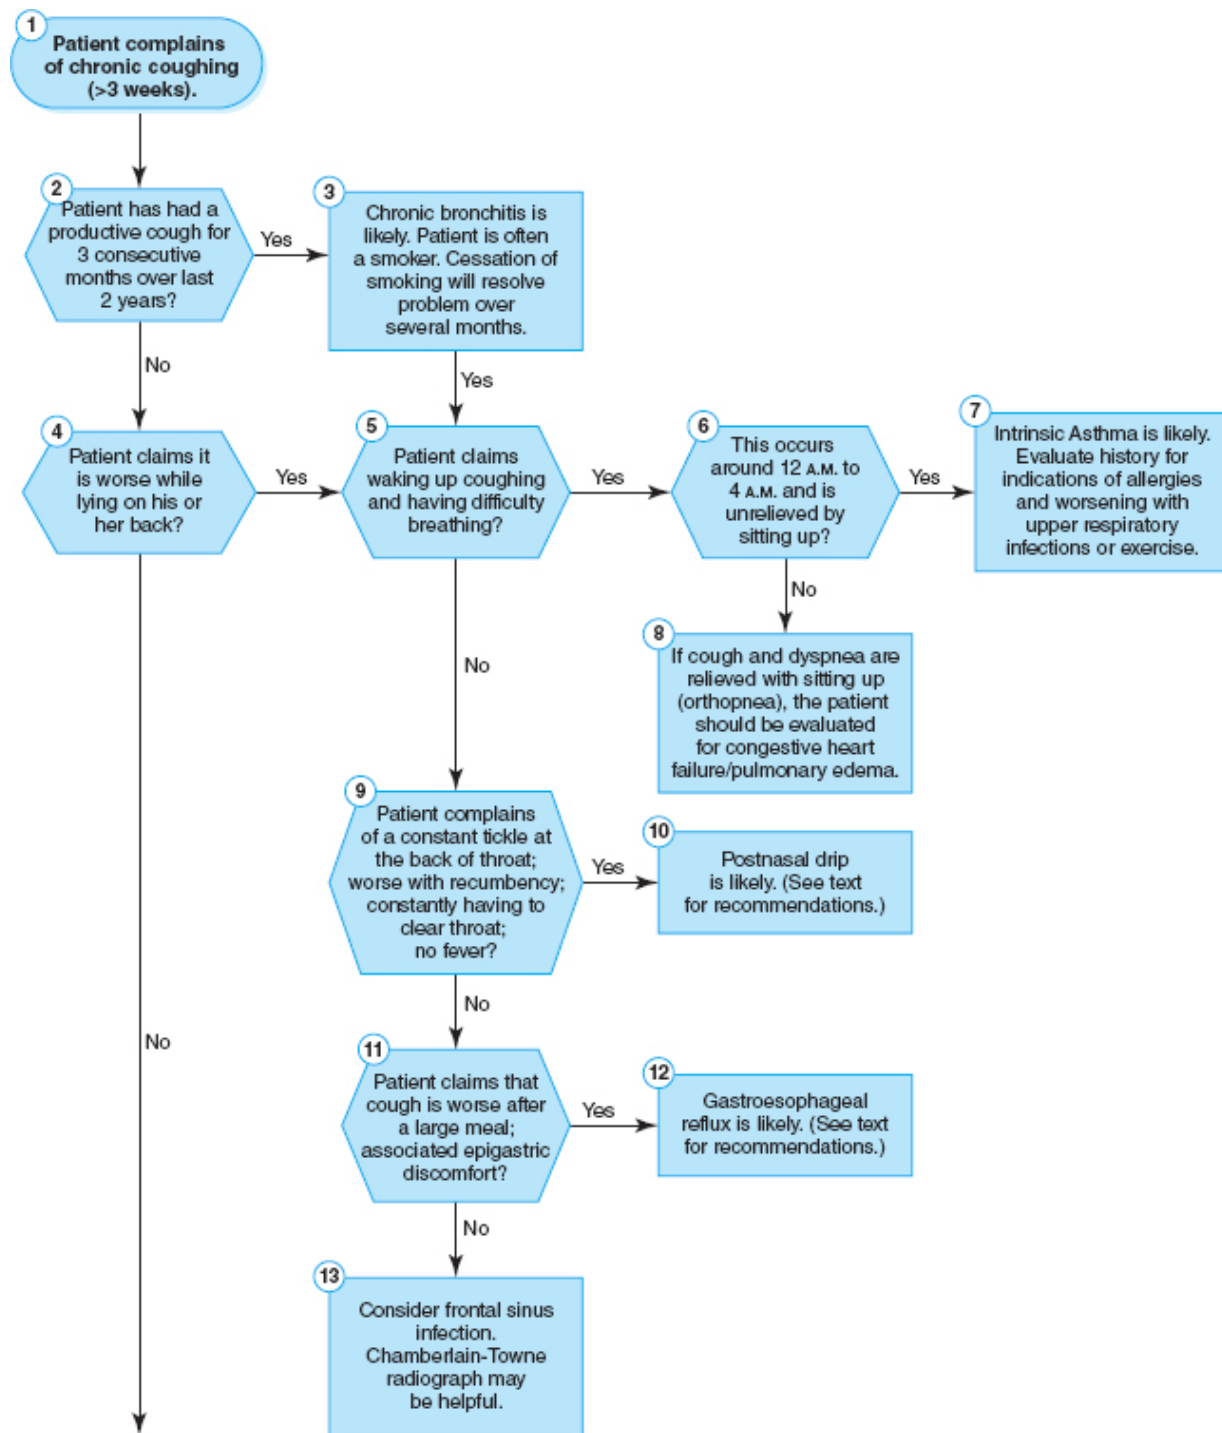

Patients suspected of having ACE inhibitor-provoked cough should be referred back to the prescribing physician. It is important to note that switching to another ACE

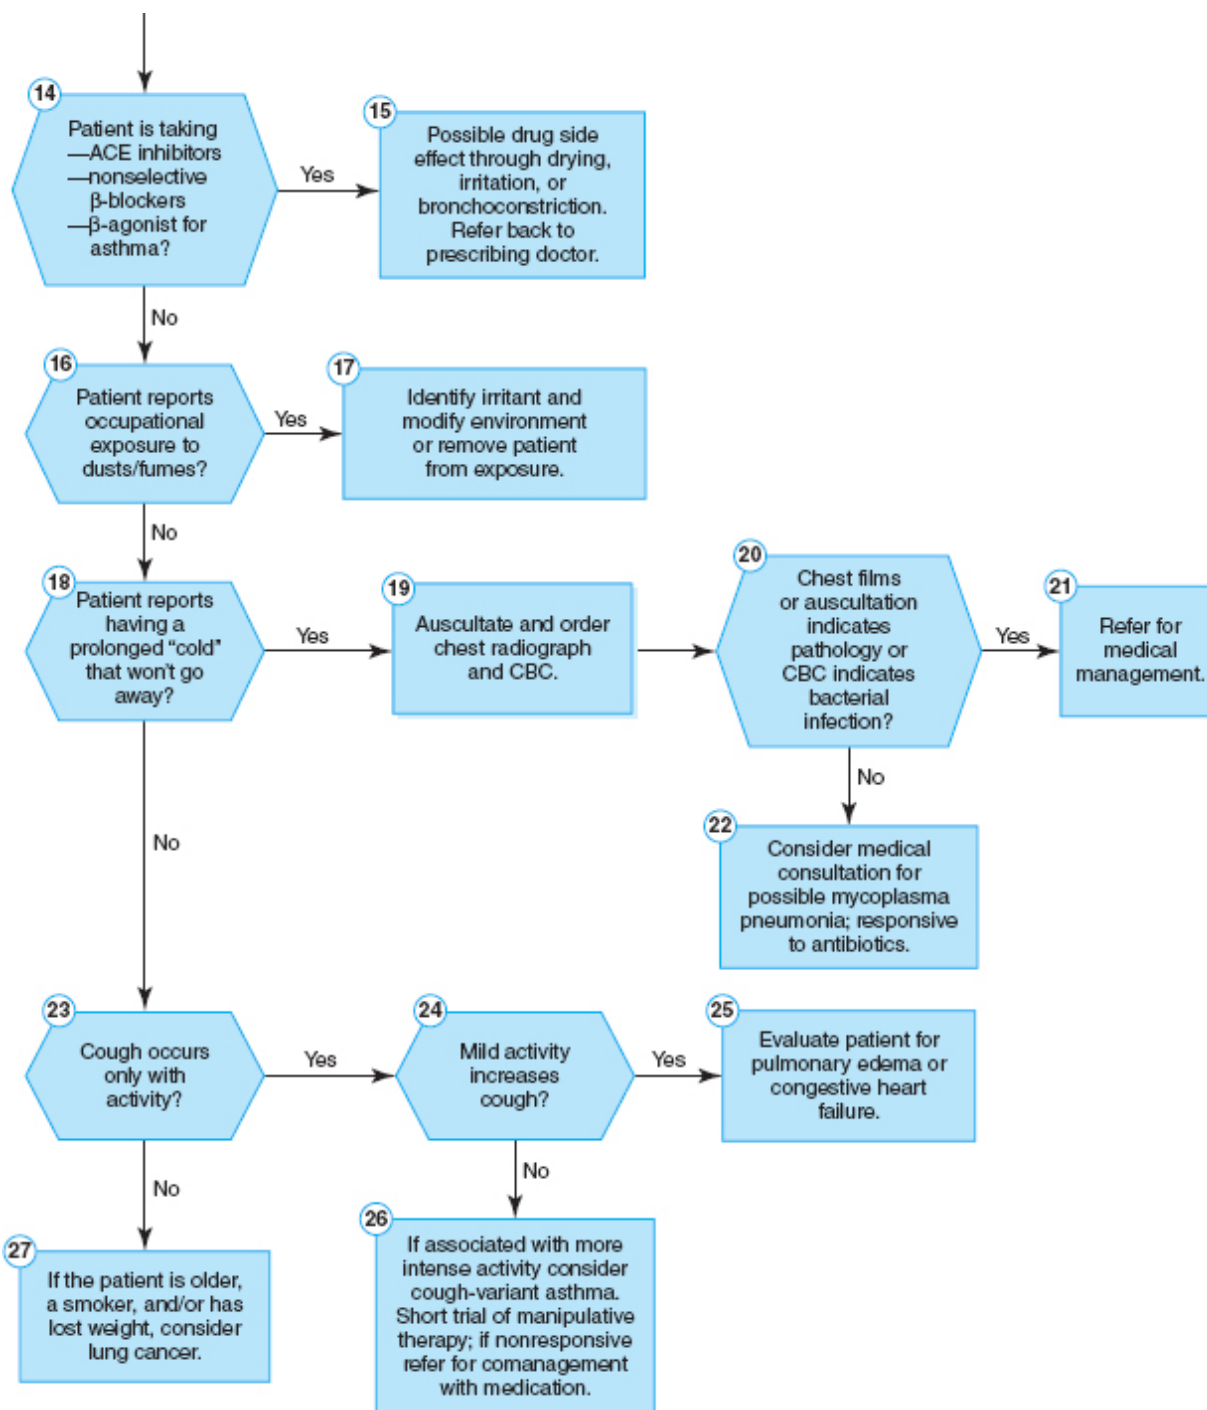

inhibitor usually is not effective. Therefore, a switch to another antihypertensive is usually necessary.

Sinusitis may benefit from myofascial work over the temporal and masseter muscles, acupressure perinasally, or moist heat over the sinuses. Congestion-provoking positions should be avoided. Diathermy may be helpful in some cases. Patients suspected of having a sinus infection based on clinical examination and radiographs usually require referral for a decongestant and antibiotics. Some chiropractors employ a nasal-specific balloon therapy to drain the sinuses. It is anecdotally reported to be effective when performed by a chiropractor trained specifically in this approach.

## Algorithm

An algorithm for evaluation and management of chronic cough is presented in **Figure 41-1**.

**Figure 41-1** Chronic Cough—Algorithm

# Selected Causes of Cough\*

## Pneumonia

### Classic Presentation

The patient appears to have a respiratory infection with an associated productive cough and fever. The specificity of the presentation is increased by knowing whether the patient is immunocompromised, elderly, alcoholic, or a chronic smoker.

### Cause

Inhalation or aspiration of oropharyngeal secretions containing microorganisms leads to lung infection. There are numerous causes, each with its own clinical presentation and treatment. Generalization will be made to assist in the distinction of pneumonia from other causes of respiratory infection.

### Evaluate

In general, if the pneumonia is bacterial, the patient will appear to be more sick, with a higher fever and possibly chills. This is not always true, especially in the elderly and immunocompromised. Viral causes are usually more mild with a low-grade fever; however, the symptoms are more prolonged. Radiographs may be helpful, but there is no consistent pattern in all cases of any one cause. However, abnormal findings on a chest radiograph, such as lobar consolidation, patchy infiltrates, or pleural effusion, are characteristic of pneumonia and would warrant referral. Rales are often heard.

### Management

Antibiotic treatment is necessary with bacterial pneumonia. Viral causes are not responsive. However, mycoplasma pneumonia may be responsive because it is an atypical organism.

# **Pulmonary Tuberculosis**

## **Classic Presentation**

Patients with primary infection are often asymptomatic unless immunocompromised. Patients who are symptomatic usually have reactivated TB. The patient will complain of fatigue, weight loss, low-grade fever, chronic cough, and night sweats.

## **Cause**

Inhalation of mycoplasma tuberculosis will result in widespread lymphatic or hematogenous spread and an immune response that results in granulomatous walling-off of the organism. Primary TB rarely progresses to symptomatic presentation unless the patient is immunocompromised, such as the elderly or those with HIV infection (with or without AIDS).<sup>16</sup> An increase in the number of TB cases is due to those with HIV, immigrants, and prisoners. Dissemination throughout the lungs is often called miliary TB.

## **Evaluation**

The patient presentation is not always classic. Patients known to be infected with HIV, immigrants, and the elderly should always be monitored for the development of pulmonary or other organ involvement. Auscultation may reveal post-tussive apical rales. Radiographs may demonstrate nodules or infiltrates in the apical or posterior segments in the upper lobes. However, there is much variation. Calcified areas (Ghon lesion) indicate healed primary TB. The definitive diagnostic tool is sputum stain (Kinyoun or Ziehl-Neelsen) and culture. Fiberoptic bronchoscopy may be necessary if not enough sputum is available. Skin testing is unable to distinguish active, current disease from past infection. The tuberculin skin test (TST) has been the standard test for diagnosing latent tuberculosis infection (LTBI). It involves measurement of the delayed type hypersensitivity response 48 to 72 hours after intradermal injection of purified protein derivative (PPD). Interferon-gamma release assays (IGRAs) are diagnostic tests used to detect an immune response to TB infection. The most commonly used is QuantiFERON, also known as QFT. It is an ELISA-based, whole-blood test that utilizes three TB antigens (ESAT-6, CFP-10, and TB7.7). The most recent as of the publication of this text is the Gold In-Tube (QFT-GIT). It is important to note that the TST and QFT measure different aspects of the immune response for latent TB and are not interchangeable. With TST, prior BCG vaccination can produce false-positive test results.

# Management

Referral for medical management is necessary. All cases demonstrating positive findings and those in whom there is a high suspicion must be reported to local and state public health departments. This is best left to the treating physician. Because of the development of TB-resistant organisms, the Centers for Disease Control and Prevention has developed a new strategy that involves multiple drug application and monitoring. Isoniazid and rifampin are supported by other medications such as pyrazinamide and streptomycin.

## Postnasal Drip

# Classic Presentation

The patient complains of a chronic cough that seems worse while lying down (supine). The patient reports a dry or nonproductive cough. He or she may also notice a persistent tickle at the back of the throat, requiring frequent clearing of the throat.

## Cause

There is a variety of causes, including upper respiratory infection, sinusitis, allergies, drugs (e.g., ACE inhibitors), smoking, and environmental pollutants. Chronic irritation of the pharyngeal and tracheal membranes initiates the cough reflex. Postnasal drip is by far the most common cause of chronic cough.

## Evaluation

Classically, there will be a cobblestone appearance of the posterior mucosa; however, this is a nonspecific finding. Primarily, it is necessary to identify the underlying cause through a history. If there is associated nasal congestion, a suspicion of sinusitis warrants sinus evaluation with skull radiographs.

## Management

The patient is instructed to avoid any identifiable triggering stimuli. OTC nasal decongestants or antihistamines used for a short course may be effective. If a prescribed medication is the suspect, such as an ACE inhibitor, referral back to the prescribing physician is necessary. Failure to respond to conservative

measures requires referral for prescribed decongestants or antihistamines. An evaluation of sinusitis is warranted if this treatment trial fails. There is a nasal-specific technique used by some chiropractors for the treatment of sinusitis; however, it should be used only by those with special training and experience. Physicians often will use a trial of antibiotics first before more invasive procedures.

## **Chronic Bronchitis**

### **Classic Presentation**

The patient complains of a chronic productive cough for three months or more in at least two consecutive years. The patient is a smoker.

### **Cause**

Airway blockage occurs as a result of metaplasia of cells, smooth muscle hypertrophy, and increased mucus production. It appears that chronic cigarette smoking is the major risk factor. However, air pollution, respiratory infections, and allergies have all been implicated as contributory. Chronic bronchitis and emphysema often coexist in the later stages of COPD.

### **Evaluation**

Initially, the patient is asymptomatic. Unlike the purely emphysematous patient, the patient with chronic bronchitis is often overweight and may show some degree of cyanosis. Dyspnea is primarily exertion related. The prominent feature at presentation is a chronic productive cough. Auscultation often will reveal rhonchi or wheezes. Chest films may show an increase in markings with an associated cardiomegaly. ECG changes may indicate right ventricular hypertrophy.

### **Management**

The primary treatment is the same for prevention: cessation of smoking and avoidance of any known irritants such as dusts or other pollutants. Complications such as associated asthmatic reaction or infections warrant comanagement with a medical physician.

## **Bronchogenic Carcinoma**

# Classic Presentation

The patient is older than 40 years of age, has a history of smoking, and complains of a persistent cough, hemoptysis, weight loss, and anorexia.

## Cause

Primary lung cancer is due most often to cigarette smoking. Additional causes include exposure to therapeutic radiation, heavy metals, or industrial toxins such as asbestos. Bronchogenic carcinoma is classified according to cell type, including squamous cell, adenocarcinoma, small cell, and large cell carcinomas. In general, squamous cell and small cell carcinomas are more central in location, demonstrating a tendency for widespread metastasis. Adenocarcinoma and large cell carcinoma are usually more peripherally located in the lungs. Because the lungs themselves are insensitive to pain, widespread involvement may occur without symptoms. Until bronchi are compressed or eroded or the pleura is involved, the patient is usually asymptomatic.

## Evaluation

By the time obvious symptoms and signs are evident, the cancer has often reached a stage that is not amenable to treatment. About one-fifth of cases may demonstrate lymphadenopathy, splenomegaly, and clubbing of the fingers.

Horner's syndrome (miosis, ptosis, and anhidrosis) from a Pancoast (apical) tumor is seen in a small number of cases (< 5%). Auscultation may reveal a solitary wheeze or nothing at all. Laboratory tests may reveal nonspecific but incriminating evidence of metastasis, including increased calcium, alkaline phosphatase, or anemia. Sputum cytologic examination will confirm the diagnosis in over half of cases if the cancer is centrally located. Chest radiographs usually will demonstrate nonspecific yet important clues, including hilar masses, atelectasis, pleural effusions, or mediastinal widening. If suspicious findings are evident, computed tomography or magnetic resonance imaging is helpful in determining the degree of involvement and may suggest the type based on location and pathologic process viewed.

## Management

Treatment includes surgery, chemotherapy, and radiation therapy based on the type and staging of disease. Although the overall five-year survival rate is less than 15%, patients with early squamous cell cancer may have a much

higher rate (35% to 40%).<sup>17</sup> Chiropractors treating patients with lung cancer or other cancers that metastasize should be concerned about spinal or joint pains. These may indicate metastasis and warrant first a radiograph of the area and then possible referral for bone scan coordinated with the patient's oncologist.

\*See also [Chapter 40](#), Dyspnea, for asthma and [Chapter 38](#), Chest Pain, for gastroesophageal reflux.

Part VII

Head and Face Complaints

# CHAPTER 42

## Eye Complaints

### Context

The prevalence of undetected vision problems appears to be between 5% and 10% in preschool children.<sup>1</sup> Of these, approximately 2% to 5% have amblyopia, “lazy eye.”<sup>2</sup> Left uncorrected, vision loss may be permanent. Of school-age children, 90% to 95% have “normal” eyesight.<sup>3</sup> The majority of the children with eyesight problems have refractory errors.

In the elderly, vision loss is more common. In one large study<sup>4</sup> approximately 70% of the nursing home residents over the age of 65 years had good vision. Approximately 15% had adequate vision (15/50 to 15/70) and 15% had poor vision of 15/100 or worse (1% had no light perception). Sixty percent of people over the age of 65 years have some opacification of the ocular lens, although they are not necessarily impaired. Past the age of 75 years, 5% of all individuals have exudative macular degeneration (another 25% have the dry, less severe form)<sup>5</sup> and 5% have glaucoma.<sup>6</sup> Approximately 50% have significant cataracts (higher frequency in women). Whites have a higher incidence of macular degeneration, whereas blacks have a higher incidence of untreated cataract, open-angle glaucoma, and diabetic retinopathy.<sup>7</sup> Up to 25% of those wearing glasses had inappropriate visual correction.<sup>8</sup>

Vision loss in the elderly can be a significant factor in fatal car crashes. States that require vision testing for those over the age of 65 years have a lower incidence.<sup>9</sup> It is also important to recognize the increased risk of falling when eyesight is poor. Proprioceptive compensation is often diminished in the elderly; therefore, maneuvering in dimly lit areas places the low-vision senior at risk.

Eye complaints may reflect local pathology in the eye, a reaction to systemic infection or metabolic abnormalities, or vascular/neurologic pathology (**Figure 42-1**). Most causes of visual loss that are not congenital are treatable or curable. To facilitate an organized approach, each eye complaint is discussed separately under each section. A list of common patient complaints and possible causes follows:

- Loss of vision—may be due to vascular disease (local cause due to retinal infarct; central processes such as stroke are usually associated with other findings), increased intraocular pressure (glaucoma), increased opacification of the lens (cataract), retinal detachment (trauma, vitreoretinal traction, or neovascularization), tumors (distinguished by type of visual field defect and associated cranial nerve findings)
- Blurred vision—refractory error (near- or farsightedness), cataracts
- Diplopia—monocular (cataract or refractory error), binocular (cranial nerve problem due to tumor, drugs, myasthenia gravis, diabetes, or drugs)
- Flashing lights—migraine prodrome, vitreoretinal detachment, epilepsy
- Floaters—usually benign; sudden onset of many may indicate retinal detachment
- Photophobia—certain medications, migraine, corneal inflammation, iritis, albinism, fever
- Dry eyes—aging, medications (diuretics and anticholinergics), Sjogren's syndrome, Bell's palsy

- Eye pain—acute-angle glaucoma, foreign body
- Red or pink eye—conjunctivitis, iritis, or uveitis
- Itchy eyes—allergies

**Figure 42-1** Anatomy of the eye, as seen in cross-section.

## Review of General Terminology

- Accommodation—to focus on near objects the eyes “accommodate” through contraction of the ciliary muscles, increasing the curvature (convexity) of the lens
- Presbyopia—loss of accommodation with aging
- Amblyopia—loss of vision due to disuse (“lazy eye”)
- Myopia—nearsighted; the eye is longer; light rays focus in front of the retina (requires a concave or diverging lens to move the focal point back)
- Hyperopia—farsighted; the eye is shorter; light rays focus at a point behind the retina (if they could pass through; requires a convex or converging lens to move the focal point forward)
- Astigmatism—the refractory errors in the vertical and horizontal axes differ, requiring a cylindrical lens for

correction

- Strabismus—deviation of the eye; esotropia = internal deviation; exotropia = external deviation (strabismus may lead to permanent vision loss through cortical suppression of the weak eye)
- Exophthalmos—abnormal protrusion of the eye usually caused by hyperthyroidism due to proteinaceous buildup behind the eye
- Nystagmus—a rhythmic beating movement of the eyes comprised of a fast and slow movement

## General Strategy

### History

## Vision Loss

### Determine whether

- The vision loss is acute (often vascular or traumatic) or chronic (macular degeneration, presbyopia), transient (amaurosis fugax, multiple sclerosis, papilledema) or permanent (macular degeneration, retinitis pigmentosa, stroke).
- The vision loss is painful (traumatic or acute-angle glaucoma) or painless (macular degeneration, cataract, open-angle glaucoma, amaurosis fugax). If the vision loss is painless, does the patient have indicators of hypertension, diabetes, or a history of smoking (amaurosis fugax, diabetic retinopathy)?
- The vision loss is unilateral (vascular or neurologic; may eventually become bilateral) or bilateral (usually glaucoma or cataracts).

- The vision loss is central (cataract or macular degeneration [slow onset] or retinal detachment [sudden onset usually]) or peripheral (glaucoma in initial stages or retinitis pigmentosa).
- The vision loss is associated with a headache (migraine [transient prior to headache usually] or temporal arteritis [permanent]).

## **Blurred Vision**

### **Determine whether**

- Blurriness is in one or both eyes
- Onset is sudden or gradual
- The patient is diabetic (in addition to diabetic retinopathy, diabetics have an increased risk of glaucoma and cataract formation)
- Distant or near vision is affected
- Corrective lenses have improved vision (last change in prescription)

## **Diplopia**

### **Determine whether**

- Patient has monocular (refractory error or cataract) or binocular (vascular, cranial tumor, myasthenia gravis, drug effect, or multiple sclerosis) diplopia
- Binocular, whether patient has indicators of tumor, diabetes, or multiple sclerosis

---

## **Flashing Lights and/or Floaters**

Determine whether

- Flashing lights are associated with a headache
- Floaters are acute (possible retinal detachment if sudden onset of many) or chronic (usually benign)

## **Photophobia**

**Determine whether**

- There are associated complaints such as redness or itchiness or headache
- The patient is taking any medications that may cause photophobia
- The patient has a fever

## **Dry or Gritty Eyes**

**Determine whether**

- The patient has indicators of hyperthyroidism (exophthalmos may prevent proper lubrication)
- The patient has indicators of Sjogren's syndrome

---

## **Eye Pain (without Vision Loss)**

Determine whether

- It is felt superficially (local pathology) or behind the eye (referred pain from headache or tumor)
- There are accompanying signs or symptoms such as a urinary tract infection (Reiter's syndrome)

# Red or Pink Eye

## Determine whether

- The redness occurred suddenly without associated itching or pain (subconjunctival hemorrhage from coughing or sneezing)
- There is associated debris and itching (conjunctivitis)
- There are associated signs of allergies

## Examination

- Observe and inspect for redness, dryness, eye deviation, lid lag, and exophthalmos.
- Perform a battery of tests to check for extraocular muscle weakness, symmetry of the eyes, and use a cover test.
- Test for pupillary reaction and accommodation.
- Test for visual acuity with a Snellen eye chart or Jaeger chart with adults; with children, picture cards or oriented E charts are valuable.
- Test for color perception in male children and those not previously tested.
- Examine the anterior chamber with a temporally positioned light.
- Refer for slit-lamp or fluorescein stain if corneal abrasion or foreign body is suspected.
- Refer for further testing when glaucoma is suspected.

## Evaluation

### History

# Vision Loss

Although it may appear that simply asking the patient whether he or she has difficulty seeing would be an effective screen for vision loss, studies have shown that it is not. It is estimated that 1 million individuals have glaucoma and are unaware of significant vision loss. When adult patients were asked, “Do you have difficulty seeing distant objects?” the sensitivity for detecting vision worse than 20/40 was only 28%.<sup>10</sup> The question, “Can you see well enough to recognize a friend across the street (while wearing glasses)?” had a sensitivity of only 48%.<sup>11</sup>

When vision loss is sudden, a vascular cause is likely. When there are other associated neurologic signs, a site proximal to the eye is the cause. When vision loss is the only neurologic sign and its appearance is without pain, amaurosis fugax (microembolism from carotid arteries) or retinal detachment is likely. The patient will often describe either occurrence as “like a curtain was pulled down over my eye.” The difference is that amaurosis fugax usually lasts only for minutes, while vision loss from retinal detachment does not improve without treatment. The vision loss from temporal arteritis is also painless and often sudden or over a few days due to infarction of the optic nerve head. Associated signs of temporal arteritis are a temporal headache, neck and upper trunk myopathy (polymyalgia rheumatica), and general arthralgia prior to the loss of vision.

Other than trauma, acute, painful loss of vision is usually due to acute-angle glaucoma. Associated indicators are age over 60 years, a family history, nausea and vomiting, provocation from prolonged periods in a dark environment, and drugs that cause dilation of the pupils, such as anticholinergics (antiparkinsonian drugs, antidepressants, and some gastrointestinal drugs).

Gradually developing vision loss or blurriness is common with progressive refractory errors, glaucoma, cataracts, diabetic retinopathy, and macular degeneration.

- Diabetes mellitus is the leading cause of blindness in the United States in patients between the ages of 20 years and 74 years.
- Age-related macular degeneration is the leading cause of legal blindness for individuals 60 years and older.
- Glaucoma is the second-leading cause of blindness in the United States and is thought to be the leading cause among African Americans.
- Cataracts are the most common cause of treatable vision loss in the elderly.

With chronic open-angle glaucoma, the patient often will have a bilateral peripheral vision loss (often in the nasal field). Historical indicators of predisposition to glaucoma include a family history (occasionally), topical or systemic corticosteroid use, prior surgery or trauma to the eye, and diabetes. Cataracts are also seen in the elderly, producing a gradual loss of central vision. Associated indicators include a change in color vision and halos around lights, affecting the patient's ability to drive at night. There are different types of cataracts; however, with nuclear cataracts, some patients report an improvement with near vision early in the course of the disorder. Macular degeneration is usually bilateral with progressive central vision loss.

## **Red Eye**

Patients complaining of itchy eyes, a foreign-body sensation, tearing, and eyelid edema likely have bacterial or viral conjunctivitis, especially if the symptoms first occurred in one eye and over the following two days involved both eyes.

When the complaint is bilateral from the onset, allergic conjunctivitis is more likely. The discharge is purulent and more profuse with a viral or bacterial cause and more watery with allergic conjunctivitis.

## Examination

Some initial observational clues that are helpful include the following:

- Groping, squinting, or craning of the neck often will indicate loss of vision.
- Eye deviation (strabismus), unequal or absent movement of the eyes, ptosis (Horner's or oculomotor nerve), or inability to close the eyes (facial nerve) are indicators of nerve damage.
- Exophthalmos or lid lag indicates hyperthyroidism.
- Loss of the outer eyebrows indicates hypothyroidism; scaling of the eyebrows indicates seborrhea.
- Red or pink eyes with discharge suggest conjunctivitis; without discharge and with pain suggest acute uveitis.

A general screen for the eye should include visual acuity testing, extraocular muscle function, tests for eye position with a pen light and cover card, pupillary reflex, a corneal status check with a flashlight, accommodation, and color vision testing in male children or those not tested in the past. A brief discussion of each follows:

- Extraocular muscle function is tested in several ways. By shining a light about 1 ft away from the patient's eyes the corneal light reflex (Hirschberg test) determines whether the light shines on the same spot on each eye. If not, there is deviation of one of the eyes. Next, the cover test is performed. Have the

patient look straight ahead and cover one eye. With the macular image suppressed, the covered eye will drift into a relaxed position. If, when the examiner uncovers the eye, a jump is noted it indicates that a weakness is present and the eye needed to reestablish fixation. Finally, test the six cardinal positions of gaze by holding an object such as a pencil approximately 1 ft away and having the patient track movement into up-and-out, straight-lateral, and down-and-out paths on both sides. Third-nerve palsy is indicated by deviation that is generally down and out. With complete involvement there is paralysis of the eyelid; the examiner must lift the lid to see the deviation. Esotropia and inability to abduct the eye are indicative of sixth nerve involvement. The patient may rotate his or her head to the weak side. A torsional or oblique deviation with head tilt away from the involved side is found with fourth-nerve palsy. In general, when a muscle is weak, the image separation will be greatest while looking into the normal direction of action. Many of these nerve palsies are associated with diplopia. In particular the diplopia will be binocular, meaning that diplopia is present with both eyes open and disappears when either eye is covered. Diplopia that is monocular, meaning that it is present only when the involved eye is open and disappears when it is closed, indicates a refractive error in most cases.

- The pupillary light reflex tests the function of both the second and third cranial nerves. By having the patient look into the distance, normal eyes will have pupils that dilate. By shining a light from the side, two reactions should occur: (1) pupillary constriction on the side tested, and (2) constriction on the opposite side (consensual reflex). If a pupil is large and poorly reactive, a third-nerve palsy is likely. If it is small and poorly reactive, a Horner's syndrome may be present.

Fixed and constricted pupils (meiosis) are seen with glaucoma treatment, use of narcotics, or damage to the pons. Fixed and dilated pupils (mydriasis) are seen with severe brain damage or deep anesthesia. Unequal pupils seen without light stimulation that react equally to light are probably anisocoria, a normal variant.

- Accommodation is tested by having the patient look in the distance and then introducing an object into his or her field of gaze. The normal response is pupillary constriction and convergence of the eyes.
- A simple test to observe the anterior chamber is to shine a light from the side across the eye. A nasal shadow across the iris due to a shallow anterior chamber may be seen with glaucoma. Diffuse redness indicates conjunctivitis. On occasion, a corneal lesion or scarring may be seen. For a complete evaluation, referral for slit-lamp evaluation and fluorescein stain is necessary.
- Color blindness affects about 8% of white males (only 4% of black males). Females are affected only 0.4% of the time. Testing should be performed on boys age 4 years to 8 years with an Ishihara test comprising a series of polychromatic cards. The child must identify a pattern made up of a single color of dots against a multicolored background.

A fundoscopic examination is more difficult for the chiropractor because tropicamide dilation drops cannot be used. However, with careful observation, some abnormalities may still be visible. A list of possible findings follows:

- Disc pallor—optic nerve atrophy
- Papilledema—increased intracranial pressure
- Vessel nicking, narrowed arteries, silver-wire arteries, and copper-wire arteries—usually due to hypertension

- Microaneurysms—seen with diabetes
- Soft exudates (cotton-wool patches)—fluffy and irregular; seen with diabetes, hypertension, lupus, subacute bacterial endocarditis, and papilledema
- Fatty exudates—well defined, small, regular, and often seen in clusters; found in diabetic and hypertensive retinopathy
- Hard exudates (drusen)—normal with aging

## Visual Acuity Testing

Screening tests for children between the ages of 3 and 5 years should include inspection, the cover test, visual acuity tests, and stereovision assessment. Taken together, an estimated negative predictive value of 99% for amblyopia, strabismus, and/or high refractive problems may be achieved.<sup>12, 13</sup> Unfortunately, stereovision testing is not available in most chiropractic offices. For children, the Snellen eye chart is relatively insensitive (25% to 37%).<sup>14</sup> Other visual acuity tests include the Landolt C, the Tumbling E, Allen picture cards (familiar objects or animals), and others.<sup>15</sup> The advantage of these tests is that the ability to read is not tested as much as the ability to determine orientation of a letter or recognition of an object or animal.

Snellen eye charts should always be used as the initial screening for visual acuity in adults. With the Snellen eye chart test, the patient is expected to read with one eye at a time, covering the other with a card. The patient should keep his or her glasses (unless they are reading glasses) or contacts on. Encourage patients to read to the smallest line possible. The recorded measurement includes two numbers. The first number represents the distance the patient was standing (20 = 20 ft) and the second number indicates the distance at which a normal eye could read that specific line (letter size = 20 micrometers; 20 = a normal eye could see

this line at 20 ft). For patients who have difficulty reading, a hand-held version such as the Jaeger card may be used. In the United States, an individual is legally blind if vision is 20/200 or less in the better eye with correction. If peripheral vision is reduced to 10° or less in both eyes (tested on perimetry) the patient is also considered legally blind even if his or her central vision is better than 20/200.

A simple test for visual acuity that tests for refractory errors is the pinhole test. Repeating the Snellen test with the patient looking through a 2-mm pinhole in a card will improve performance if the cause is a refractory error. The patient may state that the image is dimmer (this is due to less light being allowed into the eye).

Confrontation testing is used to test for visual field defects. All fields are the same for the examiner (except in the temporal field). Therefore, when a patient is asked to say “now” when a finger or object enters his or her visual perception, the examiner should see it at the same time. With a temporal field examination, it is necessary to start with the finger or object behind the patient and advance it forward. The patient should see it at approximately 90°. Visual field testing may indicate where the problem is in the vision relay system. A brief, generalized list follows:

- Central scotoma—optic nerve involvement
- Nasal quadrant deficits—glaucoma is a common cause
- Bilateral temporal field deficits—compression at the optic chiasma (often from a tumor)
- Homozygous hemianopic deficit (same side in both eyes)—optic tract to the calcarine cortex

## **Red or Pink Eye**

When there is purulent discharge associated with eyelid involvement with crusted material and no associated

preauricular lymph node involvement, the patient will probably have a bacterial conjunctivitis requiring referral. When crusting of the eyelids is a predominant finding, a blepharitis (bacterial infection of the sebaceous follicles and meibomian glands) has occurred through extension of the conjunctival infection. When the conjunctivitis is more watery or mucus-like, with no crusting, and associated with preauricular node involvement, a viral cause (usually adenovirus) is likely. Other conditions, such as corneal abrasion or infection, often are associated with pain, impaired vision, light sensitivity, and unequal pupils. These added findings dictate referral to an ophthalmologist for further evaluation. Also, patients with eye inflammation who have had prior eye surgery, wear contact lenses, or have a history of herpes simplex keratitis should be referred to an ophthalmologist.

A similar presentation may occur with the use of eye drops (prescribed or over-the-counter [OTC] products). This is usually bilateral and is a diagnosis of exclusion. Referral back to the prescribing physician for evaluation or discontinuation of an OTC eye drop is usually effective.

## **Management**

Immediate referral to an ophthalmologist is needed in the following cases:

- Acute glaucoma
- Abrasion of the cornea or foreign body implantation
- Temporal arteritis
- Retinal detachment or vitreoretinal traction
- Suspicion of bacterial conjunctivitis
- Acute cerebrovascular event

Nonemergent referral to an ophthalmologist is needed in the following cases:

- Suspicion of open-angle glaucoma, age-related macular degeneration, cataracts
- Cases where there is progressive loss of vision without a known cause
- Patients interested in radiokeratotomy or laser ablation therapy

Referral to an optometrist (with the possibility of comanagement) should be made in the following cases:

- Children age 4 years and over with vision of 20/40 or worse in either eye or a difference between two eyes of one line or more on the Snellen eye chart
- All patients with indication of diabetic retinopathy (to determine need for ophthalmologic referral)
- Patients who wear glasses but have lost the corrective ability of the lenses

Recommendations for prevention of vision loss include the following:

- All children between the age of 3 and 4 years should have a visual screening.
- All individuals over age 40 years (particularly blacks) should have a tonometry and ophthalmoscopic examination every three to five years to detect glaucoma.
- All diabetics should be closely monitored for any vision changes and have a minimum of an annual eye examination; emphasis on control of diabetes is crucial to the prevention of diabetic retinopathy.
- All hypertensive patients should be educated regarding the higher probability of vision loss with chronic

hypertension and should strictly adhere to a program to reduce hypertension.

Therefore, the chiropractor may act as a screening source for many eye problems. Although there are anecdotal and in some cases paper presentations of recovery of eyesight with chiropractic care, it is too early to recommend this approach as an isolated attempt.<sup>16</sup> Comanagement with an optometrist or ophthalmologist is highly suggested for purposes of both patient safety and documentation. Although older theories focused on a proposed sympathetic nervous system irritation, a more convincing theory suggests cerebral hibernation as a cause, with manipulation “reviving” the quiescent nerve cells. The theory is based on an observation that when cerebral blood flow is deprived from an area of the brain, cell death occurs. However, if the vascular reduction is less than that causing death, a protective cellular hibernation with no apparent electrical activity occurs. When the blood flow or neural stimulation is returned to the area, cellular function returns.<sup>17</sup> One study<sup>18</sup> claims such a response in cerebral blood flow following manipulative therapy. With regard to lesser vision problems such as phorias and tropias, there is a theory that the relationship between cervical input into the vestibular nuclei and other connections may have an effect on cranial nerves or extraocular muscle function. There have been two small studies<sup>19, 20</sup> of patients without glaucoma who demonstrated a reduction in intraocular pressure after spinal manipulation. Unfortunately, tonometry is known to be quite variable, and the results might be flawed by this deficiency.

New refractive surgical procedures are commonly used for the correction of myopia and, in some cases, astigmatism. Due to the fact that the cornea provides approximately two-thirds of the eye’s refracting ability (the remainder is provided by the lens), and given that currently

the length of the eye cannot be altered, these new refractive techniques attempt to make changes in the cornea that allow refocusing of an image onto the retina. The results of these surgeries can be rather dramatic; however, they are based on the degree of myopia and associated astigmatism. There are three procedures:<sup>21</sup>

- 1.** Radial keratotomy (RK)—with anesthetic eye drops, a thin diamond surgical instrument is used to make a series of radial incisions that causes a relative flattening of the cornea.
- 2.** Photorefractive keratotomy (PRK)—with anesthetic eye drops, an excimer laser is used to remove specific, small amounts of corneal tissue.
- 3.** Laser in situ keratomileusis (LASIK)—with anesthetic eye drops, a flap of corneal tissue is made with a microkeratome; an excimer laser is also used to remove corneal tissue, and then the flap is returned to its original position.

Prior to an individual being considered a candidate for these refractive surgical procedures, certain inclusion and exclusion criteria are used:

- Must be 18 years of age or older
- Must not be pregnant or nursing
- Must be able to demonstrate stable lens correction for at least one year
- Must discontinue use of soft lenses for one week and rigid lenses three to four weeks before the surgical procedure
- Must be free of medical conditions that might contraindicate surgery or specifically surgery of the cornea; ocular conditions include severe dry eye, corneal scarring, severe uveitis, severe untreated blepharitis, or kerataconus; also exclusionary are

medical conditions such as collagen vascular diseases, keloid formation, or an immunocompromised status (relative contraindication)

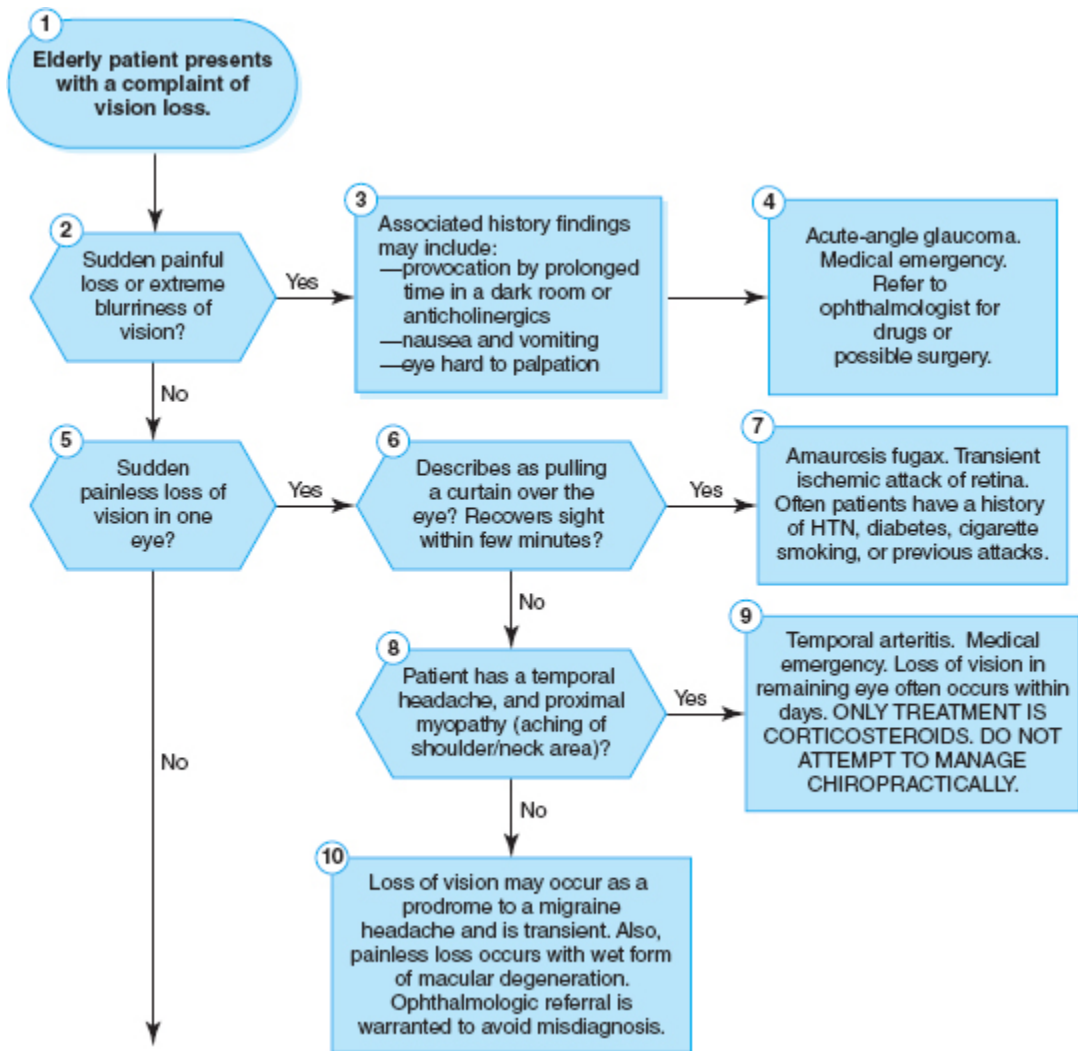

Generally, patients with up to -6.00 diopters of myopia may benefit from RK and PRK, whereas patients with visual acuity less than -6.00 diopters will have better results with LASIK. Newer options in development are implantation of an intrastromal corneal ring and the use of intraocular lens (lens implantation).

These surgeries are not entirely without risks, and some have not withstood the test of time and large retrospective studies. Compared to LASIK, recovery from PRK takes slightly longer and the patient may have some discomfort due to healing of the corneal surface. Glare and halos may develop but usually diminish over time. It appears that patients with brown eyes may have this temporary side effect more often than those with blue eyes.<sup>22</sup>

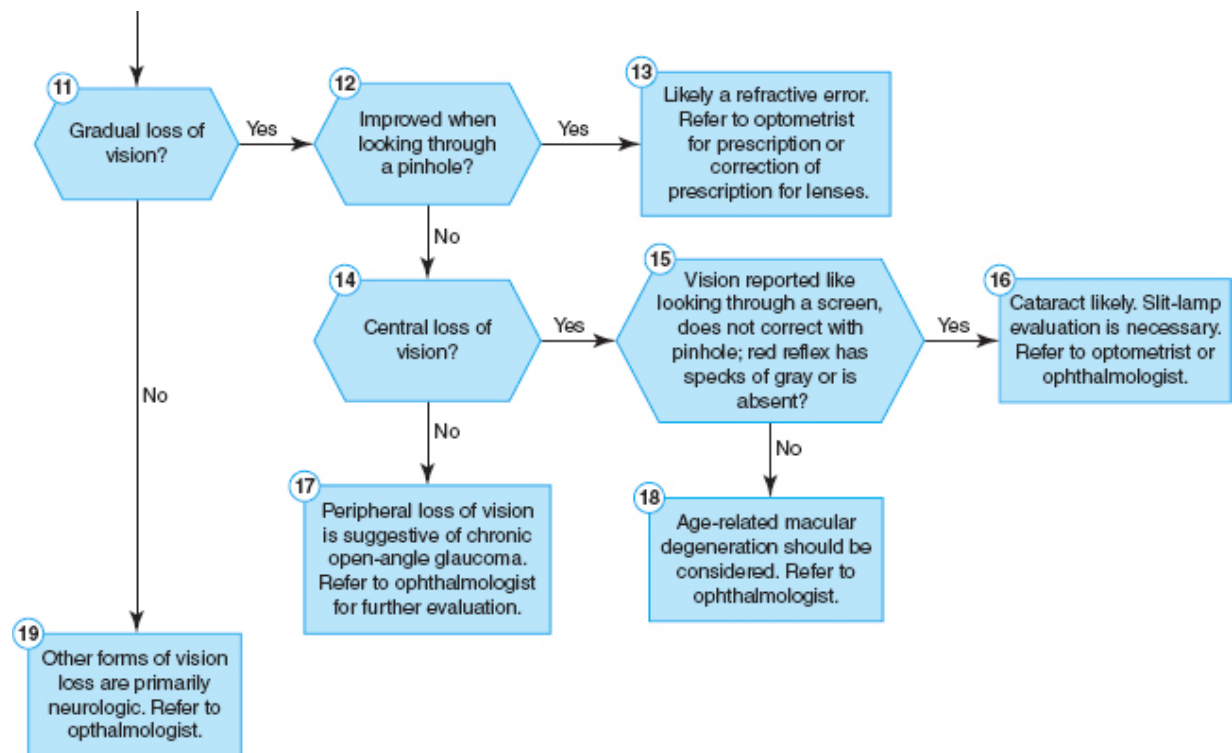

Patients who are classified as legally blind are not able to obtain a driver's license and have some restrictions in contact or vehicle-operated sports. These individuals are eligible for assistance with education, visual aids, and seeing-eye dogs.

## Algorithm

An algorithm for evaluation and management of vision problems in the elderly is presented in **Figure 42-2**.

**Figure 42-2** Vision Problems in the Elderly—Algorithm

# **Selected Causes of Vision Loss**

## **Acute Angle-Closure Glaucoma**

### **Classic Presentation**

A patient with acute glaucoma is likely to seek emergency care because of severe pain. If a patient presents to a chiropractic office, the presentation would be eye pain associated with a complaint of apparent halos around lights, blurred unilateral vision, and possibly nausea and vomiting. The patient may report having been in a prolonged dark environment such as a movie theater, during stress, or having had his or her eyes dilated for medical purposes. The patient is usually a senior with a positive family history for acute angle-closure glaucoma.<sup>6</sup>

### **Cause**

Blocked outflow of aqueous humor from the anterior chamber causes increased pressure and severe pain. The “angle” is formed between the cornea and the root of the iris. The outflow canal that is blocked consists of a trabecular network and the canal of Schlemm. Preexisting narrow angles are found in the elderly (due to lens enlargement), patients with hyperopia (farsighted), and Asians.<sup>7</sup> Fortunately, acute-angle glaucoma accounts for less than 10% of all glaucoma cases.

### **Evaluation**

Because the patient is likely to see an emergency physician, examination is not commonly necessary. However, if less acute, the chiropractor should be aware of acute glaucoma as a possible cause of eye pain. The patient will have eye redness (ciliary flush) and a cloudy-looking cornea. The depth of the anterior chamber can be assessed with a penlight. Shining the penlight from the side, a shadow will be visible over the nasal half of the iris. The eye is hard to palpation.

### **Management**

This is a medical emergency. A permanent correction may be accomplished with laser peripheral iridectomy. Left untreated, the patient will have permanent vision loss in three to five days.

## **Open-Angle Glaucoma**

### **Classic Presentation**

Unfortunately, a patient with early open-angle glaucoma has no warning symptoms. If asymptomatic, a patient would present with a complaint of a peripheral visual field “cut,” usually the nasal half.

### **Cause**

The cause is unknown; however, a surfacing theory is that glaucoma is an optic nerve disease that may be related to specific vascular changes.<sup>23</sup> In addition, these vascular changes may be caused by free radicals (as in stroke or similar diseases). The intraocular pressure is chronically elevated in patients with this type of glaucoma, yet the cause is unknown. It is usually bilateral and seen earlier in blacks than other ethnic groups. The patient may be genetically predisposed to an adverse reaction to topical or oral corticosteroids, leading to the development of glaucoma. Past eye surgery or trauma may also predispose the patient.

### **Evaluation**

The evaluation for glaucoma in the chiropractic setting is difficult. There would have to be a high level of suspicion (given most patients are asymptomatic) and the tools and expertise to perform a comprehensive examination. These include tonometry (the measurement of intraocular pressure), ophthalmoscopic visualization of specific changes, and visual field testing. The measurement of intraocular pressure increase is not a reliable indicator. Required is inspection of the anterior chamber angle with a special lens (goniolens) with the slit-lamp biomicroscope. Two screening tools have been advocated: (1) frequency-doubling perimetry, and (2) oculokinetic perimetry. Future studies will determine their usefulness. If the glaucoma is advanced, visual field testing may reveal an upper nasal field cut. Ophthalmoscopic changes include cupping of the disc and nasal displacement of the vessels.

### **Management**

Ophthalmoscopic referral is necessary. Initial treatment is with medication. Failure to improve usually requires a referral for laser trabeculoplasty.

## Cataracts

# Classic Presentation

The patient is usually a senior complaining of progressive, painless, central vision loss or blurred vision. Ironically, some patients may report an improvement in close vision in the initial stages of cataract formation.

## Cause

Cataracts are the leading cause of blindness in the world.<sup>24</sup> Cataract surgery is the most commonly performed surgical procedure in the United States, with 1.5 million operations annually.<sup>25</sup> More than half of individuals over the age of 65 years will develop age-related cataracts. A cataract is due to opacification of the lens. There are several different types and causes, including congenital (often due to rubella and cytomegalovirus intrauterine infection) and secondary to diabetes, chronic corticosteroid use, or uveitis. However, the most common type of cataract is the one associated with heredity and aging—senile cataract.

Some different types of cataracts are described below.

- Nuclear cataracts are found in the central part of the lens and are the most common type of age-related cataracts. Older age, female gender, and smoking are risk factors. Potential risk factors are diet, estrogen levels, and cardiovascular factors.
- Cortical cataracts are found surrounding the central lens and are more common in black individuals.
- Posterior subcapsular cataracts are found behind the lens and are associated with sunlight exposure as a risk factor. They are more common in white individuals, especially those taking corticosteroids.
- Mixed cataracts are a combination of the above types.

Cataracts are also secondary to ocular trauma, diabetes, alcohol use, and with some medications including corticosteroids (associated with the posterior subcapsular type). Chronic ultraviolet light exposure appears to be the main cause with aging. Most patients over the age of 50 years have some degree of lens opacification, yet not all have a visual impairment. Risk factors include cigarette smoking or alcohol abuse.<sup>26, 27</sup>

## Evaluation

The vision loss is central and not improved by looking through a pinhole. There is a normal pupillary reaction. Ophthalmoscopic examination may reveal flecks of gray appearing with the red reflex, or obliteration of the red reflex in advanced cases. Visualization of the opacity is possible in later stages, but a slit-lamp examination is necessary to locate it (and therefore the type of cataract).

## Management

Prevention of nuclear cataracts may be in part due to attention to adequate protein, vitamin A and niacin, thiamin, and riboflavin.<sup>28</sup> The decision to have cataracts removed must be a weighted process, taking into account the age of the patient, the degree of cataract formation, and, most important, the effect on function. For example, an 80-year-old patient confined to bed may not have the same benefits as a younger, more active patient. Surgery involves one of two procedures: (1) extracapsular surgery, and (2) phacoemulsification. Extracapsular surgery leaves the posterior capsule of the lens intact, providing a firm anchoring for the implant. Phacoemulsification, called no-stitch surgery, involves fractionation of the lens with sound waves. The surgical management includes removal of the lens and placement of a permanent artificial lens called an intraocular lens (IOL). The most prevalent practice is to use an ultrasonic probe that emulsifies the lens through vibration. The lens is removed and an IOL is inserted. New improvements will include alternatives to ultrasonic energy, such as laser photolysis, and new technology that allows for rapid dispersion of heat with a smaller incision.<sup>29</sup> Foldable silicone implants have been developed that can be inserted through smaller incisions and with newer techniques can be implanted with no sutures. Bifocal or multifocal lenses are also available in some locations.<sup>30</sup>

## Age-Related Macular Degeneration

### Classic Presentation

The patient may present differently based on the underlying type. A patient with atrophic (dry) degeneration will complain of slowly developing, painless, central vision loss. A patient with the disciform (wet) degeneration presents with sudden, painless loss of vision. Prior to loss the patient may notice parts of words missing or straight lines appearing crooked.

### Cause

Age-related macular degeneration (ARMD) is the leading cause of blindness in the geriatric population. It affects up to 30% of the elderly to varying degrees. Ninety percent of cases are the dry, slowly progressive form.<sup>5</sup> Associated risk factors include smoking and a family history of ARMD. Asians have a very low risk; whites have a higher risk. Individuals with light blue or green irises or exposure to intense blue light are also at risk. The layer between the retinal pigmented epithelium and choriocapillaris is called Bruch's membrane. Degeneration of this membrane and the retinal pigmented epithelium results in the atrophic form. This degeneration, specifically the lipofuscin aggregation, is due to oxidative damage that is both light and oxygen dependent. Damage to Bruch's membrane by drusen allows an angiogenic stimulant to promote ingrowth of new vessels (neovascularization) and the exudative or wet form occurs.

## Evaluation

Fundoscopy findings include drusen (yellow-white spots) and hyper- or hypopigmentation of the fundi with the atrophic form. Hemorrhages and exudates are seen. Patients at risk for ARMD are often told to use a straight line or Amsler grid to detect any new distortion, which would require immediate consultation with an ophthalmologist.

## Management

There is no treatment for the dry form of ARMD, but low-vision aids and adaptation to gradual loss are usually sufficient to allow mobility. Patients with the wet form of ARMD often require laser photocoagulation to ablate the neovascular membrane. The location of the membrane affects the success of the laser ablation. In some cases, restoration of some central vision may reduce general vision, yet, ironically, prevent blindness. Up to 60% of patients need repeat treatment because of regrowth. Obana et al.<sup>31</sup> evaluated the carotenoid levels of the retina in patients with ARMD and found them to be lower than patients without ARMD. Smoking is a well-established risk factor for ARMD in patients with a genetic predisposition.<sup>32</sup>

Morris et al.,<sup>33</sup> evaluating the relationship between zinc and antioxidant intake and ARMD, found that intake of alpha- and beta-carotene, lycopene, total retinal A, total vitamin A, and total vitamin E were significantly inversely related to the prevalence of pigmentary abnormalities (PA). Specifically, consuming foods high in alpha- or beta-carotene lowered the odds of PA. It appears that a diet high in vitamin A and antioxidants, in particular beta-carotenes (large amounts of fruits and vegetables), may reduce the risk of developing ARMD.<sup>34</sup> An important new treatment method for wet ARMD is with intravitreal bevacizumab. This approach, based on anticancer treatment, targets the neovascularization aspect of the wet-type of macular

degeneration. It is a monoclonal antibody drug designed to block the growth of new blood vessels. An injection into the eye, usually followed by one per month for two months, causes significant anatomical and functional improvement.<sup>35, 36</sup> This new approach has strong literature support but only for a one-year follow-up. Long-term efficacy is still being evaluated. Specific recommendations include the following amounts taken daily: 200 mg of selenium, 1,000 mg vitamin C, 400 IU of vitamin E, and 25,000 IU of natural beta-carotene. There are mixed reports regarding zinc supplementation as a prevention for ARMD.

## **Retinitis Pigmentosa**

### **Classic Presentation**

The patient is often a youngster who notices (or a parent notices) poor night vision.

### **Cause**

This disorder is hereditary, with recessive, autosomal-dominant, and X-linked modes identified. It may also occur as part of Bassen-Kornzweig syndrome or Laurence-Moon-Biedl syndrome. Degeneration of the retina, particularly the retinal rods, occurs. This is why night vision loss is one of the earliest signs. A peripheral-ring scotoma usually expands to include some central vision loss by middle age.

### **Evaluation**

Fundoscopic examination will reveal dark pigmentation in the equatorial region of the retina, often associated with a yellow, waxy disk. Definitive diagnosis requires specialized testing that includes dark adaptation, electroretinography, and electrooculography.

### **Management**

No treatment is currently effective. Genetic counseling is recommended for those affected. Retinoid supplementation is advocated by many, yet the results have not been clearly reproducible. There appears to be a possible role for vitamin A and taurine (amino acid).<sup>37</sup> In the future it is hoped that genetic engineering may allow replacement of the defective gene. Retinal transplantation is currently being researched. Currently, “retinal glasses” are

being used as a means for patients to retain some degree of functional eyesight.

## **Amaurosis Fugax**

### **Classic Presentation**

The patient is usually over the age of 50 years and complains of an episode of vision loss in one eye that lasted a few minutes and then the vision returned. The patient often describes the loss and recovery of vision like a shade being pulled down and raised, respectively. There is often a history of diabetes, hypertension, or smoking.

#### **Cause**

Emboli originating in the ipsilateral internal carotid travel to the retina via branches of the ophthalmic artery, causing a “fleeting blindness,” amaurosis fugax. The same risk factors for atherosclerosis are found, such as hypertension, diabetes, and chronic cigarette smoking.

### **Evaluation**

An ipsilateral carotid bruit may be heard. Fundoscopic examination will usually reveal signs of hypertensive disease. In addition, whitish emboli and/or refractive cholesterol emboli may be seen. Patients should be sent for Doppler studies and possibly angiography to determine the extent of stenosis.

### **Management**

After an attack, the patient should be warned of a predisposition to stroke or loss of vision if a subsequent attack occurs (16% of patients).<sup>38</sup> Aspirin and antiplatelet drugs are used in patients with mild stenosis. Endarterectomy has a high success rate in patients with severe stenosis. There is a subgroup of patients who are younger and have no signs of atherosclerosis or stenosis. The belief is that these patients may suffer from retinal artery spasm. These patients will be placed on a calcium channel blocker. For obvious reasons, patients who have had an attack of amaurosis fugax are probably at somewhat greater risk with cervical adjustments. Other techniques should be employed.

## **Optic Neuritis**

# Classic Presentation

The patient presents with an abrupt loss of vision in one eye. Central vision is affected and may progressively worsen over the next two days. If the patient presents two to three weeks later the vision often has returned to normal. However, now the patient has some eye pain associated with eye movement.

## Cause

Inflammation of the optic nerve is usually due to demyelinating disorders, specifically multiple sclerosis (MS). It may occur less commonly with a host of other problems such as infection (mumps, measles, influenza, or varicella virus), autoimmune disorders (lupus), bee sting, meningitis, or infarction from temporal arteritis.

## Evaluation

Ophthalmoscopic evaluation by a specialist is required.

## Management

In the past, oral prednisone was used; however, it has been discovered that this approach, in addition to not being effective, doubles the risk of recurrence in the following two years in the same or opposite eye.<sup>39</sup> Currently, intravenous methylprednisolone sodium succinate, followed by oral prednisone, effects a quicker recovery and has a fortuitous side effect of delaying the onset of MS in some patients.<sup>40</sup>

# CHAPTER 43

## Facial Pain

### Context

Initial distinction between facial pain and headache is necessary. Facial pain may arise from several anatomic sources, including the ears, oral cavity, sinuses, cervical spine, and eyes. Although there is obvious overlap and the possibility of referral, patient localization and associated findings are usually revealing.<sup>1</sup> Facial pain is best approached from a temporal perspective. Sudden onset with recurrent attacks is typical of several neuralgias. Deep, boring, aching pain is more characteristic of oral, ear, eye, and sinus problems and intracranial pathology. Dental causes are often distinguished by oral stimuli such as cold, hot, sweetness, or pressure.

### General Strategy

### History

- Distinguish among facial, ear, eye, oral, and headache pain.
- Determine whether the onset is sudden and recurrent (neuralgic) or chronic (intracranial or eyes, ears, nose, and throat [EENT]).

- Determine the quality of pain; sharp, lancinating pain of relatively short duration suggests neuralgias; deep, boring pain is more characteristic of dental, sinus, and intracranial masses.

## **Neuralgias**

- Determine whether the pain is acute or chronic.
- If acute, determine whether there are any triggers such as shaving, cold, eating, or other (trigeminal neuralgia).
- Determine whether the pains are sharp and stabbing in the mouth and awaken the person at night (possible glossopharyngeal neuralgia).
- Determine whether there are any associated neurologic symptoms (neuralgia secondary to other processes such as multiple sclerosis).

## **Oral Cavity**

- Determine whether there has been any recent prolonged dental work and/or last dental examination.
- Determine whether pain is related to eating cold, hot, or sweet foods.

## **Sinus**

- Determine whether there is a prior or current history of an upper respiratory infection.
- Determine whether there are positional exacerbations of the pain (i.e., bending forward or lying down).

# Temporomandibular Joint

- Determine whether opening the mouth increases the pain.
- Determine whether there is a history of grinding teeth.
- Determine whether there is a history of popping or clicking at the temporomandibular joint (TMJ).

## Myofascial

- Determine whether the pain location includes the periaural or temporal area.
- Determine whether the pain is in the region of the masseter (cheeks) and associated with prolonged opening of the mouth or movement of the jaw.

## Psychologic

- Determine whether the patient may be depressed or have periods of stress, drug addiction, or a dysfunctional home environment.
- Determine whether there is a family history of similar complaints.

## Evaluation

- Examine the eyes, ears, nose, throat, and TMJ for any obvious pathology with a focus on dental abnormalities.
- When a sinusitis is suspected, transillumination or specific skull radiographs may be helpful in determining involvement.

- When a diagnosis is not clear, referral for special imaging is warranted.

## Management

- If tolerable, patients with neuralgias may benefit from a trial treatment with manipulative therapy; if unresponsive after two to three weeks, referral for medical management is suggested.
- Sinus pain is often self-resolving, but the patient may benefit from facial massage, cervical adjustments, and physical therapy; over-the-counter decongestants have some value with limited use; failure to respond is suggestive of a sinus infection that may require antibiotic management.

## Relevant Neurology

The trigeminal nerve is responsible for general sensation of the head and face. The skin of the face and forehead is supplied by three divisions of the trigeminal nerve. The nose, forehead, and scalp to the vertex of the skull are supplied by the ophthalmic (V1) division; the cheek and below the nose to the lip are supplied by the maxillary (V2) division; the jaw to the front of the ear is supplied by the mandibular (V3) division. The trigeminal nerve also supplies the mucosa of the oral and nasal cavities, the perinasal sinuses, the teeth, and most of the dura. The angle of the jaw and scalp of the back of the head are supplied by C2 and C3. Bogduk and Marsland<sup>2</sup> demonstrated that referral pain overlapping the V1 division of the trigeminal nerve may be due to facet irritation in the upper cervical region.

## Evaluation

### History

## Neuralgias

Generally, neuralgias are differentiated by a classic onset in older patients (after age 50 years) with a description of sharp, excruciating jolts of facial (or oral) pain that are recurrent and often progressive. The same presentation in a younger patient would suggest other conditions such as multiple sclerosis, a trigeminal neuroma, and, more rarely, an acoustic neuroma.

Trigeminal neuralgia is the most common facial neuralgia. The short, sudden, electric shock-like pains usually follow either the second or third trigeminal branch. Trigger areas may be reported by the patient. Even light touch to, for example, the nasolabial fold or upper lip may trigger an onset if the maxillary branch is involved. An area lateral to the lower lip may trigger an attack with mandibular division involvement.

When the less common glossopharyngeal neuralgia is the cause, pain is felt deep in the oral cavity and palate. Pain often occurs during the night, awakening the patient. Triggers involve relatively common benign activities such as talking, swallowing, yawning, or eating. It appears that salty, spicy, or bitter foods may be triggers. Postnasal drip is occasionally found as a trigger for some patients. Patients may also report having fainted upon coughing or yawning.<sup>3</sup>

## Dental

When dental pulp is inflamed (pulpitis) as a result of caries, trauma, or dental surgery, pain is provoked by hot or cold foods and sweets. When the pulp undergoes necrosis, local gas is produced, which, when expanded by heat, increases pressure and causes pain. Cold decreases the gas pressure and relieves the pain. There are apical foramina that connect the pulp to the periodontal ligament and periapical alveolar bone. Infection or inflammation may spread through this connection, leading to a tooth that is sensitive to compressive pressure from chewing or percussion. This is also found with a cracked tooth.

## **Myofascial**

Myofascially related temporomandibular problems are often evident from a history of early-morning jaw pain or if the patient is aware of grinding the teeth throughout the night or day. Other indicators may be pain upon opening the mouth. The pain is often felt at the pretragus area or temporalis muscle and may radiate into the face (see [Chapter 3](#)).

## **Sinus**

In many cases there may be a history of an upper respiratory problem currently or preceding the development of facial pain. It may be possible to localize which sinuses are involved by questions regarding positional exacerbation or relief. The pain from frontal sinus involvement is relieved by standing or sitting. It is likely that the patient will report worse pain at night or when lying down and improvement after arising in the morning or as the day progresses. Those patients with maxillary sinus involvement may report the opposite: relief when lying down, which allows better

drainage. Sphenoid sinusitis is unusual in that it may refer to the vertex of the skull, the eye, or the neck.

## Examination

The examination for facial pain should focus on a detailed examination of the mouth, paying particular attention to dental status and any oral lesions. The examination continues with palpation of facial structures in an attempt to reproduce pain. Patients with neuralgias may have their pain triggered by light touch around the mouth or cheek areas. Palpation of the TMJ while the patient opens and closes the mouth will usually localize the problem. Further evaluation is discussed in [Chapter 3](#).

Acute sinusitis is usually quite obvious, with localized tenderness to either palpation or percussion over the involved sinus. Bending forward may increase pressure and therefore pain in the sinus. When the maxillary sinus is involved, referral to the teeth may produce a complaint of toothache, and percussion of the maxillary teeth may produce discomfort. Transillumination of the sinuses may be decreased. Radiographic evaluation of the sinuses includes the following views ([Figure 43-1](#)):<sup>4</sup>

**Figure 43-1** Radiographic views of the maxillary, ethmoid, and frontal sinuses.

- Waters view for maxillary sinuses
- Caldwell view for ethmoid sinuses
- Chamberlain-Towne view for frontal sinuses

## Management

Chiropractic management of facial pain is based entirely on the suspected source. If there is a dental source, referral to a dentist is appropriate. If the patient appears to have one of the neuralgias, such as trigeminal neuralgia, a brief treatment trial of chiropractic care may be attempted if the patient is amenable; however, there are no studies

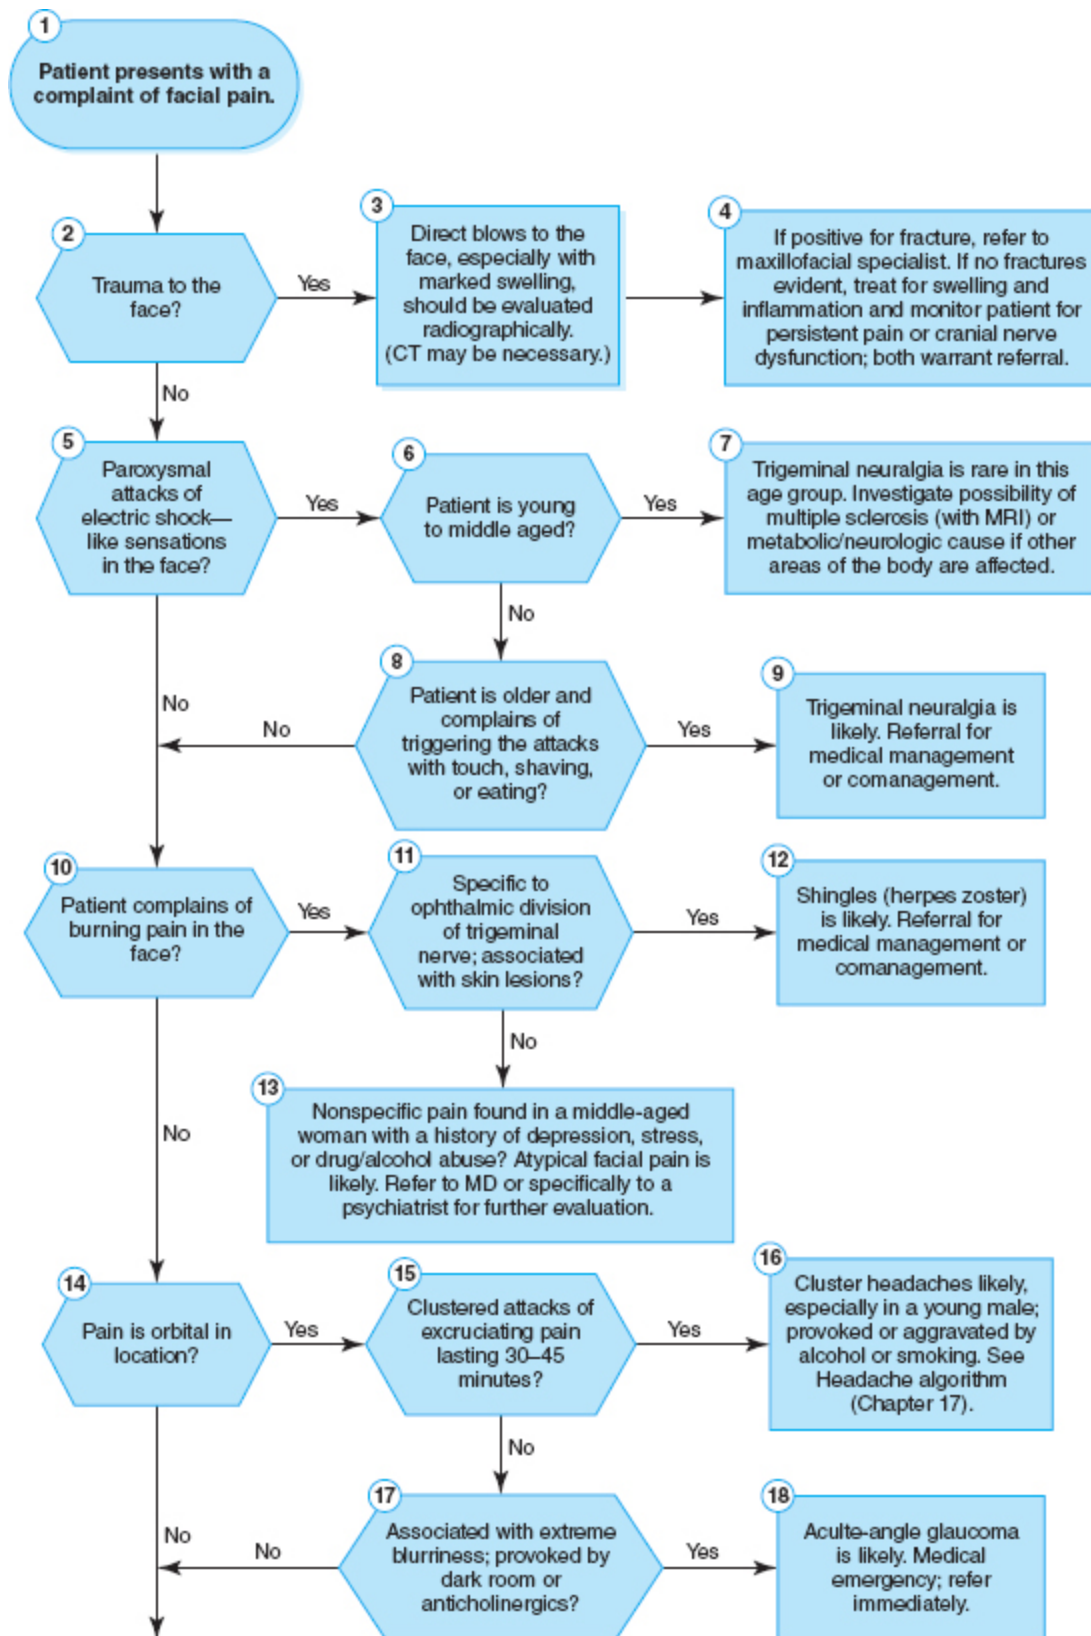

indicating success with the facial neuralgias in the chiropractic literature. The rationale for this approach is the anatomic relationship between the spinal nucleus of the trigeminal nerve and the upper spinal nerves in the trigeminocervical nucleus. Medical management of trigeminal neuralgia is with an antiseizure medication such as carbamazepine (Tegretol). If this is unsuccessful, surgical decompression may be effective in cases where anomalous blood vessels are pressing on the trigeminal nerve. Recently, implanted electrical stimulation devices have shown some success.<sup>5</sup> Radiofrequency rhizotomy is reserved for patients with a limited life expectancy. Glossopharyngeal neuralgia is managed similarly. Microvascular decompression appears to be very successful.<sup>6</sup>

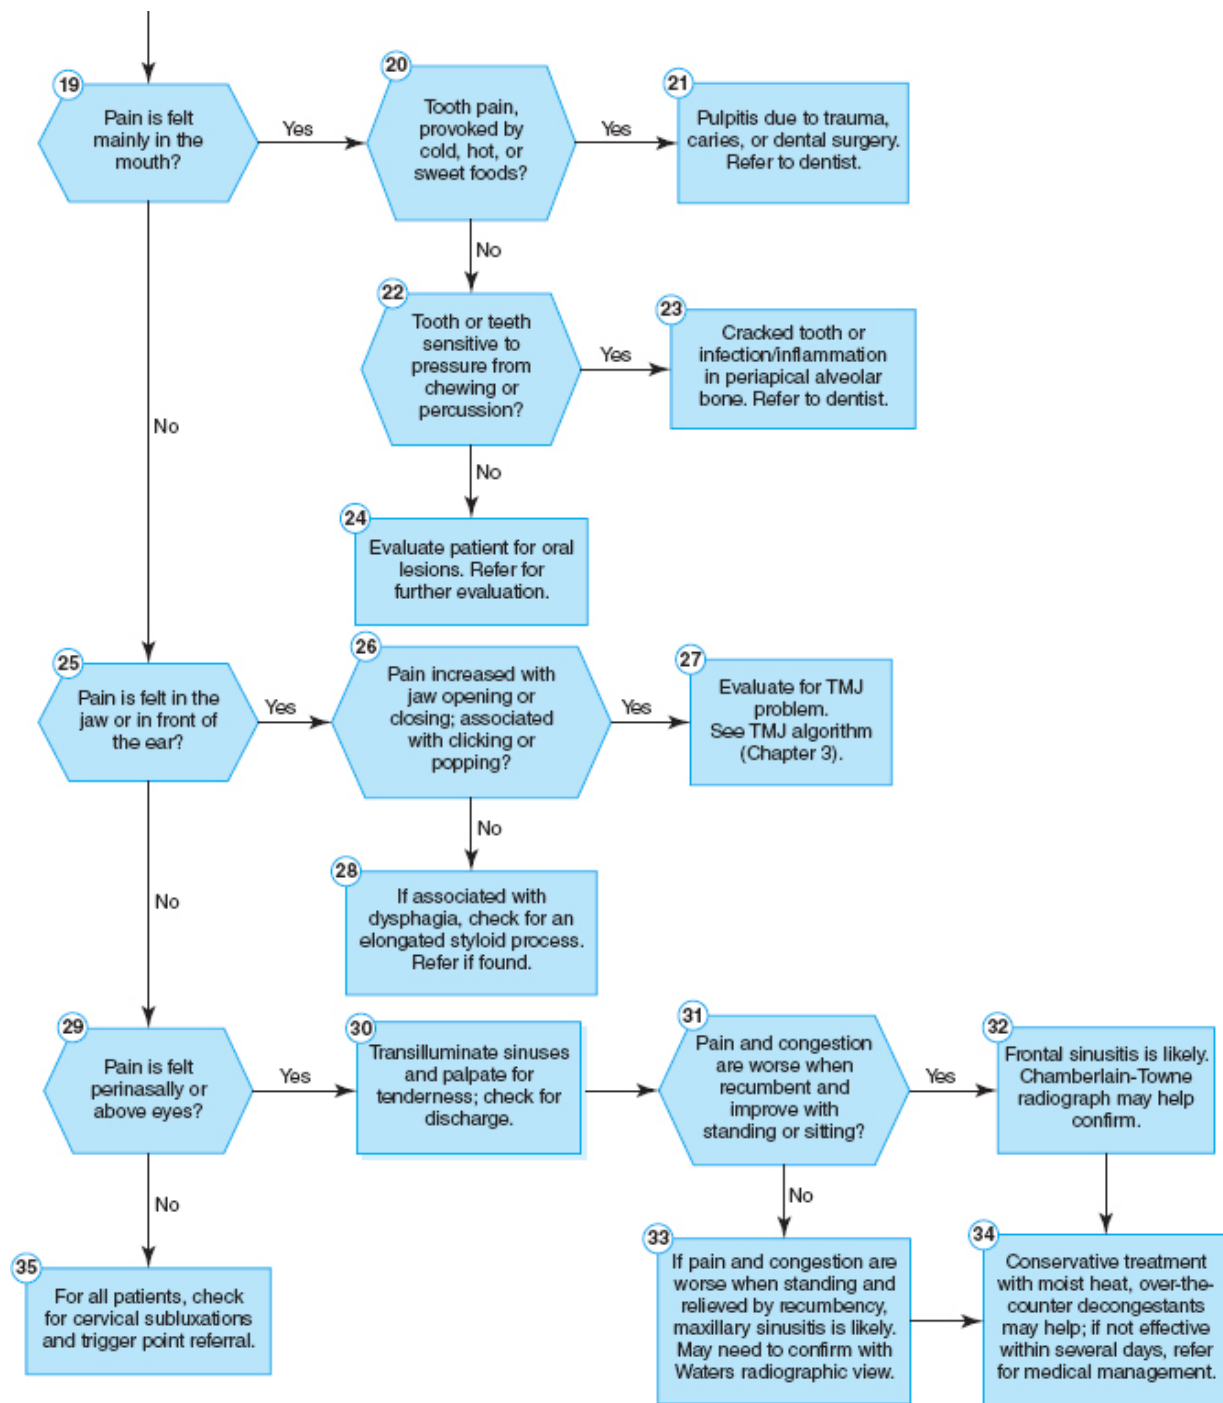

Sinusitis pain is often self-resolving. This may be aided by moist heat and possibly aided through facial massage. Cranial manipulation is advocated by some osteopaths and chiropractors. When there is an underlying infection, conservative measures to reduce sinus pressure will often fail and require medical referral for antibiotics and in rare cases drainage.

The reader is referred to [Chapter 3](#) for appropriate patients.

## Algorithm

An algorithm for evaluation and management of facial pain is presented in [Figure 43-2](#).

**Figure 43-2** Facial Pain—Algorithm

# Facial Pain Caused by Neuralgias

## Trigeminal

### Classic Presentation

Usually a middle-aged or older (>50 years) patient (usually female) presents with a complaint of sharp, electric shock-like pains that start at the mouth and shoot toward the ear, eye, or nose on the same side. The attacks are recurrent and often progressively become more frequent. The patient is often distraught and may be considering suicide.

### Cause

The cause is unknown. Triggers include sensory stimulation from touch, the wind, shaving, or eating.

### Evaluation

The neurologic examination is negative. If positives are found, especially in a younger patient, suspect multiple sclerosis. Other causes include trigeminal neuroma and other tumors. If suspected, referral for imaging studies may be necessary.

### Management

Current medical management includes carbamazepine (Tegretol). Surgical decompression may be effective if anomalous blood vessels are pressing on the trigeminal nerve. Radiofrequency rhizotomy is reserved for those individuals with limited life expectancy. Acupuncture is often tried as an alternative. Implanted electrical stimulation devices may be of benefit.<sup>5</sup>

## Glossopharyngeal

### Classic Presentation

Patient presents with a complaint of deep, stabbing, or electric shock-like pain in the mouth (tongue, tonsils, throat, or sometimes ear). It may awaken the patient at night. There may be a history of syncope from coughing.

## **Cause**

The cause is unknown. Triggers may include swallowing, yawning, talking, or chewing.

## **Evaluation**

Neurologic examination is negative.

## **Management**

Management is the same as for trigeminal neuralgia—carbamazepine. Surgical microvascular decompression appears to be an effective treatment.<sup>6</sup>

## **Atypical Face Pain**

## **Classic Presentation**

A middle-aged woman (between 30 and 50 years of age) complains of constant facial pain that is described as burning. The woman often will have a history of psychiatric problems, depression, drug addiction, high-stress personal life, and a positive family history (60% of patients).

## **Cause**

The cause is unknown.

## **Evaluation**

Neurologic examination is negative. If suspected, evaluation for depression may be appropriate.

## **Management**

Cervical spine manipulation theoretically may be of benefit, but there are no reports in the literature. Analgesics should be considered; if not effective, referral for stronger medication.

---

# CHAPTER 44

## Ear Pain

### Context

A complaint of ear pain usually raises the concern of an ear infection. It is interesting to note that although commonly a cause in children, in adults, one study<sup>1</sup> indicated that ear pain was referred in 60% of patients. Even more interesting is that 80% of those with referred pain were found to have temporomandibular (TMJ), cervical spine, or a dental (50%) pathology or dysfunction. Therefore, it appears that ear pain is often best evaluated and treated by one of three specialists: the chiropractor, the pediatrician, or the dentist.

Otitis media is the most common diagnosis in children and the second most common diagnosis in medicine; approximately two-thirds of all children in the United States are affected by age 2 years.<sup>2, 3</sup> Depending on the type (acute otitis, recurrent acute otitis, otitis media with effusion, chronic otitis media), management may include antibiotics, decongestants, tympanostomy tubes, or other surgical procedures. The major medical concern with otitis media with effusion is that it is believed that associated hearing loss in infants can impair language development.<sup>4, 5</sup> Other studies have criticized the methodology used in studies that claim risk.<sup>6</sup> Most cases of hearing loss associated with otitis media with effusion resolve spontaneously in six to eight weeks.<sup>7</sup>

# General Strategy

## History

- Determine whether the pain is due to trauma (lacerations, hematoma, temporal bone fracture).
- Determine whether the pain is superficial (skin lesions) or deep (otitis externa, media, or cholesteatoma).
- Determine whether the pain is unilateral or bilateral (bilateral is more common with otitis externa).
- Determine whether there are associated auditory or vestibular symptoms (otitis media, labyrinthitis, cholesteatoma).
- Determine whether there are associated signs or symptoms of infection (acute otitis media).
- Determine whether there are any oral, TMJ, cervical spine, or facial symptoms.

## Evaluation

- Evaluate the outside of the ear and palpate for tenderness; otoscopically evaluate the ear.
- Examine the TMJ, cervical spine, and mouth.

## Management

- Refer for obvious cases of bacterial infection.
- Follow Agency for Healthcare Research and Quality guidelines<sup>8</sup> with regard to otitis media with effusion.
- Refer to dentist for dental pathology.
- Manage TMJ and cervical spine problems initially; refer if unsuccessful.

# Relevant Anatomy and Physiology

The external ear is innervated by several sensory nerves, as follows:

- Arnold's nerve (sensory branch of the vagus)
- Jacobson's nerve (sensory branch of the glossopharyngeal)
- Auriculotemporal nerve (sensory branch of the trigeminal; V3)
- A branch of the facial nerve
- Greater auricular and lesser occipital nerves (C2 and C3)

However, the common end-point for central projections from the primary neurons of the above nerves is in the spinal nucleus of cranial nerve V. This spinal nucleus merges with the dorsal horn of C1 through C3 in the trigeminocervical nucleus. This convergence explains why referred pain to the ear is so common.

A central concept in ear complaints and disorders is dysfunction of the eustachian (auditory) tube. The eustachian tube is extremely important in that it provides a drainage and ventilation source for the middle ear via a communication with the nasopharynx.<sup>9</sup> Normally, the eustachian tube remains closed except when swallowing or yawning. Through swallowing, the middle ear is ventilated about three to four times per minute. Narrowing or blockage of the tube may occur through tube lining edema. This is often due to viral infections or allergies. Congenital narrowing of the canal may also occur. In children, the canal is usually narrow and more horizontal than it is in adults, leading to an age-related predisposition to eustachian tube

involvement. A temporal sequence of dysfunction may occur. If the blockage is temporary or partial, air in the middle ear is trapped and absorbed, with a resultant negative pressure. This may be visible otoscopically as a retracted tympanic membrane. If transient, yawning, swallowing, or autoinflation (forced exhalation through closed nostrils) will cause a popping or crackling sound with some relief. If more chronic, the negative pressure will draw fluid into the ear, causing a serous otitis media. If the fluid becomes infected, the patient may develop acute otitis media.

## Evaluation

## History

The history can quickly determine whether the cause is due to barotrauma effects; infection; or referral from the teeth, TMJ, or cervical spine (**Table 44-1**). Bilateral pain is uncommon and often indicates external otitis. Other clues include whether the person has recently gone swimming, cleans the ears by overinserting cotton swabs, or sticks other foreign objects in the ears, such as pencils.

Young children with signs of an upper respiratory infection with fever may have a bacterially caused, acute otitis media. Associated temporary conductive hearing loss is common. Left untreated, the pain may migrate to behind the ear when the mastoid air cells become involved. The pain is often severe and causes disruption of sleep. Infants may constantly grab their ears. If ear pain is associated with vertigo and hearing loss, consider labyrinthitis. If the pain is better with swallowing, chewing, or yawning, barotrauma or serous otitis media is possible. If the pain occurs with air travel only or diving, barotrauma is likely the cause. With air

travel the pain is often worse on descent. Sharp, stabbing pains are felt deep in the ear.

Pain made worse with chewing or yawning is suggestive of a TMJ disorder. Associated complaints will include clicking or popping of the jaw or occasional locking of the jaw. The pain is often unilateral. Dental pathology is also a possible cause of referral. When dental pulp is inflamed (pulpitis) as a result of caries, trauma, or dental surgery, pain is provoked by hot or cold foods and sweets. When the pulp undergoes necrosis, local gas is produced, which, when expanded by heat, increases pressure and causes pain. Cold decreases the gas pressure and relieves the pain. There are apical foramina that connect the pulp to the periodontal ligament and periapical alveolar bone. Infection or inflammation may spread through this connection, leading to a tooth that is sensitive to compressive pressure from chewing or percussion. This is also found with a cracked tooth.

## **Examination**

A general screen of the patient with ear pain consists of the following:

- Observe the area for lacerations, skin lesions, or discharge from the ear canal.
- Take the patient's temperature.
- Otoscopically evaluate the canal for inflammation, obstruction, infection, or fluid distention.
- Screen for possible TMJ referral pain.
- Screen the cervical spine with palpation, compression, and distraction.
- Evaluate the teeth and palpate/percuss for tenderness, especially in the molar region.

Otoscopic evaluation of the ear will often reveal an underlying cause. Some classic otoscopic appearances follow:

- Otitis externa—erythema and edema of the ear canal with a purulent discharge

**Table 44-1** History Questions for Ear Pain

Primary Question	What Are You Thinking?	Secondary Question	What Are You Thinking?
Did the pain occur after being hit in the ear?	Lacerations, fracture, hematoma, perforated ear drum, perilymphatic fistula.	Any fluid leaking from the ear? Pain associated with dizziness or tinnitus?	Fracture. Perilymphatic fistula or perforated ear drum.
Did the pain occur after or during flying or scuba diving?	Barotrauma, eustachian tube dysfunction.	Severe pain felt mainly on the descent?	Eustachian tube dysfunction, especially in a patient with an upper respiratory infection or allergies.
Was the pain felt after swimming?	Otitis externa, ruptured tympanic membrane.	Past history of severe or recurrent ear infections? Ear is painful to touch and/or itchy?	Ruptured tympanic membrane. Otitis externa.
Do you have a cough or fever and/or other signs of a respiratory infection?	Acute otitis, labyrinthitis.	Are you also dizzy or have any hearing loss? Is the pain associated with a fullness with a “blocked” ear sensation?	Labyrinthitis more likely (rare). Acute otitis more likely.
Do you insert anything into your ears such as paper clips, pencils, cotton-tipped swabs, towel tips?	Foreign body, otitis externa.	Is your ear tender to touch or itchy?	Otitis externa likely.
Is the pain made worse with jaw motion?	TMJ, dental problem, elongated styloid.	Is the pain worse when eating cold, hot, or sweet foods? Is the pain worse with biting down? Is the pain worse with opening the mouth wide or associated with popping and clicking of the jaw? Is the pain in front of the ear and worse while opening?	Cavity or pulpitis likely. TMJ or cracked tooth. TMJ likely. Elongated styloid.
Is the pain worse with neck movement?	Cervical spine dysfunction.	Do you have associated neck pain?	Cervical spine arthritis or subluxation.

- Acute otitis media—absent or distorted light reflex indicating bulging of the tympanic membrane; the tympanic membrane may be hypomobile with pneumatic challenge

- Serous otitis media—tympanic membrane may appear yellow-amber in color; air-fluid level or air bubbles may be evident
- Chronic otitis media—diminished or absent landmarks on the tympanic membrane; perforation is often seen

Numerous skin lesions may affect the ear. A list of some of the more common includes:

- Furuncles from infected hair follicles may appear.
- Polyps due to granulomatous processes may appear in the ear canal.
- Keloid is an overgrowth of scar tissue that is often the result of trauma (often due to ear piercing), more commonly seen in blacks.
- Sebaceous cysts are more common behind the lobule of the ear; they have a central black punctum (indicates blocked sebaceous gland).
- Tophi are small, whitish-yellow nodules found on the helix or antihelix in individuals with gout; they are usually hard and nontender.
- Chondrodermatitis presents as painful nodules on the rim of the helix.

When results of the otoscopic examination and outer inspection of the ear are normal, referral pain is likely. Focus on a thorough examination of the teeth, TMJ, and cervical spine.

## **Management**

There is much debate with regard to the management of otitis media. Regarding chiropractic management, it is common practice for many chiropractors to use manipulation and other mechanical maneuvers to improve

otitis media, but a recent review<sup>10</sup> found no evidence to support or refute this approach. Interestingly a review in 2013<sup>11</sup> reflected a major shift in opinion by the medical profession regarding the initial management of otitis media. The authors from an international otolaryngology organization stated that management should begin with watchful waiting. They recommended that herbal eardrops or homeopathic treatments may help decrease pain and even lead to faster resolution, and those that fail to improve with observation or CAM (after 48–72h) should be treated with antibiotics and, in some cases, surgical intervention. They go on to recommend a preventive strategy that includes elimination of risk factors such as second-hand smoke, and encouraging breast feeding and discouraging bottle-feeding, and maintaining proper nutrition and vaccinations. They also suggested that probiotics and xylitol may be helpful.

With acute otitis, it is generally accepted that antibiotics are warranted because of the bacterial etiology. If the otitis is in fact viral (recurrent otitis or otitis media with effusion), however, the approach is not clear. It is known that otitis media with effusion will self-resolve in six to eight weeks. However, when recurrent, it is often suggested to use drainage tubes (tympanostomy tubes). The evidence for their effectiveness has come under criticism. One study<sup>12</sup> indicated that more than half of these procedures were either inappropriate or had equivocal clinical indications. Clarification has come from recommendations for otitis media with effusion made by the Agency for Healthcare Research and Quality (AHRQ) guidelines of 1994.<sup>8</sup> If the child has no craniofacial or neurologic abnormalities or sensory deficits, the AHRQ panel recommends initial treatment to consist of observation or antibiotic treatment. The panel recommends against myringotomy with or without tympanostomy tubes. After three months, antibiotics or tubes are recommended in children with a

bilateral hearing deficit of 20-dB hearing threshold level or worse. One environmental influence that can be modified includes avoidance of exposure to cigarette smoking. There also appears to be an association with daycare facilities and bottle-feeding in infants. The panel also found that decongestants and/or antihistamines, corticosteroids, and tonsillectomy were ineffective treatments for otitis media with effusion.

There are many anecdotal reports of the benefits of chiropractic treatment. However, only one recent study<sup>13</sup> showed a benefit. This well-designed study used otoscopic and tympanographic data to evaluate the effectiveness of chiropractic adjusting on acute otitis, chronic serous otitis, and a mixed type. Preliminary results are encouraging. More research is needed.

The following are brief recommendations for ear pain based on condition.

## **Barotrauma**

- Swallow, yawn, and autoinflate often during a flight descent.
- Take decongestants several hours before arrival.
- Use nasal spray one hour before arrival.
- Do not sleep during the descent phase (leads to markedly negative pressure).
- Warn individuals who have tympanic membrane perforation that diving is not allowed because the unbalanced thermal stimulation may lead to vertigo.
- Advise individuals with normal hearing in only one ear to avoid diving because of the risk of otologic injury to the good ear.
- Caution patients with upper respiratory infections to avoid diving.

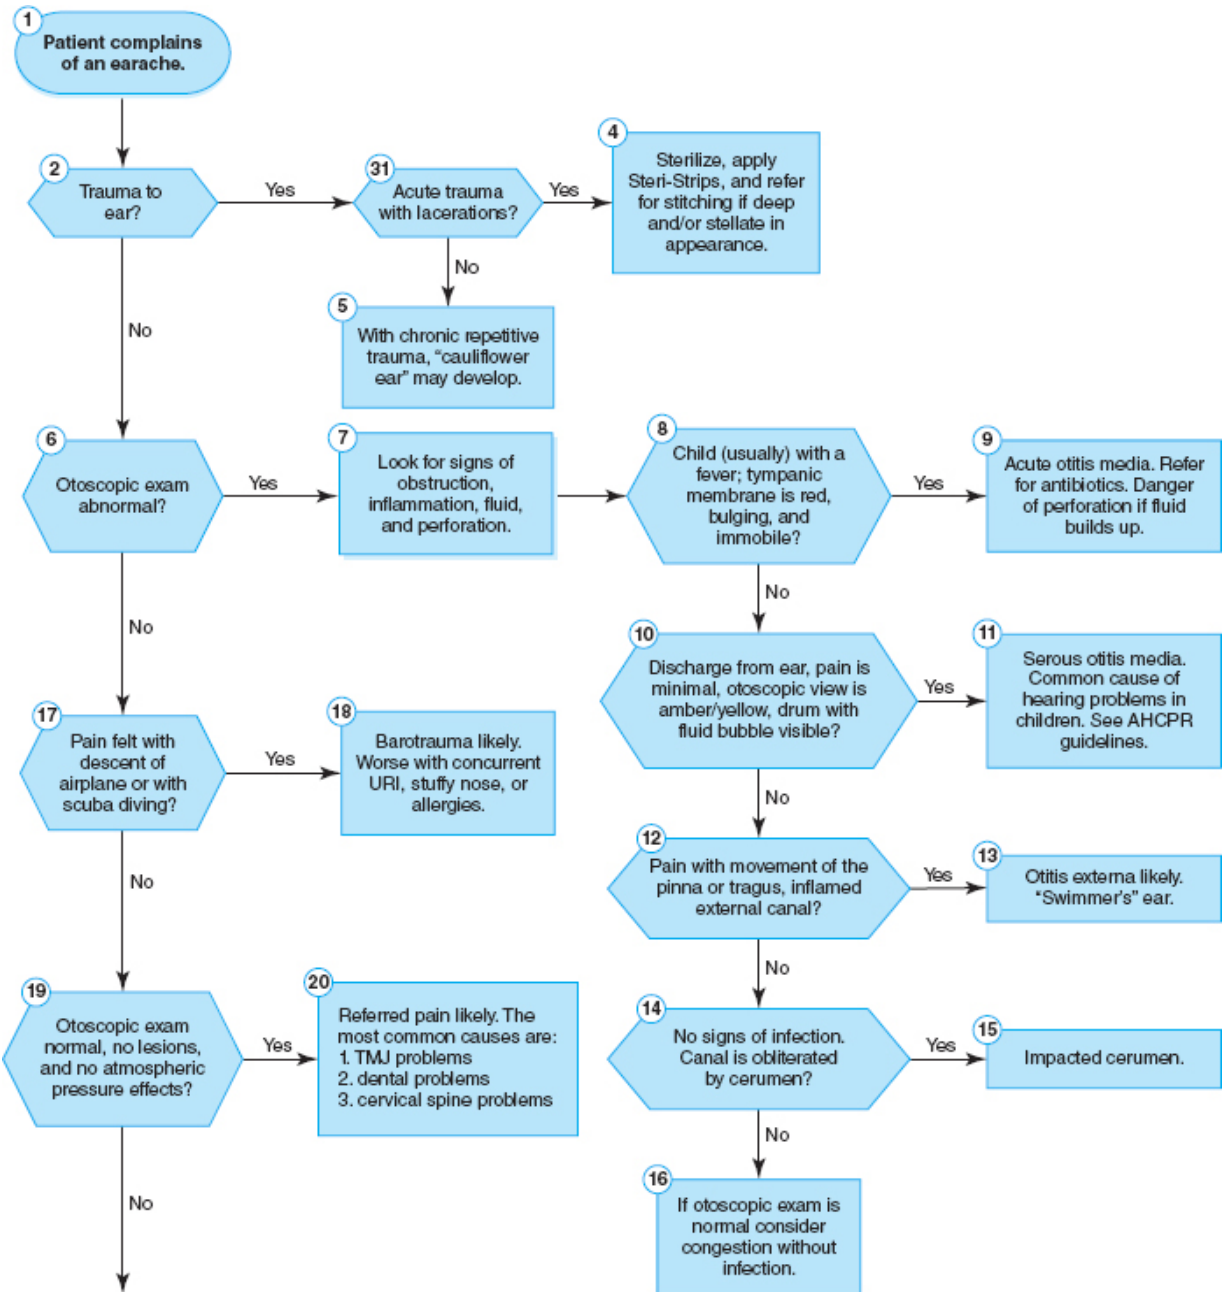

# Otitis Externa

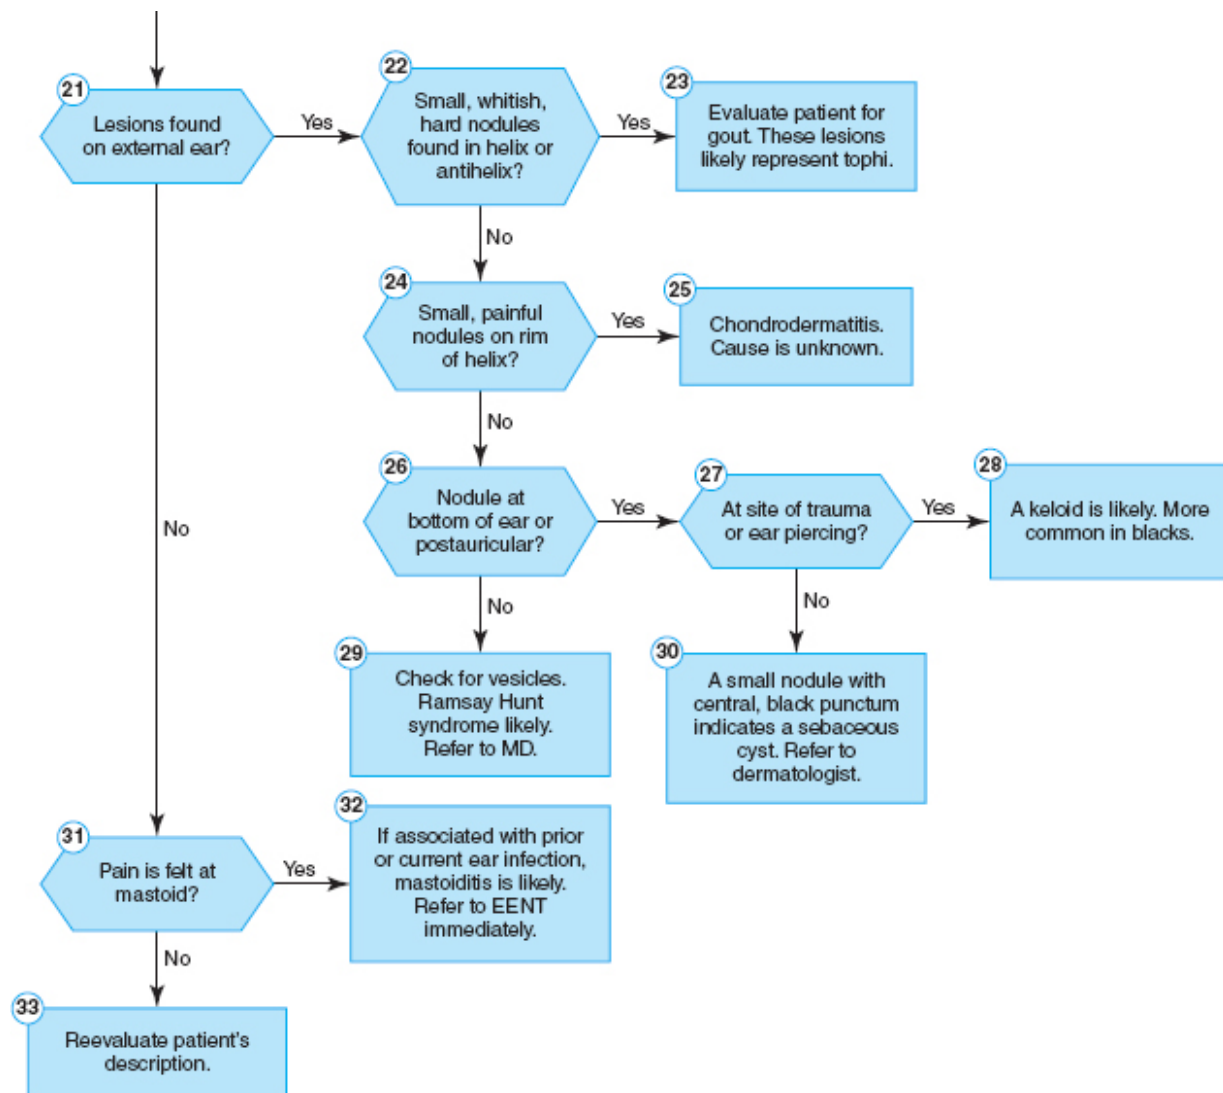

- Patients should be instructed to keep the ear dry, avoid overinsertion or cleaning with cotton swabs, and avoid scratching the ears.
- Patient should be warned not to swim in potentially contaminated water.

There is a belief among some chiropractors that otitis media is best managed conservatively with cervical spine manipulation and/or massage and diet recommendations. The effectiveness of chiropractic manipulation requires research. Articles by Hendricks and Larkin-Thier,<sup>14</sup> Hobbs and Rasmussen,<sup>15</sup> and Philips<sup>16</sup> review these concepts.

## Algorithm

An algorithm for evaluation and management of ear pain is presented in **Figure 44-1**.

**Figure 44-1** Ear Pain—Algorithm

# Selected Causes of Ear Pain

## Barotrauma

### Classic Presentation

The patient complains of severe ear pain on airplane descent. A sharp, stabbing pain in the ear may be felt. Another presentation is a patient who feels a similar sharp pain with underwater diving. The pain is usually felt within the first 15 ft of descent.

### Cause

The cause is failure of equalization of pressure in the middle ear by a narrowed eustachian tube. This is usually due to mucosal edema from an upper respiratory infection or allergy or from a congenitally narrowed tube. Vascular congestion, specifically venous congestion, may also occur but be more prolonged symptomatically.

### Evaluation

Otoscopic evaluation should be performed to determine whether there is any associated rupture of the tympanic membrane or otitis externa or media.

### Management

Suggestions to the airplane traveler are to use frequent yawning, swallowing, and autoinflating (forced exhalation against closed nostrils) during the descent. If unsuccessful, the use of a systemic decongestant several hours before descent and a nasal decongestant one hour before descent is usually successful. In recalcitrant cases, myringotomy or the insertion of ventilating tubes is necessary, or the avoidance of flying altogether. Serous otitis media may follow an episode of barotrauma.

### Serous Otitis Media

# Classic Presentation

A patient presents with a complaint of fullness for several weeks, and possible hearing loss or pain associated with past history of upper respiratory infection, an episode of acute otitis, or barotrauma.

## Cause

A persistently closed eustachian tube allows a negative pressure to develop in the middle ear, which then causes transudation of fluid into the middle ear space. This is more common in children because of a more horizontal canal, and in both adults and children because of infection, allergy, or barotrauma.

## Evaluation

Otoscopic evaluation will reveal a dull, hypomobile tympanic membrane. Occasionally, bubbles may be visible. Hearing loss, if present, is conductive.

## Management

Although a short course of corticosteroids or antibiotics is often prescribed, there appears to be little long-term benefit. Medical recommendations for tympanostomy tubes for the treatment of recurrent otitis have been questioned. It is estimated that the recommendations in more than half of cases are either inappropriate (23%) or based on equivocal indications (35%).<sup>12</sup> (The reader is directed elsewhere<sup>14-16</sup> for a discussion of chiropractic management.) In adults, persistent otitis media may be an indication of nasopharyngeal carcinoma.<sup>17</sup>

## Acute Otitis Media (AOM)

### Classic Presentation

The patient is often a child or infant (although adults are affected) with fever who complains of deep ear pain, a pressure sensation, and decreased hearing.

#### Cause

Potential risk factors for AOM include:

- Younger than 2 years old (eustachian tube is shorter and angled less)
- Male gender
- Daycare attendance
- Fall or winter season
- Exposure to cigarette smoke
- Genetic factors
- Prior history of AOM

Recurrence of AOM is common. A recent study<sup>18</sup> examined the contribution of a number of suspected factors and concluded that the use of pacifiers, less breastfeeding, infants of older age, the winter season, upper respiratory tract infections and adenoid hypertrophy all increase risk of recurrence. Exposure to secondhand smoke did not seem to be a factor in this study.

In primary care, AOM accounts for 30 million patient visits in the United States, costing an estimated \$5 billion annually.<sup>19</sup> Seemingly straightforward, the diagnosis of AOM is actually difficult. Some studies have indicated that 40% of the time doctors are uncertain of their diagnosis.<sup>20,21</sup> There are varying criteria, making the diagnosis even more ambiguous; however, the Agency for Healthcare Research and Quality (AHRQ) standard is probably the most accepted.<sup>22</sup> The criteria, in essence, states that in addition to signs of a middle ear effusion, there must be rapid onset (over 48 hours) plus an additional sign or signs including otalgia (pulling of ear in an infant), otorrhea, irritability (in infant or toddler), and/or fever. One study indicated that if these criteria were used, there would be a reduction in the diagnosis of AOM by more than 20%.<sup>23</sup> Co-infection with viruses is common, although in less than 10% of cases viruses are the only cause. Ironically, most ear infections resolve without any treatment, so the role of bacteria or viruses is unclear.

Acute otitis often represents the next stage after serous otitis with eustachian tube involvement. Viral infections and other causes of eustachian tube inflammation cause blockage and subsequent negative pressure development. Middle ear fluid resulting from a negative pressure provides a culture medium for bacteria. Also, migration of microorganisms along the eustachian tube mucosa may occur without blockage. Common organisms are *Moraxella catarrhalis*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Streptococcus pyogenes*. Episodes are more common in the fall, winter, and spring. More than 66% of children under age 3 years have at least one episode. There is mounting evidence that there is a strong genetic component to the length of time one has middle ear effusion and the number of episodes.<sup>24</sup>

## Evaluation

The patient will often have a fever. The tympanic membrane will appear erythematous and be hypomobile. Bullae may also be seen. When empyema occurs, the tympanic membrane may bulge, indicating impending perforation. The diagnostic value was measured in a meta-analysis in 2010.<sup>25</sup> For

tympanic membrane bulging there was a positive likelihood ratio of 51 (95% confidence interval { CI} , 36-73) and for redness a positive likelihood ratio of 8.4 (95% CI, 7-11). Mobility of the tympanic membrane is tested using the pneumatic attachment to the otoscope (bulb), sometimes referred to as insufflation. One study indicated that only 10 to 15 mm of pressure is needed to assess drum mobility and that most bulb attachments can generate up to 1,000 mm or more.<sup>26</sup> For children older than 18 months, a soft-tipped speculum should be used to provide an adequate seal. It is crucial that the otoscope is checked on a regular basis given the findings of one emergency department study indicating that 22% of the time there was a worn bulb or a weak battery.<sup>27</sup> A recent study evaluated the ability of the physician to diagnose AOM and found that, although many studies have been limited by bias, the most helpful indicator is a cloudy, bulging, immobile tympanic membrane.<sup>28</sup> An additional indicator is the color of the tympanic membrane: A normal color makes AOM highly unlikely, whereas a red membrane substantially increases the likelihood.

## Management

Referral for further evaluation and determination of the need for antibiotic treatment is warranted because of the seriousness of potential complications. However, it should be noted that in a 2010 *JAMA* review and meta-analysis,<sup>25</sup> the conclusion was that antibiotics are only modestly more effective than no treatment. They add that the concern about use is that antibiotics cause adverse effects in 4% to 10% of children. Although the introduction of a vaccine to prevent recurrent AOM occurred a number of years ago, the use of pneumococcal conjugate vaccine (PCV), in particular PCV7, is not recommended based on the conclusions of a 2009 Cochrane review.<sup>29</sup> Also, the use of this vaccine caused a decrease of *S. pneumonia* cases and an increase in *H. influenzae* cases. The concern by medical physicians, though, is that left untreated there may be complications that include labyrinthitis, meningitis, mastoiditis, hearing loss, and facial paralysis. One to several weeks of untreated or inadequately treated acute otitis can lead to these serious consequences. Clues of complication may include the development of a headache, sudden hearing loss, vertigo, or fever with chills.

## Chronic Otitis Media

### Classic Presentation

The patient presents with a history of recurrent acute ear infections. Currently, he or she complains of ear discharge that is worse with colds and swimming. There is little pain, but often a complaint of some hearing loss.

## Cause

Chronic infection of the middle ear and mastoid may lead to perforation of the tympanic membrane and degeneration of the tympanic membrane or ossicles. This results in a conductive hearing loss. Common organisms include *Pseudomonas aeruginosa*, *Proteus*, and *Staphylococcus aureus*.

## Evaluation

Otосcopy often reveals perforation of the tympanic membrane and discharge. Tests for hearing reveal a conductive hearing loss.

## Management

Initial treatment consists of antibiotic drops to the ears, systemic antipseudomonal antibiotics, removal of infected debris, and either avoidance of swimming or the use of ear plugs. Surgery eventually may be necessary to reconstruct the tympanic membrane.

## Cholesteatoma

## Classic Presentation

The patient presents similarly to the patient with chronic otitis media; however, the patient may have more dizziness or pain.

## Cause

With a chronic dysfunction of the eustachian tube, negative pressure pulls the upper tympanic membrane inward to form a sac, which can grow and become infected. If the cholesteatoma enlarges it may erode or compress the tympanic membrane, ossicles, or the mastoid.

## Evaluation

Otосcopic evaluation may reveal a retraction pocket and exudate. Hearing loss is conductive.

# Management

The treatment of choice is surgical removal and sometimes a surgically created connection between the ear canal and mastoid.

## Otitis Externa

# Classic Presentation

The patient is often a swimmer complaining of ear pain, itching, and discharge. The patient is more likely to present during warm, humid weather.

# Cause

Infection of the ear or ear canal is caused by exposure to infected water or is caused by scratching or overaggressive use of cotton applicators. The infection is usually due to bacteria such as *Pseudomonas* or *Proteus* or fungi such as *Aspergillus*. The fungal growth is assisted by excessive moisture in the ear.

# Evaluation

Pain is produced by pulling on the ear. The ear canal demonstrates erythema and edema, associated sometimes with a purulent discharge.

# Management

Referral for antibiotic drops is necessary. Additional preventive advice includes keeping the ear dry and avoiding cotton swabs or other mechanical trauma (e.g., pencils) in the ear canal.

# CHAPTER 45

## Hearing Loss

### Context

Hearing loss is a frightening occurrence, which, when sudden, would cause most patients to seek the attention of a medical doctor or emergency department. The acuteness and degree of loss would be steering factors that would influence a patient's decision to seek immediate attention. Mild to moderate loss, especially over time, or if assumed to be related to congestion from a respiratory infection, post-airline flight, or cerumen would allow most patients to adopt a "wait-and-see" attitude for at least several days. Another context is the patient who is not aware of the degree of loss because of the chronicity of the problem or he or she assumes that it is related to aging. The chiropractor is more likely to see these patients with chronic, mild loss or those unaware of loss. If a screening examination for hearing loss is conducted on patients complaining of loss and on the elderly, most cases can be discovered. Although some cases of hearing loss are nonrecoverable, sudden loss often spontaneously recovers over 7 to 10 days.<sup>1, 2</sup>

Although chiropractic was launched from an anecdotal reporting of hearing recovery, it is unfortunate that the literature is barren of any significant case reports or large studies. Nonetheless, there are still anecdotal reports, often given at seminars and among colleagues, warranting at least a consideration for study.

Hearing loss in the infant or child is most often due to congenital causes or acquired secondary to infection. In older adults, hearing loss is often age-related due to degeneration of hair cells in the organ of Corti. Following osteoarthritis and hypertension, hearing loss is the third most common chronic condition in seniors.<sup>3</sup> Estimates of prevalence are about 25% to 40% in patients 65 years and older.<sup>4</sup> After 75 years of age the prevalence increases to between 40% and 66%, and then to 80% after age 85 years. It is important to note that there is a strong correlation between hearing loss and depression in the older patient. Although hearing loss in the elderly is primarily due to presbycusis, up to 30% of the elderly have hearing loss secondary to cerumen impaction and chronic otitis media.

## **General Strategy**

## **History and Examination**

- Determine whether the hearing loss was sudden (trauma, viral, or vascular) or chronic/insidious.
- Determine if associated with dizziness.
- Determine whether there are any underlying systemic or whole-body processes such as diabetes, multiple sclerosis, or Paget's disease.
- Determine whether there was an associated event such as trauma or infection.
- Differentiate between conductive and sensorineural loss with simple tuning fork tests.
- Refer for audiologic or imaging studies when hearing loss is evident.

## **Management**

- Refer to otolaryngologist or neurologist when appropriate. Some examples include the following:
  1. ear infection or mastoid involvement
  2. suspected medication-induced hearing loss from prescribed ototoxic medication
  3. possible acoustic neuroma or other tumor
  4. perilymphatic fistula that is interfering with patient's lifestyle
- Refer for hearing aid if the following circumstances apply:
  1. patient has a diagnosis of presbycusis and hearing loss is interfering with lifestyle
  2. patient has had surgical correction for otosclerosis and now suffers some sensorineural loss
- Use a trial treatment with chiropractic manipulative therapy (CMT) when it appears that a complex of symptoms such as post-whiplash syndrome is apparent or when medical management offers no clear-cut solution.

## **Relevant Anatomy and Physiology**

Hearing is a remarkable sense that performs a transformation of mechanical vibration into electric potentials that are then processed and integrated into a composite impression of one's environment. The interface of this transformation is the fluid environment of the middle ear. The structural components of this system are the ear canal, the eardrum, and the bony ossicles. The efficiency of this impedance-matching system may be compromised, leading to a decrease in the perception of loudness but leaving the quality of the sound unaffected. This is referred to as a conduction hearing loss. Dampening of sound may

occur with blockage of the ear canal by cerumen or a foreign body, or by middle ear effusion. If the ossicles are sclerotic (otosclerosis) or damaged due to trauma/pathology, sound is not transmitted efficiently.

Pathology of the hair cells of the organ of Corti, the cochlear nerve, or in rarer cases, the central transmission of these sound signals will result in a sensorineural loss that is clinically represented by both a decrease in loudness and a distortion of sound quality.

Hearing is not only a function of loudness threshold and frequency perception; a patient's individual requirements (e.g., a musician), the ability to concentrate, environmental distraction, and central processing are also factors. The audible range of frequencies is between approximately 16 and 16,000 Hz, with the majority of speech limited to 300 to 3,000 Hz. The overtones that affect the quality of speech, however, are above 3,000 Hz. Loudness is measured in decibels (dB). This is a logarithmic scale, not linear. Therefore, a 20-dB tone carries 100 times the energy of a 1-dB tone; a 30-dB tone, 1,000 times that of a 1-dB tone. The threshold level is an important indicator of hearing loss. Normally, a whisper can be heard, indicating a hearing threshold of between 0 and 20 dB. Normal speaking is between 40 and 60 dB; a shout is 80 dB or above. A 10- to 15-dB threshold loss is often not noticed. Generally, a loss averaging between 20 and 25 dB between 300 and 3,000 Hz (speech frequencies) is noticed by the patient. A loss exceeding 30 to 40 dB is a significant handicap for conversation.

## Evaluation

## History

In obtaining the history (**Table 45-1**), determine the following:

- whether the patient has had a sudden or insidious loss and whether it is bilateral
- whether there has been any specific event onset such as past infection or trauma, including head trauma and barotrauma from scuba diving or airplane travel
- whether the patient has been prescribed any ototoxic medications
- whether there is past or current history of occupational or recreational noise exposure
- the extent of functional impact on patient's life (social and occupational)
- whether there are any previous diagnoses or treatment, including hearing aids or surgeries

Age of onset, acuteness of onset, and associated signs are extremely valuable in narrowing the diagnosis. Hearing deficits in an infant or young child should suggest congenital deafness or the sequelae to infection or ototoxic medication. Known ototoxic medications include:

- Antibiotics, including aminoglycosides, erythromycin, vancomycin
- Anticancer medications, including cisplatin, carboplatin, and vincristine sulfate
- Loop diuretics, including furosemide and ethacrynic acid
- Anti-inflammatory medications, including aspirin and quinine

Although the daily intake of aspirin that can cause hearing loss is not known, it is believed that 80 mg per day is safe. In most cases of aspirin-induced hearing loss, the patient will regain hearing after discontinuing aspirin. In one

study<sup>5</sup> evaluating almost 27,000 men for hearing loss related to analgesic use, researchers concluded that regular use of aspirin, NSAIDs, or acetaminophen increases the risk of hearing loss in men, with the highest risk group being those 50 years of age and younger. A similar association was found for women in a study<sup>6</sup> published in 2012; however, the researchers found no association with aspirin but there was an association with ibuprofen and acetaminophen. In all studies, the relationship is dose-dependent with those chronically taking these medications more than twice per week.

**Table 45-1** History of Questions for Hearing Loss

Primary Question	What Are You Thinking?	Secondary Question	What Are You Thinking?
Was the hearing loss sudden?	Trauma, vascular, or viral infection.	Was there an injury to the head? Was there trauma to the ear? Is there a recent history of coronary bypass surgery or a history of stroke or transient ischemic attacks? (If appropriate) Did the hearing loss resolve within 10 days?	Fracture of the temporal bone. Barotrauma to the tympanic membrane or a perilymphatic fistula. Vascular infarction of cochlear nerve (usually would involve other areas with other signs or symptoms). Viral infection likely.
Does the hearing loss fluctuate (come and go)?	Ménière's, recurrent otitis media, cerumen impaction, eustachian tube dysfunction.	Hearing loss associated with recurrent bouts of dizziness? Recurrent ear infections? History of allergies and/or extreme pain with airplane descent, bilateral?	Ménière's disease is likely. Chronic otitis media. Auditory tube dysfunction.
Is the hearing loss chronic?	Presbycusis, otosclerosis, congenital acoustic neuroma, ototoxicity, noise pollution.	Is it difficult to hear on the phone? No problem in noisy rooms? (With an older patient) Difficulty carrying on a conversation in crowded rooms or understanding women's voices or those with accents? Are you taking high doses of aspirin or other "pain killers," chemotherapy, or antibiotics (aminoglycosides)? Do you or have you worked with loud power tools or in a loud machinery environment?	Otosclerosis is likely. Presbycusis is likely. Ototoxicity is likely. Sensorineural loss due to hair cell trauma (organ of Corti).

Insidious onset in the middle-aged patient is suggestive of otosclerosis. In the elderly patient, various forms of presbycusis are the first suspicion. When sudden and

associated with signs of infection, transient benign processes that are viral are suggested. When the hearing loss is more profound and permanent, a bacterial etiology is more likely. Accumulated otologic trauma from environmental noise should be sought in the middle-aged and elderly. Common sources are loud machinery and loud music (concerts or headphones). Hearing loss may be a complication of many disorders; especially noted are collagen vascular diseases, vasculitis, multiple sclerosis, osteogenesis imperfecta, and compression from Paget's disease.

Conductive hearing loss generally does not interfere with speech discrimination. The patient even may be able to hear better in noisy environments. This is due to the blockage of low-frequency sounds. This phenomenon is analogous to wearing earplugs, when the general loudness is attenuated, but the distinctness of the sound may be increased because of the blockage of other frequencies. The patient with a sensorineural deficit usually will have difficulty with speech discrimination. Patients often note that women's voices and British accents pose more of a problem. They especially find it difficult to screen out ambient noise in a noisy environment. Their hearing loss is generally in the higher ranges, whereas most environmental noise is low frequency, the range they hear best.

Sudden loss with accompanying vertigo is suggestive of labyrinthine etiology. If the attacks are recurrent with progressive hearing loss, Ménière's disease is suspected. If the vertigo gradually improves over several weeks, bacterial labyrinthitis is most likely.

## **Examination**

- Examine the ear for signs of lesions, cerumen impaction, or infection.

- Screen with tuning fork tests, including Weber and Rinne tests.
- Use an otoscope/audiometer combination, if available, to screen for loss within speech frequency ranges.
- Refer for audiologic testing if a deficit is found.

Examination of the ear with an otoscope focuses on a search for signs of impacted cerumen, otitis media, vesicles (Ramsay Hunt syndrome), cotton swab injury, cholesteatoma, and any other obvious pathology. Patients who express a concern about hearing loss or patients with findings of hearing loss on either the whispered-voice test or audioscope test should be sent for further audiologic testing. A literature review by Bagai et al.<sup>7</sup> on the accuracy and precision of the clinical examination for hearing loss indicates that the best screening test for hearing loss for the elderly patient is the whispered-voice test. In-office audiologic testing with an audioscope may be performed as an alternative to the whispered-voice test or as an additional test to objectify findings of the whispered-voice test. The reviewers conclude that the Rinne and Weber tests should not be used for screening for hearing loss, and in fact these tests are designed only to discriminate between sensorineural versus conductive hearing loss.

The whispered-voice test is prefaced by explaining to the patient how the test will be performed. Standing behind the patient (out of patient's field of vision) the examiner gently occludes and rubs the external auditory canal of the nontested ear while whispering three letters and three numbers in no perceivable sequence. The patient is then instructed to repeat the letters and numbers heard. A pretest screen can be performed by repeating "99" loudly to determine if the patient understands and is able to repeat.

Type of hearing loss may be tested with two tuning fork tests, Weber and Rinne, to attempt to differentiate between conductive and sensorineural loss. Recommended are 512-

Hz and 1,024-Hz tuning forks. The Weber test is performed several ways. The vibrating tuning fork is applied to the middle forehead, glabella, or middle incisors (some authors have the patient bite on the vibrating handle). With a conduction loss, the sound is heard more loudly in the affected ear. It is heard equally in both ears with normal patients and in patients with bilateral sensorineural loss (e.g., presbycusis). A conductive loss of only 5 dB will cause sound to localize to the “bad” ear.

The Rinne test evaluates bone versus air conduction. The vibrating tuning fork is applied to the patient’s mastoid. The patient is instructed to indicate when the sound disappears. At this point the examiner places the tines of the tuning fork approximately 1 cm from the patient’s ear. The sound should now be audible for about twice as long as when applied to the mastoid (bone). Air conduction is usually twice as long as bone conduction. Masking of the opposite ear with a noise box or any other external sound source such as compressed air or suction may help. A conductive loss of at least 20 dB is necessary to cause a negative response; sound is not longer with air conduction. Therefore, less severe hearing loss is not detectable with the Rinne test.

An in-office audiologic evaluation may be performed with an otoscope containing a built-in audiometer. Audioscopes produce pure tones at 500, 1,000, 2,000, and 4,000 Hz at 20, 25, and 40 dB. The patient is instructed to identify a test tone at the lowest decibel level of 20 dB. If not audible, a second test at 25 dB, and a third, if necessary at 40 dB, is used to determine the patient’s threshold. When the threshold is identified, a start button sequences the instrument through the various frequencies in apparent random order. The patient is instructed to raise a finger each time he or she hears a tone. Missing even one tone warrants referral to an audiologist for further evaluation. A normal test is good at ruling out loss of hearing in the

frequencies of speech. However, if a deficit is detected, it may be a false positive. The sensitivity for detecting hearing loss is 94%. Interestingly, the specificity is 72% in a standard physician's office and 90% in an audiologist's office.<sup>8</sup>

Through the use of an audioscope and a self-administered questionnaire, the Hearing Handicap Inventory for the Elderly Screening Version (HHIE-S), older patients can be reliably screened for hearing loss.<sup>9</sup> The HHIE-S is a ten-item, five-minute questionnaire that focuses on the degree of social and emotional handicap created by hearing loss.<sup>10</sup> A hearing handicap of >8 on the HHIE-S is relatively sensitive for a hearing loss of 40 dB. More serious hearing loss does not seem to change the scoring. If no hearing handicap is detected on the HHIE-S, there is only a marginally decreased probability of hearing impairment (not good for ruling out hearing loss). The ten questions are:

- 1.** Does a hearing problem cause you to feel embarrassed when meeting new people?
- 2.** Does a hearing problem cause you to feel frustrated when talking to members of your family?
- 3.** Do you have difficulty hearing when someone speaks in a whisper?
- 4.** Do you feel handicapped by a hearing problem?
- 5.** Does a hearing problem cause you difficulty when visiting friends, relatives, or neighbors?
- 6.** Does a hearing problem cause you to attend religious services less often than you would like?
- 7.** Does a hearing problem cause you to have arguments with family members?
- 8.** Does a hearing problem cause you difficulty when listening to TV or radio?
- 9.** Do you feel that any difficulty with your hearing limits or hampers your personal or social life?

**10.** Does a hearing problem cause you difficulty when in a restaurant with relatives or friends?

The patient is instructed to answer yes (4 points), sometimes (2 points), or no (0 points) to each question. Scores may range from 0 (no handicap) to a maximum of 40. General use delineates probability of impairment through the following categorization:

- 0-8 = 13% probability
- 10-24 = 50% probability
- 26-40 = 84% probability

Audiologist referral is helpful when a hearing loss has been detected or in the case of infants and others unable to communicate effectively.

Referral to an audiologist results in a standard series of tests performed in a soundproofed environment. These tests include:

- Pure-tone audiometry: assesses the patient's threshold of hearing for low frequency (250 Hz) and high frequency (8 kHz)
- Word recognition testing: determines the percentage of monosyllabic words that a patient can recognize/repeat (speech discrimination score)
- Speech reception threshold measurement: measures the lowest decibel level at which a patient can repeat at least 50% of spondaic words (i.e., 2-syllable words that have equal emphasis on each syllable, such as baseball)
- Bone-conduction testing: tests for otosclerosis, acoustic reflexes for acoustic neuromas, and tympanometry for otitis media

Loss of speech discrimination ability is highly suggestive of a central cause of hearing loss. Additional testing to differentiate between central and peripheral causes of hearing loss consist of the following:

- Small-tone increment discrimination—Small differences in frequency are appreciated with more sensitivity with a peripheral cause than in the normal ear.
- Tone decay—When a tone is played over earphones, the tone appears to diminish in intensity when, in fact, it remains the same; this occurs with a central cause.
- Recruitment—Loud sounds are heard normally. This occurs with a peripheral cause.

Further testing not requiring a patient response is the brainstem auditory-evoked potential (BAEP). Surface electrodes are placed over the scalp and ears. A high-frequency click at a fixed rate and intensity is delivered and the electrical responses are measured. Seven short-latency waves can be measured within 10 milliseconds of the click. The latency of response may be used to localize the lesion site. For acoustic neuroma the true-positive rate is high at 98% (false-positive about 1%).

## Management

- If there is a buildup of cerumen, suggest over-the-counter ear wax dissolvers; if ineffective, refer to primary care physician for ear lavage.
- If an acoustic neuroma, tumor, infection, or systemic process is suspected as the cause, refer to appropriate specialist for management.
- For those patients with persistent chronic otitis media, surgical management may include myringotomy (a small incision in the tympanic membrane) and tubes

placed in the ear to normalize pressure by aspirating contents and aerating the middle ear. This will usually restore hearing immediately. Otolaryngologists should determine any underlying condition that might cause eustachian tube obstruction, such as allergic disease and nasopharyngeal carcinoma.

- There are varying degrees of tympanic membrane perforations. Small perforations, usually due to either trauma or otitis media, may heal spontaneously whereas larger perforations may require surgical repair with a fascial graft (tympanoplasty).
- Another conductive hearing problem, ossicular chain discontinuities, may result from trauma or chronic, persistent ear infections. Surgical treatment includes reconstruction of the ossicular chain using implants or transposed ossicles.
- Cholesteatomas are cystic masses that form usually secondary to chronic ear infections. This mass may be limited to the middle or extend to the mastoid cavity. Otoscopic signs include superior and posterior tympanic membrane perforation and white keratinaceous debris. Although there is no medical treatment, surgical management may be suggested. The standard is a mastoidectomy to remove the cholesteatoma.
- Treatment may be warranted when there are associated signs of headache, dizziness, and neck pain post-whiplash (assuming more serious causes have been ruled out).
- Comanagement with an audiologist is appropriate when hearing loss is affecting lifestyle, all serious causes have been ruled out, and the patient is likely to have presbycusis.

Management will vary depending on scope of practice restrictions and interest. Referral is often necessary.

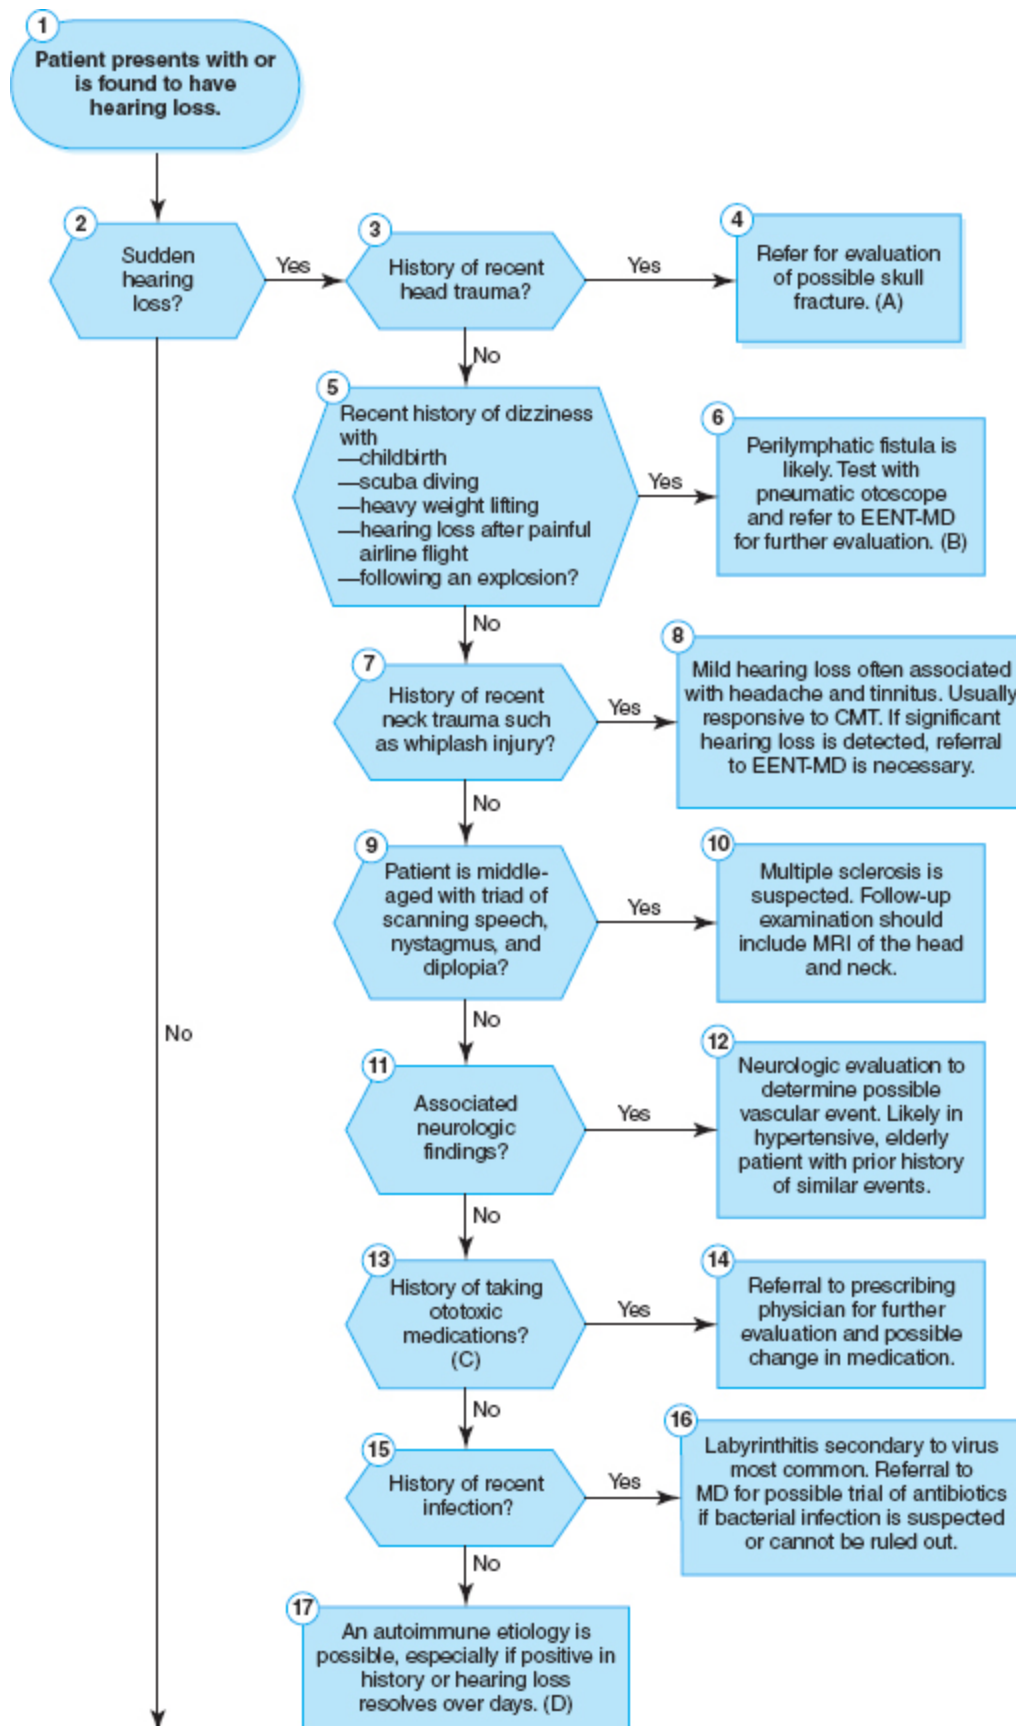

However, if the hearing loss is either the result of cerumen impaction or a transient phenomenon from a whiplash injury with concomitant headache, dizziness, and/or neck pain, the chiropractor may be helpful.

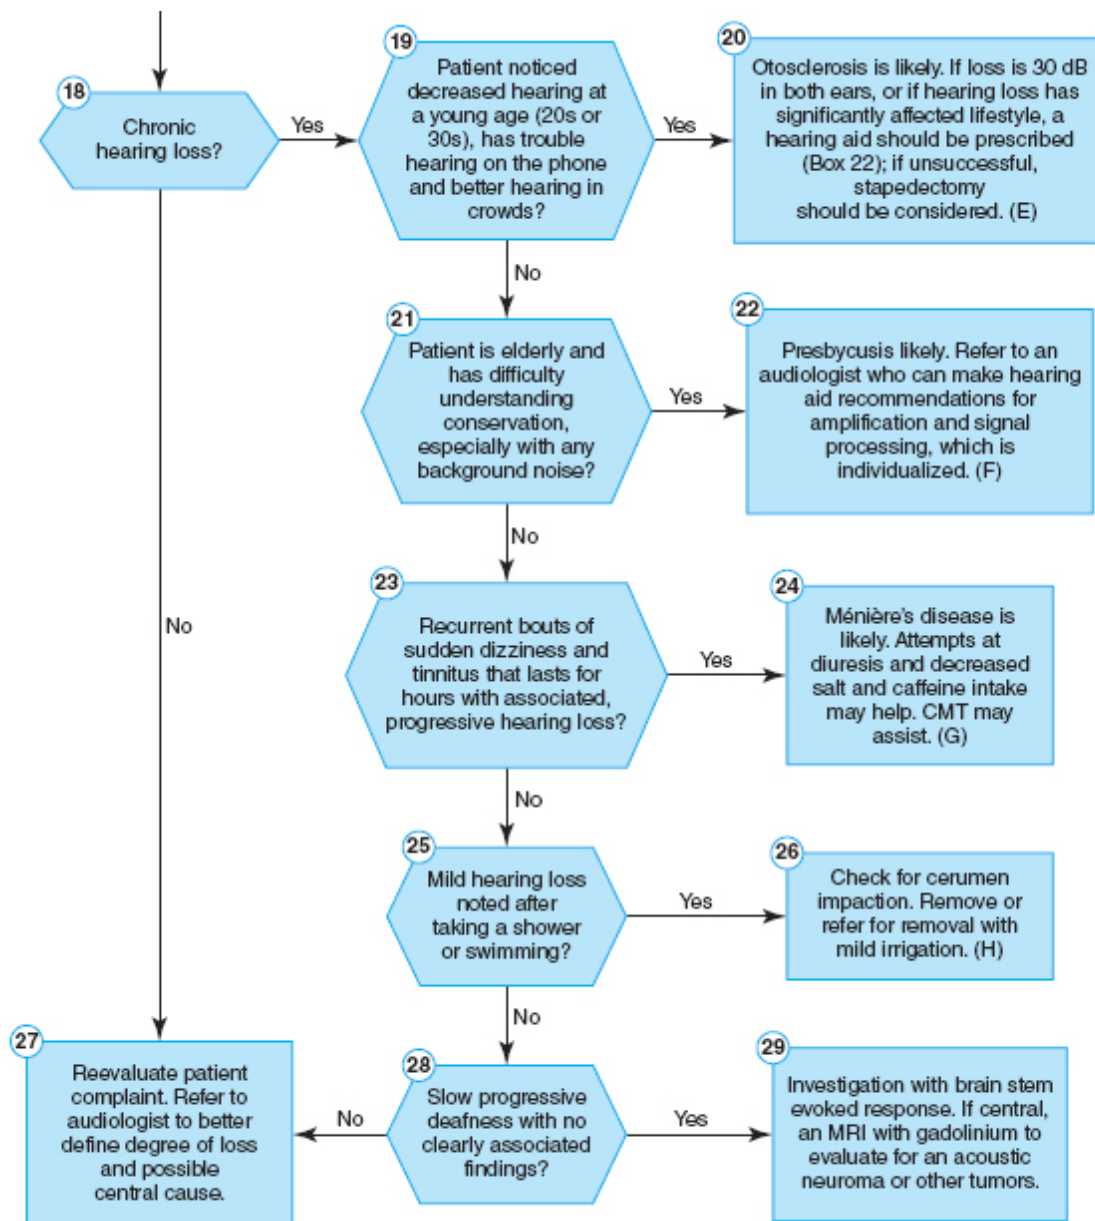

For pediatric hearing loss, dependent on cause, cochlear implants are now in common use. As of 2013, more than 300,000 cochlear implant surgeries have been performed.<sup>11</sup> Pioneered in the 1960s, major break-throughs occurred in the 1990s so that currently mainstream schooling is the norm, reducing the number of “deaf schools.” These implants are worn at ear level and consist of an implanted element that contains a receiver and electronic array that are placed within the cochlea. External components include a microphone, a speech processor, and a transmitter coil. Bilateral devices are now being utilized so that sound localization and hearing in noisy environments are improved. Cochlear implants are not perfect. They do not restore normal hearing and their function is limited by ambient noise. Music perception is also limited although these limitations are currently being researched for viable improvements.

With presbycusis, comanagement with an audiologist for prescription of a hearing aid is appropriate. For those who do not benefit from standard hearing aids, implantable hearing aids are now available. Although speech recognition and quality of life were greater with the implants, one study<sup>12</sup> found that two devices, the Esteem and the Carina, had problems including taste disturbance and device failure.

## Algorithm

An algorithm for evaluation and management of hearing loss is presented in **Figure 45-1**.

#### Annotations

- A. Hearing loss subsequent to fracture is usually due to a transverse fracture of the temporal bone.
- B. A perilymphatic fistula is a defect in the round or oval window that allows communication between the inner and middle ear. Surgery is often necessary.
- C. Some common ototoxic drugs include salicylates, aminoglycosides, loop diuretics, and some anticancer medications.
- D. A short course of corticosteroids is often used with acute hearing loss.
- E. Otosclerosis is a progressive, conductive hearing loss disorder characterized by sclerosis of the bony capsule and ear ossicles, leading to a conductive hearing loss.
- F. Presbycusis is a progressive sensory hearing loss that is age related. There is a selective deterioration of high-frequency hearing with an associated loss of hair cells of the organ of Corti.
- G. Ménière's is a disease characterized by an increase in endolymphatic fluid pressure. There is a selective loss of low frequencies early in the course of the disease.
- H. Cerumen (wax) absorbs water and expands, causing a conductive hearing loss. With swimmers check for otitis externa (swimmer's ear); often in need of antibiotic drops.

**Figure 45-1** Hearing Loss—Algorithm

# Selected Causes of Hearing Loss\*

## Otosclerosis

### Classic Presentation

A patient in his or her 20s or 30s presents with a complaint of difficulty hearing on the telephone. He or she notices that there is no difficulty hearing a conversation in a noisy room or environment. The patient may note a similar history in a parent. The difficulty hearing is usually bilateral.

### Cause

The cause is unknown; however, there is a familial tendency with onset occurring in the late teenage years to the 30s. There is a progressive sclerosis of the bony capsule and ear ossicles with a consequent decreased mechanical transmission of sound, producing a conductive hearing loss. The stapes is often the first bone to be affected, with the foot plate being fixed to the oval window. However, if the lesions are large enough to compress the cochlea, a sensory hearing loss will occur that is often permanent. Some practitioners feel that otosclerosis is caused by an inflammatory reaction to the measles virus.<sup>13</sup>

### Examination

Evaluate for other causes of obstruction such as cerumen or exostoses/osteomas, which may block the ear canal. With the Rinne test, bone conduction is louder and longer than air conduction. The Weber test will localize to the involved ear if unilateral. Referral for audiologic testing is important.

### Treatment

Although 10% of the white population has some degree of otosclerosis, only a small percentage develop appreciable hearing loss. Those who do may benefit from microsurgical techniques. Stapedectomy or stapedostomy are

usually performed if the patient has significant hearing impairment. Others decide to live with the problem.

## **Presbycusis**

### **Classic Presentation**

An elderly patient presents with a complaint of hearing difficulty. He or she may notice that hearing is worse in noisy environments such as crowded rooms. Other complaints may be difficulty hearing women's voices or people with British or other accents. There may also be an associated increase in tinnitus.

### **Cause**

It is believed that there is damage to the hair cells of the organ of Corti, producing a selective high-tone frequency hearing loss, usually bilateral. The contribution of noise trauma to presbycusis varies among individuals. It is particularly hard to hear consonants.

### **Evaluation**

Standard Rinne and Weber testing may demonstrate a conductive hearing loss if there is cerumen or a middle ear effusion. However, the hearing loss from presbycusis is a sensorineural loss. Referral for audiologic testing is warranted if the hearing loss is a concern.

### **Management**

There are numerous types of hearing aids available. With newer technology, some of the previous complaints have been decreased or eliminated. It is important that the patient work with the audiologist to develop a strategy for determining the degree of amplification and signal processing needed. New programmable devices allow for more sound filtering and can be set for different environmental scenarios.<sup>14</sup>

Although most patients with sensorineural hearing loss live with the dysfunction or use a hearing aid, those who are profoundly affected (> 80 dB loss on the better ear) may benefit from cochlear implants. Although implants have been used primarily in the pediatric population, it appears that they are a reasonable and successful option for those patients with severe hearing loss.

## Acoustic Neuroma

### Classic Presentation

A patient in their 50s or 60s presents with a complaint of mild but constant hearing loss and dizziness sometimes with associated tinnitus. The onset is gradual and may be ignored initially. There are rarely acute attacks.

### Cause

A benign schwannoma of the vestibular nerve is called an acoustic neuroma. It is located in the cerebellopontine angle, where other cranial nerves are susceptible to compression. Most commonly this involves the facial nerve. As the tumor grows it may cause brainstem compression. Ninety-five percent of the time these are unilateral (bilateral may occur with neurofibromatosis). Risk factors may be smoking, pregnancy, and epilepsy.

### Evaluation

Unless the tumor is large and pressing on other cranial nerves, there are likely to be no additional clinical findings. Auditory testing may reveal poor speech discrimination. Hearing loss is sensorineural. Stacked auditory brainstem response (ABR) is 95% sensitive and 88% specific for lesions < 1 cm (standard ABR only for lesions > 1 cm). When the suspicion is high, an MRI should be ordered. It is the definitive diagnostic tool.

### Management

Age and growth rate need to be considered prior to a decision for surgical excision. Growth is about 5 mm in the first year of detection but less than 1 mm in the fourth year following detection.<sup>15</sup> Fifty-seven percent of neuromas shrink and 70% of extracanalicular lesions grow less than 2 cm per year.<sup>16,17</sup> Preservation of hearing is better with conservative management than with radiotherapy or surgery. A distinguishing factor is speech discrimination. Sixty-nine percent of patients with 100% speech discrimination on initial detection maintain their hearing 10 years after detection.<sup>18</sup> Options that are nonconservative include gamma-knife single-dose stereotactic surgery and three standard surgical approaches including retromastoid/retrosigmoid, middle cranial fossa, and translabyrinthine that use microscopic approaches.

# CHAPTER 46

## Tinnitus

### Context

Tinnitus is a relatively common symptom, with approximately 6.4% of the population affected.<sup>1</sup> Although the most common presentation is a patient who complains of “ringing” in the ears, there are numerous sounds that a patient may complain of that fit under the umbrella term *tinnitus*. These include clicking, rushing, echoing, fluttering, and hissing. Ringing in the ears is a ubiquitous symptom and is unavoidable, yet the question for the chiropractor is whether it is temporary or permanent, and whether there are any clear clues as to its cause. Additionally, distinguishing among the other sounds the patient may be hearing may lead to an identifiable vascular, toxic, cochlear, small muscle spasm, or cervicogenic etiology.

Tinnitus may be categorized by some simple differentiations. First, is the tinnitus localized to an ear or ears or is it more central and diffuse? *Tinnitus cerebri* is the term used for the latter and may represent organic pathology. Therefore, referral for medical evaluation is appropriate. The localization to one or both ears is called tinnitus aurium and is further divided into subjective and objective. Are the patient’s hearing sounds appreciable only by him or her or are they sounds that are audible to the examiner? Subjective tinnitus is audible only to the patient and is probably the most common (99% of patients), yet the

most difficult type to identify as to cause. Objective tinnitus may sometimes be appreciated by the examiner and usually represents various vascular sounds.

## **General Strategy**

- Have the patient describe what he or she is hearing.
- Determine whether the patient hears the sounds in the ears or as central or diffuse sounds in the head.
- Determine whether the patient has associated hearing loss or vertigo.
- Determine whether the patient is taking salicylates or indomethacin.
- Determine whether the patient is taking any ototoxic medications such as aminoglycoside antibiotics.
- Determine whether the patient has been exposed to environmental noise such as machinery, loud music, or earphones.
- Determine whether the patient has been diagnosed with any endocrine, vascular, neurologic, or otologic diseases.
- Determine whether the patient experienced trauma to the head or ear.

## **Relevant Anatomy and Physiology**

Although the ear is designed to monitor the external environment, it is capable of perceiving internal “noise,” especially when the outside environment is muted or eliminated. Most objective tinnitus is due to this phenomenon and requires a search for the internal sound source. Most of these sounds are the result of vascular

turbulence or small muscle spasm in close proximity to the ear.

Subjective tinnitus of neural origin is extremely difficult to explain and to cure. Although it would seem logical to assume that part of the labyrinth system or the neural connections to the cortex are damaged, labyrinthectomy or cochlear division may still leave a patient with subjective tinnitus.<sup>2</sup> This phantom aural sensation has no known anatomic or physiologic substrate. Theoretically, the auditory epithelium, basilar membrane, or endolymph may be damaged or altered in a way to send a continuous stream of mechanical stimulus, which is interpreted as a high-frequency background hiss, yet this has not been demonstrated. This is, in fact, the theory behind excessive loud noise exposure, when the basilar membrane is forced to vibrate continuously beyond its normal amplitude.<sup>3</sup> The result is that there is a spontaneous discharge in the high-frequency range. It is known that patients who develop hearing loss often have accompanying tinnitus. Other theories focus on a decrease in vertebral artery blood flow<sup>4</sup> and, most recently, a proposed deficiency or dysfunction of serotonin.<sup>5</sup> It is known that serotonin acts as a sensory “suppressor,” preventing hypersensitivity to light and sound.

Although a sympathetic nervous system dysfunction with consequent vertebral blood flow reduction has seemed attractive, the findings of Bogduk et al.<sup>6</sup> significantly decrease this possibility as a consideration. A spinal connection to tinnitus may be the relationship of the trigeminal nerve to the ear and the upper cervical spinal segments.

## Evaluation

# History

Subjective tinnitus is by far the most common type. When related to systemic causes such as medications or the aging process, it is often continuous, high-pitched, and bilateral. Questioning with regard to medication is helpful when the latter description is a relatively recent phenomenon. When long-standing, otosclerosis or presbycusis should be suspected, especially when associated with bilateral hearing loss. Unilateral tinnitus with associated hearing loss and recurrent vertigo should suggest Ménière's disease or multiple sclerosis. When unilateral, continuous, and associated with hearing loss, an acoustic neuroma is more likely.

There are some characteristic descriptions that may identify the underlying cause when objective tinnitus is suspected, as follows:

- pulsating or rushing—vascular (cardiac murmurs, bruits, arteriovenous malformations [AVM], glomus tumors)
- humming—venous (cervical venous hum)
- low-pitched clicking or fluttering—muscular spasm (stapedius, tensor tympani, or tensor palati)

## Examination

Physical examination of the patient with tinnitus centers on the ear and auscultation for a vascular etiology. It is likely that the examination will reveal few if any clues as to the patient's complaint, yet an attempt is made to determine whether secondary causes or primary ear pathology may be contributing. When the patient complains of local ear pain, vertigo, or hearing loss, a thorough investigation of the ear

should be performed, including standard Rinne and Weber hearing tests and a search for the following:

- cerumen impaction
- otitis media
- otosclerosis

Physical examination for the source of objective tinnitus centers on auscultation for the following:

- orbital, cranial, or carotid bruits
- cardiac murmurs
- venous hum

By connecting the tubing of one stethoscope to another, the doctor can hear what the patient hears if the cause is objective. Additional examination procedures include evaluating the palate for spasm and checking the temporomandibular joint for clicking or popping. A pulsatile type of tinnitus relieved by pressure on the jugular vein confirms a venous hum.

## Management

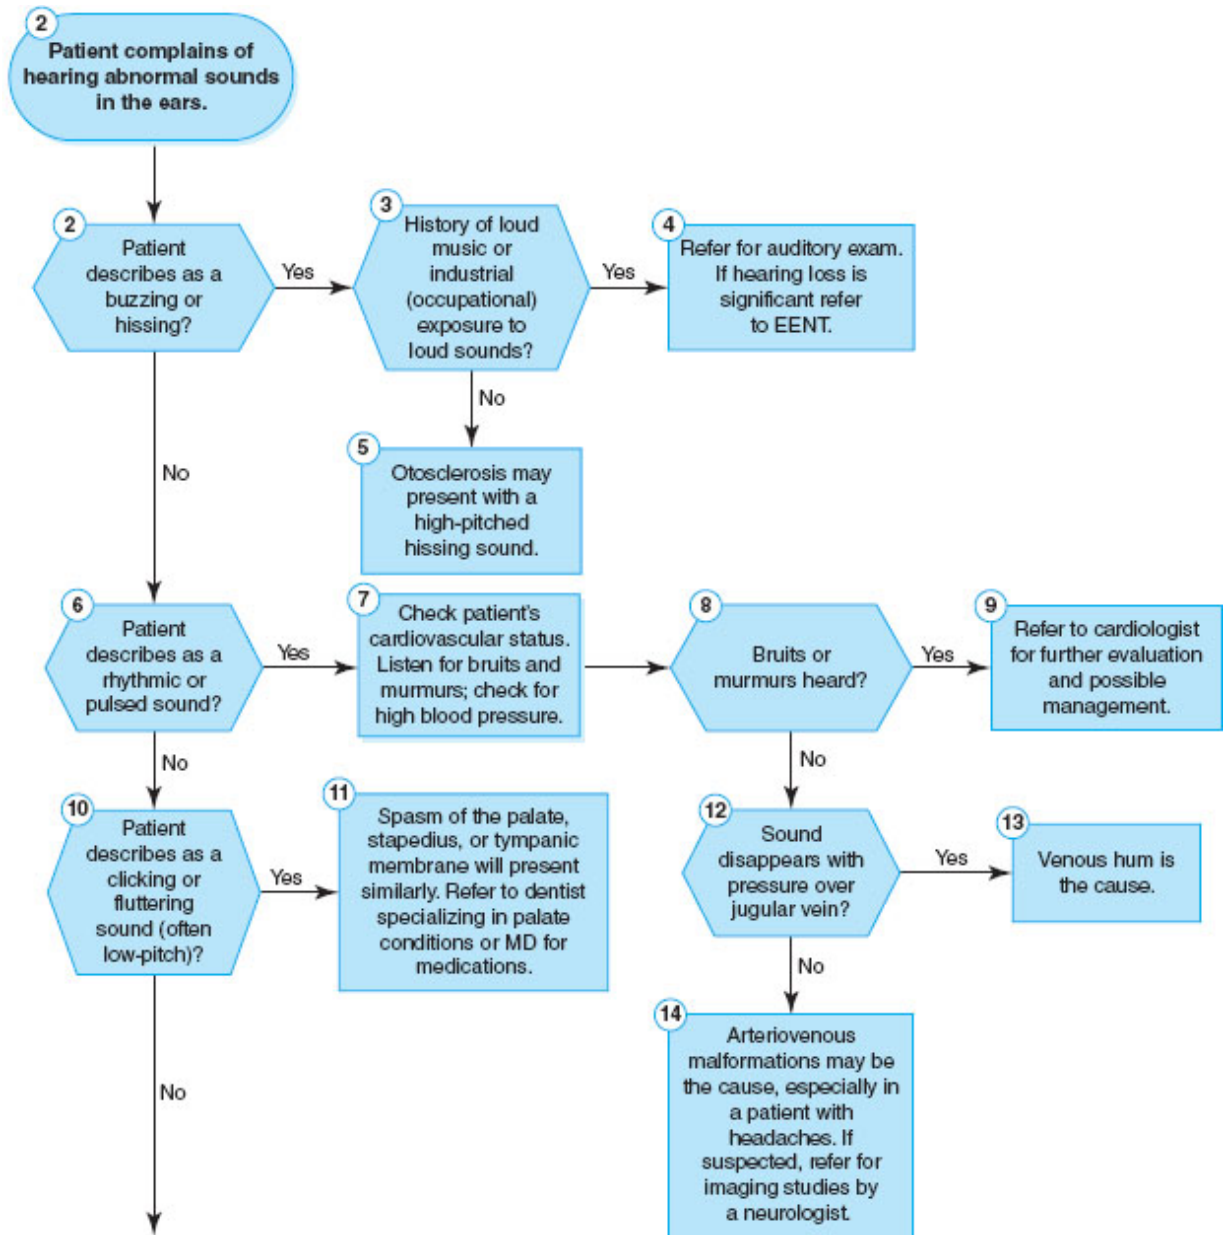

When other auditory and other sensory stimuli are reduced, the tinnitus may be unbearable for some patients. These patients often attempt sensory distraction by leaving the radio or television on when trying to sleep. Other solutions include biofeedback, which appears to have a relatively good initial response rate, and the use of a tinnitus masker (worn like a hearing aid).<sup>7</sup> Patients with hearing loss often find that the tinnitus improves with the use of a hearing aid. If the tinnitus is post-whiplash (acceleration/deceleration injury to the neck) or associated with other indicators of

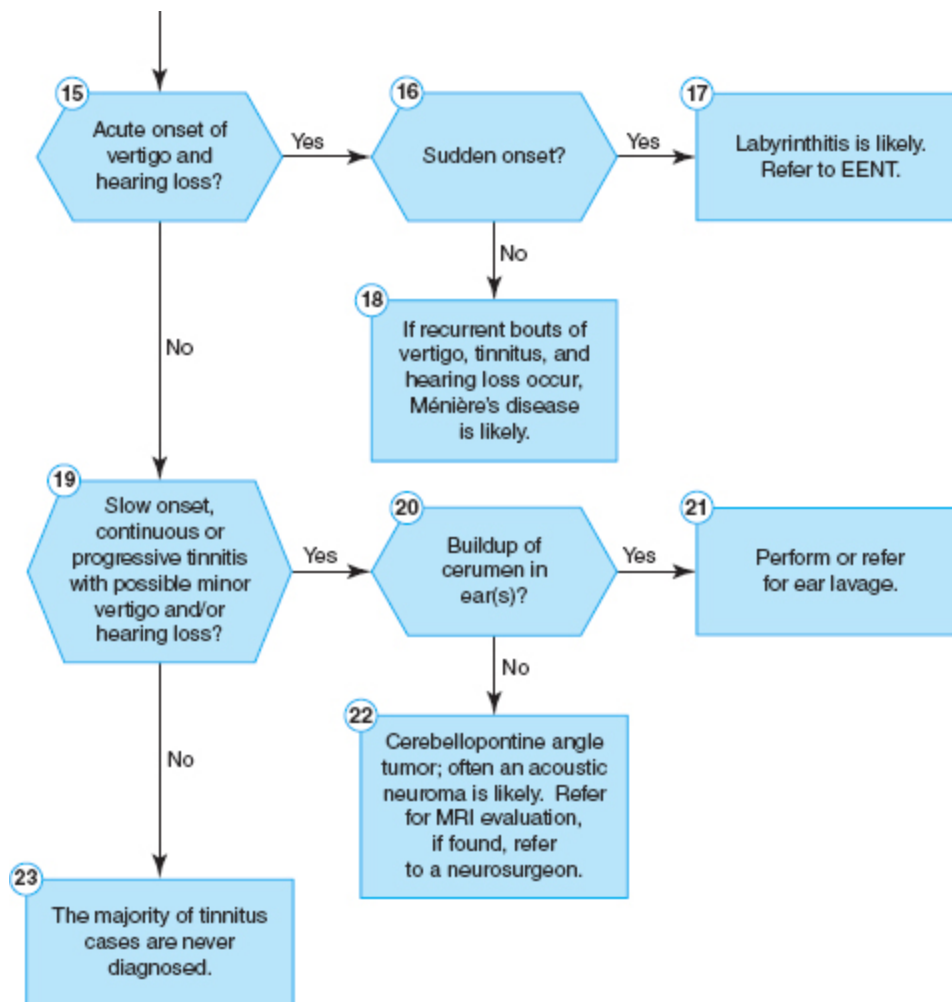

vertebrogenic vertigo, chiropractic manipulative treatment may be helpful in resolving the complaint.<sup>8</sup>

Although a number of drugs are used in the treatment of tinnitus, there is little consistent evidence of success. Patients with intractable tinnitus often undergo surgical procedures. When the tinnitus is associated with vertigo or hearing loss, surgery may be helpful.<sup>9</sup> Cochlear nerve section is used for those with isolated or intractable tinnitus, with the obvious trade-off of permanent hearing loss.<sup>2</sup> However, for some patients who are so disabled that suicide is considered, this surgery may be an attractive alternative.

## Algorithm

An algorithm for evaluation and management of tinnitus is presented in **Figure 46-1**.

## CHAPTER 47

# Epistaxis (Nosebleed)

## Context

Nasal bleeding (epistaxis) is a common, usually benign, phenomenon that warrants little concern. Occasionally, however, patients seek help when bleeding is severe and uncontrollable or when it is recurrent. Approximately 25% of the time, epistaxis cannot be tied to a specific etiology.<sup>1</sup> Most benign causes are easily identifiable, often due to drying, irritation, or inflammation of the vessel-rich nasal mucosa. These are probably more often seen in children, in whom nose blowing, wiping, and picking account for 95% of common initiators.<sup>2</sup> Another common cause is the drying effect of house heating during winter months. Trauma from a blow to the nose is quite obvious and often benign; however, if the severity of trauma is significant, underlying fracture should be investigated. A particular concern is the hypertensive patient who presents with nosebleeds. These are often profuse and poorly controlled without medical management. More rarely, bleeding dyscrasias may present with nasal bleeding. A major concern in children is the possibility of acute leukemia. This is manifested by a recently sick child with epistaxis and gingival and subcutaneous bleeding.

## General Strategy

# **Acute and Profuse**

If significant trauma occurred, consider radiographs to rule out an associated fracture. If simple measures to control bleeding are not effective, referral for medical management is important. This will usually involve the use of silver nitrate sticks or electro-coagulation and packing.

## **Acute with Minimal Bleeding**

- Control with slight pinching of the nose with the head held in neutral, not extended. In extension, blood may be swallowed, leading to nausea and/or vomiting.

## **History of Recurrent Nose Bleeds**

- Determine the frequency, amount of bleeding, and length of attacks.
- Determine whether there are any obvious causes with respect to allergies or nasal trauma from picking, blowing, or wiping; or whether the patient lives in a house where home heating produces a low-humidity environment (especially when the heater runs all night).
- In adults, determine whether the patient is hypertensive.
- Evaluate the patient for any other signs of bleeding tendencies, such as easy bruising.
- If recurrent and no obvious cause can be identified, lab tests may indicate any underlying blood dyscrasia.

- Refer if the suspected underlying cause is hypertension, mitral stenosis, a bleeding disorder, or drug related (chemotherapy, anticoagulant therapy for thrombophlebitis, etc.).

## Relevant Anatomy

Nasal bleeding is rather common because of an abundant and redundant blood supply and the vulnerability of the nose to trauma. Both the internal and external carotid arteries supply branches that feed the nasal mucosa. Epistaxis is classified as either anterior or posterior. Bleeding is most common anteriorly because of the abundance of vessels in Kiesselbach's plexus. Bleeding posteriorly is less common and more likely to be profuse. The blood vessels are quite superficial and vulnerable to various environmental factors as a result of allergies, infections, low humidity, and trauma.

## Evaluation

## History

A focused history addresses common causes associated with nasal trauma, such as chronic blowing of the nose, nose picking or wiping, and direct trauma from blows. It is particularly important to determine the humidity of the patient's living or working environment. Specifically, when heating is used all night in the winter months, the nasal mucosa dries and leaves the area susceptible to bleeding from minor trauma.

A drug history is important. The use of anticoagulant or antiplatelet drugs, such as warfarin sodium (commonly used

for deep vein thrombosis) or aspirin on a long-term basis, may predispose the patient. Drug-induced thrombocytopenia may occur with chemotherapy. Use of cocaine will cause nasal vasospasm and eventual tissue necrosis leading to bleeding (ironically, cocaine may be used in the acute management of nasal bleeding due to the vasoconstrictive effects). A family history of bleeding may indicate a rare hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber syndrome). Determine whether the patient has a history of hypertension that is poorly controlled. Also investigate any possibility of advanced liver disease.

## **Examination**

At the time of bleeding it is important to distinguish anterior from posterior bleeding.<sup>3</sup> This is often difficult because of the amount of bleeding. Posterior bleeding is classically profuse and difficult to control without silver nitrate sticks or electrocoagulation and nose packing. If trauma was involved, a close check for nasal or facial fracture is warranted. Radiographs or computed tomography may be needed to determine the extent of a facial fracture. For patients with recurrent or profuse bleeding, the evaluation should include the following:

- nasal mucosa inspection
- blood pressure measurement
- a complete blood cell count to determine thrombocytopenia (more extensive testing, including liver function tests, should be reserved for those suspected from history) or pancytopenia

## **Management**

- Patients with thrombocytopenia or pancytopenia have serious disease and require immediate medical referral.
- Nasal hygiene is important to convey to children and their parents to eliminate common benign causes. When house humidity is suspected as the cause, two suggestions should be given. First, reduce the thermostat at night so that the heater is not used as much during the evening. Second, apply a lubricant such as Vaseline around the nose before going to bed, which helps to moisten incoming air.
- For children who do not have a nasal hygiene cause, it may help to address the possibility of dairy product allergies through a trial of elimination for several weeks if the bleeding is recurrent.
- Persistent epistaxis with associated signs of bruising, fatigue, or weight loss may suggest an underlying leukemia warranting further medical evaluation.
- For patients with hypertension, referral for medical management is imperative. This type of bleeding may be potentially life-threatening if the underlying hypertension is not controlled.

# CHAPTER 48

## Sore Throat

### Context

Sore throat is the third most common presenting complaint for primary care physicians totaling approximately 3% to 4% of all visits.<sup>1</sup> Although sore throat is one of the five most common complaints in a primary care setting,<sup>2</sup> presentation in a chiropractic setting is far less common. This is largely based on an assumption by the patient that antibiotics will be given for his or her problem and that drug prescription is not within the scope of chiropractors. The rationale for antibiotic treatment of pharyngitic sore throat, however, is not so much to treat for cure of the primary infection (there is no strong evidence indicating improvement of the sore throat with antibiotic treatment beyond the natural history), but to prevent the serious complication of streptococcal throat infection—rheumatic fever. It is interesting to note, though, that fewer than 15% of adults and 40% of children with sore throat have group A  $\beta$ -hemolytic *Streptococcus pyogenes* infection, the main cause of “strep” throat.<sup>3</sup> Viral causes account for about 50% of pharyngitis. Therefore, it is important to distinguish the patient with a nonstrep cause from the patient who is likely to have a viral (nonantibiotic treatable) cause of sore throat.

The two primary management issues with the indiscriminate use of antibiotics for sore throat (accounts for 50% of antibiotic prescription in outpatient clinics) are the

inappropriate use of antibiotics, resulting in resistant bacterial strains, and the cost.<sup>4</sup> It would seem that such a common complaint as sore throat would have a clear-cut gold standard for evaluation or at least a classic presentation that would nail down the diagnosis. However, presentation varies, and the distinction between viral and bacterial pharyngitis is not always clear. There is no gold standard for the diagnosis of *S. pyogenes*. With a suggestive history and examination coupled with the appropriate use of a rapid screen for antibodies to group A streptococcus and/or throat culture, the diagnosis should be evident in the majority of patients. Ironically, one study indicated that although primary care physicians who were educated regarding probabilities of strep throat improved in their diagnosis (decreased overestimation tendencies), they had a slight trend toward increasing prescription of antibiotics.<sup>5</sup> The study concludes that it is difficult to change treatment tendencies even with an improved ability to make treatment decisions.

In general, those patients at high risk for *S. pyogenes* or its complications should be referred for antibiotic treatment. Others may be managed for symptoms and monitored for symptom persistence and severity. Failure to improve (or if the patient worsens) warrants referral for further testing or antibiotic treatment. As a potential first-contact doctor, chiropractors should have available the ability to perform a rapid antigen test for strep in an effort to save the patient from an unnecessary visit to his or her medical doctor.

## **General Strategy**

## **History**

Determine whether the patient has the following:

- indicators of high risk for *S. pyogenes* or its complications (diabetes, prior rheumatic fever, strep throat in a close-contact individual)
- recurrent attacks that are relatively mild (allergic pharyngitis)
- history of orogenital sex or other indicators of gonorrhea

## **Examination**

### **Perform the following:**

- Determine whether the patient has a fever and/or rash
- Determine whether the patient has signs of a respiratory infection
- Examine sinuses for indication of infection (transilluminate)
- Determine whether the patient has associated anterior or posterior lymph node involvement (anterior suggests bacterial, posterior suggests viral)
- Determine whether there are any lesions in the mouth or oropharynx (examine the teeth and gums, tongue, palate, and pharynx)
- Check the thyroid gland
- Perform a rapid determination for streptococcus antigen if patient appears to have either strep or viral pharyngitis; if negative, yet history and exam are highly suggestive, perform a throat culture
- Perform a screening lab test for patients suspected of having mononucleosis (monospot in two weeks if still unsure)

## **Management**

- Refer patients who are at high risk for strep.
- Refer patients who have a positive strep antigen test or throat culture for group A  $\beta$ -hemolytic strep.
- Manage patients symptomatically who have mononucleosis (unless extremely painful on swallowing or difficulty breathing).
- Manage patients for symptoms if a viral cause is suspected; monitor for worsening or persistence.

## Evaluation

## History

The focus of the history is to determine whether patients have been exposed to strep throat and those who may be predisposed. Children are more likely to acquire strep throat than adults. A positive history of exposure to a schoolmate or a family member is often found. It is important to confirm that the contact individual has had positive tests for streptococcus and was not simply treated with antibiotics as a gunshot approach. It is also important to determine whether the patient has had prior rheumatic fever or a current history of diabetes; both predispose the individual to streptococcal infection.

The next step is to determine whether there are historical indicators of other causes of sore throat.

- With diabetics, the immunosuppressed, or those taking oral corticosteroids (inflammatory diseases) or inhaled corticosteroids (asthma) there is a higher risk for candidiasis.
- Patients (in particular homosexual men) who engage in orogenital sex are more likely to acquire oral gonorrhea.

- Patients who report a mild sore throat that is recurrent and unassociated with a fever are likely to have allergic pharyngitis (unless following a more severe initial attack). There is often an associated complaint of a chronic cough or sinus congestion.
- Patients who have had extensive dental procedures who complain of difficulty swallowing and an associated sore throat may have a retropharyngeal abscess (visible only with a lateral cervical spine radiograph).

## Examination

One of the key findings is a pharyngeal exudate. Unfortunately, taken alone, this is a relatively nonspecific finding, occurring in as many as 65% of patients with viral pharyngitis and 40% of patients with mycoplasma infection. Following are some classic descriptions for various causes of exudates (it is recommended to examine a color atlas to gain better recognition):

- Streptococcal—tonsils are covered with a loose yellow exudate; tonsils are swollen.
- Herpangina—due to coxsackie virus infection; there are multiple, small (1 to 2 mm), painful ulcerations (often in children) of the soft palate and pharynx (a similar condition called hand-foot-and-mouth disease is caused by coxsackie virus but also involves the palms and soles of the feet).
- Herpes simplex—similar to herpangina in appearance; there are multiple, small (1 to 2 mm) vesicles that rupture in a few days to produce painful ulcerations; however, they may involve the lips, gingivae, or palate.

- Herpes zoster—the lesions are usually unilateral, involving the lip, tongue, or buccal mucosa; lesions are usually larger (2 to 4 mm) and go through vesiculation.
- Candidiasis—usually produces white, curdy patches on the tongue or mucosa.
- Mononucleosis—palatine petechiae are virtually diagnostic with small, red lesions with small, white bases.
- Vincent's angina (necrotizing ulcerative gingivostomatitis)—caused by fusobacterium or *Borrelia vincetii*; begins as a fulminant gingivitis with bleeding, ulcerations, and a grayish covering that spreads to the posterior pharynx; there is an associated foul breath.
- Stomatitis is not an exudate but an inflammation of the oral mucosa that may occur far enough posteriorly that it causes painful swallowing and may appear to the patient to be a sore throat. Stomatitis is caused by various entities, including infections (such as herpes and gonorrhea), medications (including methotrexate and similar immune-altering medications), and trauma.

In addition to examination of the mouth and throat, it is important to palpate for lymphadenopathy. Anterior lymph node enlargement is suggestive of a bacterial cause of pharyngitis. Posterior lymph node involvement suggests a viral source. Regional node enlargement in the axillary and inguinal regions in association with posterior neck involvement suggests mononucleosis. With a suspicion of mononucleosis it is always important to check for splenomegaly. In patients with no obvious oral involvement, palpation of the thyroid gland should be included. A scarlatiniform rash is strong evidence for streptococcal infection.

A temperature greater than 38.3°C (101°F) is found more commonly with a streptococcal infection or a complication,

peritonsillar abscess, involving unilateral swelling of a tonsil (a referral condition). Mild fever is more suggestive of a viral infection.

Unfortunately, the classic findings of fever, pharyngeal exudate, and anterior adenopathy without cough are not always found in all patients with strep throat (found in only 56% of patients). These findings are also nonspecific, occurring with other causes of pharyngitis. This, taken together with expediency issues, leads to a tendency toward overestimation of strep throat when the patient presents with pharyngitis. Reliance on clinical impression alone leads to an overestimation rate of between 80% and 95% by experienced clinicians.<sup>6</sup> For this reason laboratory evaluation is necessary.

Pharyngitis is caused by a number of infectious and noninfectious causes. Infections may be viral or bacterial, including *Chlamydia*, *Mycoplasma*, *Neisseria gonorrhoeae*, *Haemophilus influenzae* type b, Candidiasis, Diphtheria, and others. Other noninfectious causes include gastroesophageal reflux, allergic rhinitis, postnasal drainage, acute thyroiditis, persistent cough, and sinusitis, among others. Concerns regarding group A  $\beta$ -hemolytic streptococcal pharyngitis are the suppurative complications and rheumatic fever. This tends to cause an overreaction, by both patients and physicians, to treat with antibiotics as a “shotgun” approach to all sore throat presentations. Rheumatic fever is now quite rare, occurring in only 1 per million of the U.S. population.<sup>7</sup> Researchers recently evaluated the likelihood ratios for the history and physical examination of patients with sore throat in an attempt to determine various components or cluster of components in detecting strep throat.<sup>8</sup> Their findings follow:

- Tonsillar exudates, pharyngeal exudates, or exposure to strep throat infection in the previous two weeks

(positive likelihood ratios of 3.4, 2.1, and 1.9 respectively)

- Absence of tender anterior cervical lymph nodes, no tonsillar enlargement, or no exudate (negative likelihood ratios of 0.60, 0.63, and 0.74 respectively)

They conclude that there is no single element of the history or physical examination that can sufficiently diagnose or exclude the diagnosis of strep throat. However, by following an algorithmic approach, patients can be categorized into high-, moderate-, and low-risk categories. Those at high risk (combination of tender anterior lymph nodes, pharyngeal exudates, and/or recent exposure to strep throat) should be treated with antibiotics because they likely have strep throat. Those at moderate risk (absence of the high-risk elements but with a recent cough and oral temperature of  $\geq 38.3^{\circ}\text{C}$  [ $101^{\circ}\text{F}$ ]) should have further diagnostic evaluation (rapid antigen test or throat culture). Those at low risk should be managed symptomatically and are likely not to have strep throat. One study of 30,000 patients found that by encouraging the use of a rapid antigen test only, there was a decrease from 65% to 13% in the number of patients receiving a throat culture, with no change in the number of suppurative complications.<sup>9</sup>

There are two general approaches to detection of group A streptococcus. First is an in-office (or referral) check for rapid strep antigen. This approach has an estimated sensitivity of 79% to 88% and a specificity of about 95%.<sup>6</sup> Newer optical methods approach the 94% to 96% sensitivity level. Specificity was similar to that in the older methods. Based on these generalizations, it is suggested that patients with a positive test be referred for antibiotic treatment. The difficulty is the patient who appears to have strep throat, yet has a negative rapid antigen test. Most physicians would still order a culture, but would not treat until the results indicated infection with *S. pyogenes*. Given the high

specificity, some physicians would not culture. This is based solely on a cost-effectiveness decision.

In a patient with mononucleosis a complete blood count will demonstrate a lymphocytosis greater than 50% or atypical lymphocytes greater than 10%. A monospot test should be ordered for confirmation after one week, or three weeks if the first test is negative.

## Management

- Refer patients who are at high risk for streptococcal infection.
- Refer patients who have a positive strep antigen test or throat culture for group A  $\beta$ -hemolytic streptococci.
- Manage patients symptomatically who have mononucleosis (unless extremely painful on swallowing or difficulty breathing).
- Manage patients for symptoms if a viral cause is suspected; monitor for worsening or persistence. Symptomatic management includes hydration and throat lozenges; cervical adjusting and massage may help with lymphatic drainage.

Special Conditions

## CHAPTER 49

# Diabetes Mellitus

## Context

Diabetes mellitus (DM) is a disorder that results in chronic hyperglycemia due to absence of insulin, decreases in insulin, and/or decreased sensitivity of insulin receptors. DM generally is evident in two major forms: type 1, insulin-dependent diabetes mellitus (IDDM), and type 2, non-insulin-dependent diabetes mellitus (NIDDM). Type 1 diabetes becomes apparent in childhood or adolescence, while type 2 diabetes is generally not evident until later in life (over the age of 40 years). There is an ethnic distinction in that Scandinavians have a much higher proportion of individuals with type 1 diabetes (20%). In Japan and China, only 1% of diabetic patients have type 1 diabetes.

The two types of diabetes are not always clearly defined by age, with some older patients developing type 1 diabetes and some younger patients developing type 2 diabetes. Recent evidence suggests that type 2 diabetes is increasingly being found in children and adolescents.<sup>1, 2</sup> Of diabetics in the United States, 90% to 95% have type 2 diabetes.<sup>3</sup> Type 2 diabetes may affect as many as 20% of the senior U.S. population (ages 65 to 74 years). In the United States about 1.9 million individuals were newly diagnosed with diabetes in 2010. Approximately 7 million adults in the United States have undiagnosed type 2 diabetes. A study<sup>4</sup> performed in 2003 attempted to predict

the lifetime likelihood of developing diabetes. The researchers estimated that for individuals born in the United States in 2000, the lifetime probability of being diagnosed with diabetes for males was 33% and for females 39%. It is important to also note that the lifetime risk for African Americans and Hispanics is 50%.

Because of the dramatic increase in cases of type 2 diabetes, the American Diabetes Association and the National Institute of Diabetes and Digestive and Kidney Diseases issued a position statement urging that patients be evaluated for prediabetes and managed prior to the development of diabetes and its associated health consequences.<sup>5</sup> They focus on a new category referred to as prediabetes. Estimates are that at least 20.1 million people in the United States (approximately 21% of the population) from age 40 years to 74 years have prediabetes. The belief is that long-term damage occurs in this prediabetic state (especially to the cardiovascular system) prior to the full development of diabetes. In the past, the threshold level for the diagnosis of diabetes on a fasting plasma glucose (FPG) level had been lowered from 140 mg/dL to 126 mg/dL. With the introduction of the prediabetes category, the level for intervention has been lowered to 100 mg/dL for a FPG and 140 mg/dL for an oral glucose tolerance test (OGTT).

The major complications of a chronic hyperglycemic state (and associated abnormalities) are macrovascular and microvascular disease. As a result, several complications of diabetes make it an extremely important disease to control. The major complications include the following:

- Death—DM significantly increases the risk of atherosclerosis-related death (seventh leading cause of death in the United States).<sup>6</sup> Seventy-five percent of DM-related deaths are due to this macrovascular manifestation. Two-thirds of adult patients with DM have hypertension.

- Blindness—DM is the leading cause of blindness in the United States in patients between the ages of 20 years and 74 years.<sup>7</sup>
- Renal failure—DM is the leading cause of endstage renal disease in the United States; 25% to 30% of patients receiving some form of renal replacement therapy are diabetic.<sup>8</sup>
- Neuropathy—DM is the most common cause of neuropathy, affecting between 70% to 80% of individuals, and polyneuropathy, affecting 50% of all diabetics within 25 years.<sup>9</sup>
- Gangrene of the feet—Diabetics have an incidence 20 times higher than the nondiabetic population. This may lead to amputation. Smoking increases the risk.

Because of these and other complications, the estimated total annual price tag for the United States alone is \$174 billion.<sup>10</sup>

The Diabetes Complication and Control Trial (DCCT)<sup>11</sup> studied patients with type 1 diabetes and demonstrated a reduction in microvascular complications in patients who were tightly controlled (hyperglycemia controlled). These included diabetic retinopathy, nephropathy, and neuropathy. A recent study<sup>12</sup> indicated, however, that intensive treatment of type 2 diabetes over a 10-year period did not decrease illness or death from macrovascular causes.

The chiropractor will often have diabetic patients present with various musculoskeletal and neurologic complaints. It is important to place the evaluation and management of these complaints in the context of a diabetic patient. In other words, if a diabetic patient presents with numbness, tingling, or pain in the lower extremity associated (or not associated) with low back pain, the question is whether the lower extremity problem is a complication of the diabetes or due to some other nondiabetic etiology. More important, only half of patients with diabetes are aware of their

disorder.<sup>13</sup> This means that if a patient complains of symptoms of a neuropathy and no history of a diabetes diagnosis, the chiropractor could be unaware of an important component for decision making in the patient's management and prognosis.

Therefore, the chiropractor who uses laboratory facilities is in an advantageous position to detect the diabetic patient. In addition, if a patient is discovered to have NIDDM, comanagement with a strong emphasis on dietary and exercise control should be the focus of the chiropractor's involvement. Diabetic management is complex and difficult with regard to patient compliance, given that many patients may be asymptomatic. If the patient has a supportive network, including the chiropractor, the medical doctor, and the family, his or her chances for conservative control of NIDDM are increased.

## **General Strategy**

# **History**

## **Determine whether**

- the patient has risk factors, such as:
  - 1.** older than 45 years
  - 2.** obese (the single most important risk factor) BMI > 35 kg/m<sup>2</sup>
  - 3.** a family history of diabetes
  - 4.** ethnic background (type 1 more common in Scandinavians; type 2 more common in African Americans, Hispanic Americans, American Indians, Asian Americans, and Pacific Islanders)
  - 5.** a history of polycystic ovary disease

- 6.** signs and symptoms such as blurred vision or numbness and tingling in the extremities; or polyphagia, polyuria, or polydipsia
  - 7.** the patient has a history of high cholesterol or triglyceride levels
  - 8.** the patient has a history of smoking
  - 9.** the patient is physically active or not
  - 10.** the patient has a history of gestational diabetes or delivered a baby weighing more than 9 lb
  - 11.** the patient has a low level of circulating vitamin D —25(OH)D: an inverse association between low levels of vitamin D and incident type 2 diabetes.<sup>14</sup>
- the patient has a history or signs and symptoms of other disorders that may cause hyperglycemia (Cushing's disease, pheochromocytoma) or whether he or she is taking medications that may cause hyperglycemia or worsen diabetes (corticosteroids, diuretics causing hypokalemia)
  - the patient is a known diabetic—ascertain whether the patient is taking medication (insulin or a hypoglycemic agent), following a dietary program, following an exercise program, monitoring his or her blood glucose level, being monitored with a glycosylated hemoglobin

## Evaluation

- Pay particular attention to weight, blood pressure, and vision (patients with type 2 diabetes are often overweight and hypertensive).
- Check for secondary signs of diabetes, including an ophthalmoscopic examination, a check of the skin and nails, and a neurologic check for vibration or sensory deficits.
- Screen high-risk patients (see risk factors above), preferably with a fasting laboratory test; if not being

performed by primary caregiver, screen for gestational diabetes in pregnant women between weeks 24 and 28, using a one-hour glucose tolerance test.

- Use a glycosylated hemoglobin in known diabetics to check control of diabetes (coordinate with medical doctor if necessary).

## **Management**

- Type 1 diabetes should be managed by the patient's medical doctor; however, the chiropractor can provide a supportive role with the medical doctor to better guarantee tight glycemic control and prevention of complications.
- Type 2 diabetes can be comanaged with a strong emphasis on a specific dietary and exercise program.
- Given the time and resources necessary, referral to an American Diabetes Association certified diabetes self-management program is often the most reasonable approach.
- Monitor all patients for glycemic control and clinical indicators of progressive macrovascular and microvascular complications.
- Understand the management of acute diabetic ketoacidosis in emergency settings.

## **Relevant Physiology**

Glycemic metabolism is controlled by the interaction of insulin (which has mainly a hypoglycemic function) and hormones that are referred to as counter-regulatory. These counter-regulatory hormones include glucagon, epinephrine/norepinephrine (catecholamines), cortisol, and growth hormone. In general, these hormones act to

stimulate glycogenolysis and gluconeogenesis.

Catecholamines, in particular, suppress insulin secretion and stimulate hepatic glucose production. The hypoglycemic function of insulin is the result of several mechanisms, including promoting the uptake of glucose by mainly muscle and adipose tissue, inhibiting the breakdown of glycogen (promotes glycogen stores), and inhibiting the production of other sources of energy such as from free fatty acids. Both chromium and potassium are needed for the proper functioning of insulin.

There are two circadian effects that influence diabetes.<sup>15</sup> The Somogyi effect begins with a nocturnal hypoglycemia that occurs with type 1 diabetes. This may stimulate an overproduction of counter-regulatory hormones leading to hyperglycemia by 7:00 a.m. Another effect is called the dawn phenomenon.<sup>16</sup> This phenomenon occurs in most diabetic and nondiabetic individuals with a reduced tissue sensitivity to insulin between 5:00 a.m. and 8:00 a.m. These effects and exercise may have an effect on the timing and need for insulin.

During exercise, insulin need is diminished. This is due to the enhanced insulin binding at receptor sites, so that glucose uptake is increased without an increase in insulin (insulin demand reduced). Also, because the amount of circulating plasma glucose is quite small and unable to meet the demands of exercise, the inhibitory effects of insulin on liver glucose production are inhibited by the counter-regulatory hormones, in particular, glucagon and the catecholamines.

Patients with a level of plasma glucose high enough to exceed the renal threshold for glucose will have a spillover into the urine. This causes an osmotic diuresis (polyuria) leading to dehydration. This will lead to increased thirst—polydipsia. When glucose uptake in the peripheral sites is decreased, patients will often feel a lack of energy or feel

fatigued. This relative “cell starvation” may lead to a desire to eat—polyphagia.

Type 1 diabetes is due to the failure of the beta cells of the pancreas to produce and secrete insulin. The destruction of islet cells is a variable process, with the onset occurring within the first year of life through young adulthood. It is currently believed that this is due to an autoimmune response that is genetically predetermined. It is proposed that either through an infectious or toxic environmental stimulus, the body produces an autoimmune response against either altered pancreatic beta cell antigens or against part of the beta cell that resembles a viral protein. As a result, 85% of patients with type 1 diabetes have circulating islet cell antibodies, with the majority having anti-insulin antibodies detected. Islet cell autoimmunity (IA) has also been associated with specific foods and the introduction of these foods to the infant. One proposed relationship has been between cow’s milk and an increased risk of IA. Out of four cohort studies that use the presence of IA tested serologically, three studies showed no effect.<sup>17-19</sup> In two recent studies, researchers examined a possible relationship between gluten and IA.<sup>20,21</sup> This investigation was prompted by the observation that there is an increased association between type 1 DM and celiac disease.<sup>22</sup> It was found that exposing an infant before the age of 3 months and after 7 months or older increased IA frequency, especially in those with the HLA genotype HLA-DRB1\*03/04, DQB8. This implies a possible relationship to cereal feeding (gluten, specifically) and the timing of exposure in genetically predisposed individuals. It must be made clear though that these studies focused on the construct of islet cell autoantibodies and not diagnoses of type 1 DM. These studies also involved a small group of individuals. It is likely that the combination of genetics and exposure to a multitude of environmental factors will be identified as causal factors in the future, versus a single stimulator of

autoimmunity. Some of the suspected viral causes are the mumps and coxsackie B4 virus. With type 1 diabetes, patients may become ketotic and subsequently develop life-threatening metabolic acidosis. With diabetes, there is a switch from oxidative aerobic glycolysis to anaerobic glycolysis resulting in excess lactic acid formation. This combined with inadequate utilization of fats coupled with lipogenesis leads to the accumulation of fatty acids which are oxidized to ketones, another cause of acidosis.

Type 2 diabetes represents a range of glycemic disorders that are due mainly to tissue insensitivity to insulin, a blunted beta-cell response to glucose, and an increase in hepatic production of glucose. These patients usually have enough insulin to prevent ketoacidosis, but do not have enough to prevent the consequences of chronic hyperglycemia. The increase in liver production appears to be due to an increased circulating level of glucagon. Most patients in the United States with type 2 diabetes are obese. Sudden weight loss is sometimes the hallmark of an onset of diabetes for some individuals. Those who are not obese may represent a subcategory of type 1 because they often eventually need insulin. There appears to be a pattern of autosomal dominant inheritance with type 2 diabetes.

The relationship to obesity appears to be predominantly associated with an abdominal fat distribution. Apparently, fat that is in the extremities or distributed superficially in the abdomen has less of an effect on hepatic production of glucose than does fat that is “visceral.”<sup>23</sup> This visceral type of fat is distributed mainly in the omental and mesenteric regions. Both insulin resistance and hepatic glucose production are increased with this type of obesity.

The relationship between type 2 diabetes and associated hypertension, hyperlipidemia, hyperglycemia, and hyperinsulinemia has led to a proposed syndrome called insulin resistance syndrome, syndrome X, or CHAOS.<sup>24</sup> CHAOS is an acronym for coronary artery disease,

hypertension, atherosclerosis, obesity, and stroke. This acronym represents the clinical consequences of insulin resistance. It is known that the conditions associated with syndrome X are interdependent to some degree and that a reduction in one of them will have a beneficial effect on reducing risk for CHAOS by reducing other related factors.

Gestational diabetes is diabetes that is first detected during pregnancy. It carries with it the risk of fetal abnormalities, including neural tube deficits (folic acid helps), macrosomia, and fetal death. A well-controlled blood glucose level (mainly through diet) can substantially reduce the risk.

## Clinical Manifestations

Diabetic neuropathy presents in various clinical forms, including poly- and mononeuropathies (**Exhibit 49-1**).

Primarily, there are four main types:

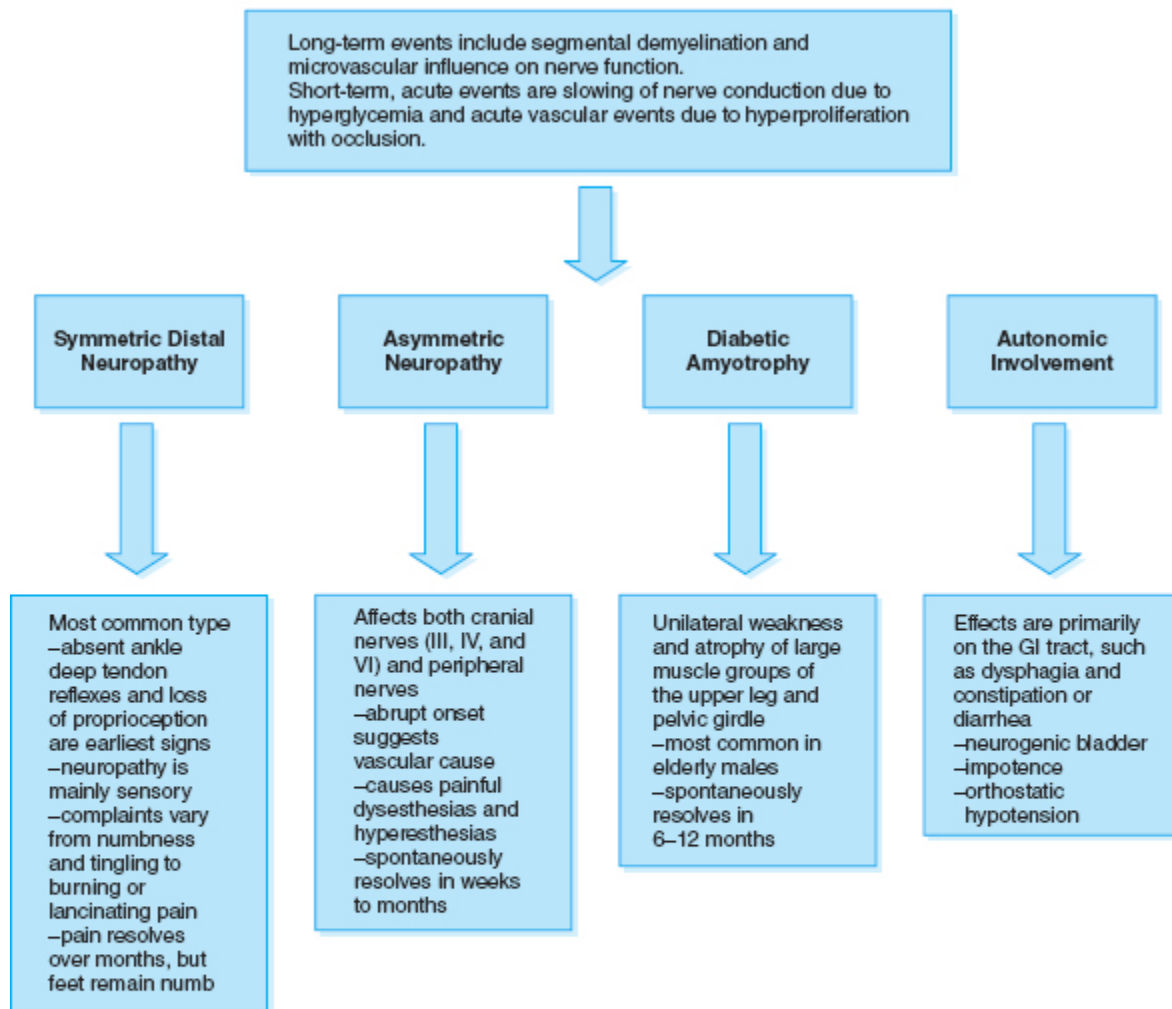

1. Symmetrical distal—The patient complains of bilateral numbness, tingling, pins and needles (dysesthesias), pain with normal sensory stimuli (allodynia), sometimes a burning sensation. Mononeuropathy of thoracic and lumbar nerves may lead to pain in supplied areas that mimics angina or myocardial infarction, cholecystitis, or even appendicitis.
2. Asymmetrical, cranial—The patient usually has a complaint of diplopia due to involvement of the oculomotor nerve.
3. Diabetic amyotrophy—Usually involves large nerve such as the femoral or median nerve involving a deep pain with weakness and atrophy of muscles in the area. Carpal tunnel syndrome is difficult to distinguish from amyotrophy in diabetic patients.

4. Autonomic—Leads to a myriad of complaints and problems such as orthostatic hypotension (splanchnic blood vessels), arrhythmias, diarrhea, incontinence, erectile dysfunction.

The loss of sensory input to joints may lead to damage (Charcot joint) with progressive, painless destruction, and the loss of proprioception may lead to imbalance when in dimly lighted areas or at nighttime.

### **Exhibit 49-1 Diabetic Neuropathy Flow Chart**

## Diabetic Neuropathy

### Diagnostic Criteria for Diabetes in Nonpregnant Patients

- Presence of the classic symptoms of diabetes such as polyuria, polydipsia, ketonuria, and rapid weight loss (for type 1), together with a random plasma glucose concentration of 200 mg/dL or higher.
  - Elevated fasting glucose concentration on more than one occasion of 126 mg/dL or higher.
  - Fasting glucose concentration less than that which is diagnostic, but sustained elevation of glucose during oral glucose tolerance test on more than one occasion. Both the 2-hour sample and another sample taken between the administration of the oral 75-g glucose dose and the 2-hour sample must meet the criteria of 200 mg/dL or higher. Pre-diabetes = HbA1c is 5.7%–6.4%; diabetes = HbA1c of 6.5% or higher
- Note:** New category established for pre-diabetes for those individuals with fasting glucose levels above 100 mg/dL. Need lifestyle intervention to prevent progression.

The underlying cause is uncertain. However, with acute onset of symptoms, the suspicion is that there is an infarction of one or several branches of the vaso nervorum (the arteries feeding the nerves), so the cause is actually vascular. When progression is slower it is believed that there

is a gradual deterioration that causes the sensory aberrations seen in many long-term or poorly controlled diabetics. The cause appears to be excess glycosylation of proteins, specifically, sorbitol accumulation in Schwann cells or nerve trunks in reaction to chronic hyperglycemia.

The following represent some of the proposed effects of chronic hyperglycemia that lead to neuronal dysfunction:

- Non-enzymatic covalent bonding with proteins alters their structure and may lead to dysfunction
- Activation of protein kinase C
- Depletion of NADPH, which indirectly leads to lower levels of nitric oxide blocking the vasodilation effect and decreased glutathione production increasing free radical formation

Alteration of the polyol pathway is the primary basis through which many of these problems result. A sequence occurs related to the hyperglycemia of diabetes. Cells that do not require insulin include hepatocytes, erythrocytes, cells of the peripheral nervous system, intestinal mucosa, renal tubules, retina, and cornea. For some of these cells, whether glucose is reduced to sorbitol determines their risk of damage. Those cells that contain aldose reductase convert excess glucose to sorbitol. These include the lens, retina, Schwann cells of the peripheral nervous system, the kidney, RBCs, hepatocytes, and cells of the ovaries, seminal vesicles and placenta. Only hepatocytes and cells of the ovaries, seminal vesicles, and placenta contain sorbitol dehydrogenase. This allows sorbitol to be converted to fructose that can then escape the cell. For cells without sorbitol dehydrogenase, sorbitol is trapped and cannot be converted to fructose. These cells become glycosylated. The  $\text{Na}^+/\text{K}^+$  ATPase pump may be affected by a decrease in intracellular myoinositol in the hyperglycemic state, decreasing neuronal conduction.

Glycosylation partially explains the damage to the eye, kidney, and peripheral nervous system. Pathologically, this leads to the microvascular changes seen in retinopathy, nephropathy, and neuropathy. Diagnostically, the glycosylation of RBCs can be taken advantage of with hemoglobin HA1<sub>c</sub> testing.

Diabetic retinopathy is due to deterioration of glycosylation to the retina, resulting in microaneurysms. Tight glycemic control may decrease the rate of these microaneurysms. The microaneurysms may progress to the development of exudates and punctate hemorrhages, together called background retinopathy. Although relatively stable, background retinopathy may progress to large hemorrhages with subsequent scarring. Following scarring, angiogenesis factor released by the ischemic retina leads to a proliferation of new blood vessels called neovascularization. As these contract into the vitreous, the retina may become detached, causing blindness.

The lens is also affected in many diabetics. Chronic hyperglycemia may lead to a change in lens shape, resulting in visual acuity that fluctuates. It usually takes six to eight weeks of tight glycemic control to correct the problem. In addition, chronic hyperglycemia may cause excess sorbitol deposition in the lens. This creates an osmotic gradient, drawing in extracellular waste products and leading to the development of a cataract. Unfortunately, tight glycemic control does not seem to prevent or reverse this process. Glaucoma is also more common in diabetics (occurring in 6% of diabetics), apparently because of scar formation at the canal of Schlemm.

Diabetic nephropathy leads to hyperfiltration and microalbuminuria. Decreasing renal function leads to glomerulopathy and subsequent renal failure. Factors that

increase the rate of failure are hypertension and a high-protein diet.

## **Evaluation**

### **History**

## **The Undiagnosed Diabetic**

A high level of suspicion is raised when a patient with a family history of diabetes presents with a complaint of bilateral (or unilateral) numbness or tingling in the feet or hands. Complaints such as blurring vision, orthostatic hypotension, polyuria, and polydipsia (increased thirst) in an older patient with associated weight gain are also highly suggestive. Symptoms of hypoglycemia following meals or simply generalized fatigue in an older patient warrant evaluation for diabetes. Hypertension, obesity, hyperlipidemia, and smoking are important as potential risk factors (or possibly associated factors). A thorough drug history is crucial to determine a contributing effect to hyperglycemia or unmasking effect on diabetes. Included are glucocorticoids, furosemide, thiazides, estrogen-containing products, beta-blockers, and nicotinic acid.

One of the first signs of type 2 diabetes in women is pruritus or signs of vaginitis. Frequent candida (yeast) infections are also suggestive. Women who have given birth to large babies (greater than 9 lb) or who have experienced preeclampsia or unexplained fetal death also should be screened for diabetes. Pregnant women should be questioned regarding gestational diabetes screening.

## **The Diagnosed Diabetic**

Type 1 Diabetes—Assuming that the patient is presenting with a neuromusculoskeletal complaint, it is important to determine how well the type 1 diabetes patient is controlled. It may well be that a complaint of radicular pain into the extremities or localized in the extremities may be a manifestation of diabetic neuropathy. This will strongly influence interpretation of examination findings, management, and prognosis (many are self-resolving). History questions regarding age at diagnosis, type of insulin, frequency of visits to the physician, development of diabetic complications, exercise and diet history, and current medication history are necessary to gauge where a patient stands with regard to risk.

Type 2 Diabetes—The main concern with the type 2 diabetes patient is adherence to a diet/exercise regimen. Questions regarding general well-being and/or the development of any diabetes-related neurovascular problems should be included. It is important to determine whether the patient has been given all the available patient information provided by the American Diabetes Association. It is also important to determine how often the patient is being evaluated for glycosylated hemoglobin. The chiropractor may provide this service if more convenient or cost effective than through the patient's primary physician.

## **Examination**

The physical examination of all patients with diabetes or suspected diabetes should focus first on the associated comorbidity problems of obesity (in type 2 diabetes), hypertension, retinopathy, and neuropathy. Therefore, blood pressure measurement (supine and standing); an ophthalmoscopic examination; deep tendon reflexes; and distal vibration, proprioception, and touch should be evaluated. In known diabetics, it is important to screen the

status of the teeth/gums, toes/toenails (in particular between the toes), and skin (especially skin injection sites).

Although the gold standard for neurological testing is nerve conduction studies, in-office evaluation should include Semmes-Weinstein monofilament testing for sensory evaluation (specificity of 96%; + LR of 10.2)<sup>25</sup> and vibration testing using two approaches: the on-off and timed vibration testing, both using a 128-Hz tuning fork. For the on-off approach apply the tuning fork to the bony prominence of the dorsum of the first toe (proximal to the nail bed), repeating twice on each foot. Point values are generated by adding one point for each successful recognition by the patient of when the tuning fork was felt to vibrate and also correctly identifying when the vibration stops with a total possible of eight points. An abnormal test would be a score of three or less, which has a strong likelihood ratio (LR) of 26.6, strongly suggesting neuropathy. The timed test, again using a 128-Hz tuning fork, involves a comparison between the examiner feeling the vibration stopping and the patient's perception. Applying the tuning fork at the same location as the on-off test, the patient indicates when he or she feels the vibration stops. The examiner compares this on their thumb and records the time when the vibration stops for them. A point value is obtained by determining the number of times the patient's perceived time was less than the examiner's. Generally, if there were three or fewer correctly perceived times, the positive LR was 18.5, strongly suggesting neuropathy. Also, testing for superficial pain has a sensitivity of about 97% and a + LR of 9.2. The absence of ankle reflexes has a sensitivity of only 60% (-LR of 0.44) but a specificity of 90% (+ LR of 6). In one study<sup>26</sup> three clinical criteria were compared to a gold standard and revealed that if two out of the three findings were present, the + LR was 10.8 with a sensitivity of 87% and specificity of 91%.

# Laboratory Testing

Screening of all patients for diabetes has not been recommended by most national guidelines, including those of the U.S. Preventive Services Task Force.<sup>27</sup> However, some associations such as the American Diabetes Association<sup>28</sup> and the Canadian Diabetes Association<sup>29</sup> recommend screening high-risk patients. The Canadian Diabetes Association makes its recommendation based on expert opinion, not literature evidence.

The laboratory evaluation for the determination of diabetes in undiagnosed patients is currently being debated with regard to the best test and the threshold level for diagnosis. The criteria set by the American Diabetes Association<sup>28</sup> are generally accepted. The categories and criteria for diabetes are:

## Prediabetes FIX

- HbA<sub>1c</sub> is 5.7%–6.4% (39–46 mmol/mol)
- a fasting plasma glucose at 100 mg/dL
- at 40 mg/dL for an oral glucose tolerance test (OGTT).

## Diabetes

- HbA<sub>1c</sub> is 6.5% (47 mmol/mol) or higher
- a fasting plasma glucose (FPG) level of 126 mg/dL or higher
- a two-hour plasma glucose (2 h PG; glucose tolerance test) of 200 mg/dL or higher

- patients with apparent signs and symptoms of diabetes with a random plasma glucose concentration of 200 mg/dL or higher

Normoglycemia is indicated by an FPG of less than 110 mg/dL or a 2 h PG of less than 140 mg/dL. Impaired fasting glucose is indicated by an FPG level of 110 mg/dL up to 125 mg/dL. Impaired glucose tolerance is indicated by a 2 h PG of 140 mg/dL up to 199 mg/dL.

The disagreement regarding these criteria revolves around two key issues. First, it appears that if the FPG is used as the only indicator, it identifies a different group than identified by the 2 h PG. In fact, it appears that many patients with an abnormal 2 h PG have normal levels of FPG.<sup>30</sup> The concern is that those patients would be missed if using the FPG only. Patients with impaired glucose tolerance have a much higher rate of cardiovascular disease and a higher mortality rate compared to those with impaired fasting glucose. Second, there is concern that the lowered threshold from 140 to 126 mg/dL for FPG will falsely identify individuals not at risk. This concern is based on a study<sup>31</sup> that found 60% of patients with an FPG of between 126 and 139 mg/dL had normal glycosylated hemoglobin levels. A simple solution to the latter concern is simply to check patients in this borderline group with a glycosylated hemoglobin.

Recommendations have changed regarding the need for oral glucose tolerance testing to identify persons at high risk for type 2 DM. A recently published review summarizes the recommendations made by the authors based on the use of a receiver-operating characteristic (ROC) curve used to determine the value of adding a two-hour glucose tolerance test to the predictive value of a fasting plasma glucose level.<sup>32</sup> The difference was minimal; therefore, the group suggested that due to the time, cost, and inconvenience,

plasma glucose levels are sufficient to identify the majority of individuals at risk.

When checking for gestational diabetes, a one-hour glucose tolerance test between weeks 24 and 28 should be ordered.

Additional laboratory findings suggestive of diabetes are as follows:

- glucosuria
- proteinuria (albumin)
- ketonuria
- budding yeasts on urinalysis
- hyperlipidemia

In the known diabetic, it is not necessary or desirable to test for a fasting glucose level. Diabetics self-monitor their blood glucose levels often. It is more important to gain a sense of whether or not there is glycemic control. This is accomplished with a nonfasting test called glycosylated hemoglobin. Because glycosylated hemoglobin is a measure of the amount of glycosylation of red blood cells (RBCs), it gives a good estimate of glycemic status over the preceding 8 to 12 weeks (the life of the RBC). Adequate control of glucose is indicated by an average glucose level of 150 mg/dL or a hemoglobin A<sub>1c</sub> of 7% to 8%.<sup>33</sup> Levels above 10% indicate poor control and a greater risk of developing complications.

## Management

Management of the diabetic patient is a complex, timeconsuming program for both the patient and the doctor. For type 1 diabetic patients, control through injection is required. Medical instruction in delivery with regard to timing and injection site is necessary. Newer delivery

systems are in development including an intranasal insulin spray. Self-monitoring of blood glucose is essential in determining insulin needs. Currently, the test is through a finger-prick test. This may soon be replaced by a noninvasive device that uses iontophoresis to extract glucose from the skin and measure it with an electrochemical-enzymatic sensor.<sup>34</sup>

Instructions on proper care of the feet to avoid gangrenous complications are also necessary. The patient usually is sent to a dietitian, who explains a comprehensive diet, including the American Diabetic Association exchange lists, the need for fiber, and artificial sweeteners as a substitute for table sugar.

For type 2 diabetic patients, the focus is on diet and exercise. The main role of the diet is to reduce weight in type 2 diabetic patients. Unfortunately about half of all diabetics do not follow their diets.<sup>35</sup> Given the complexity of management, a stratified approach may be more feasible. For those patients who are prediabetic or newly diagnosed diabetics with no visible end-organ damage (i.e., retinopathy or lab indicators of kidney involvement) a three-to six-month trial of diet and exercise advice may be appropriate monitoring with HbA<sub>1c</sub>. This staged approach could include a progressive walking program that starts with 5 to 10 minutes of walking per day and gradually increasing this amount by 5 minutes every week to arrive at a daily program of between 30 to 45 minutes. Simple diet changes can include adding a green leafy vegetable to each major meal and switching two lunches per week to low-fat yogurt and fruit. Combine that with a cup of coffee and the effect may be augmented. For those willing to commit more, convince your patient to join a gym and go through an exercise-training program. Provide and encourage your patient to use web sources to find healthy recipes and/or join a weight loss program. This also may be accomplished

through outsourcing to an American Diabetes Association certified diabetes self-management program.

For patients with signs of end-organ damage or for those unable to adhere to or benefit from a conservative approach, medical management is necessary. The patient should be reminded though that even with medication, diet and exercise are requisite to avoid the progression to insulin dependence. Thus medical management should be combined with an American Diabetes Association certified diabetes self-management program.

For type-1 DM, insulin is given by subcutaneous self-injection in the arms, abdomen, thighs or buttocks by pen injections or pump delivery systems. There are many factors affecting insulin requirements and absorption when injected including colds, fever, infections, illness, surgery, stress, and exercise. Side effects are related mainly to hypoglycemia, but also include allergic reactions, and lipodystrophy at the injection site. Some contraindicated supplements include melatonin, chaparral, tobacco, herbal tea, broccoli, cabbage, charbroiled meats, shiitake mushrooms, and turmeric. There is some hope for an intranasal insulin option which is also being proposed for the treatment of Alzheimer's.

Medical management of type 2 diabetes includes the use of the following drugs prior to resorting to insulin:

- Sulfonylureas (e.g., glipizide [Glucotrol], glyburide [Glynase, Micronase, DiaBeta], glimepiride [Amaryl], chlorpropamide [Diabinese])—close energy-sensitive potassium channels on beta cells causing influx of calcium and subsequent release of insulin.
- Biguanides (e.g., Glucophage [metformin])—hypoglycemic action is based on its effect of decreasing glucose production from the liver.
- Thiazolidinones (e.g., pioglitazone [Actos], rosiglitazone [Avandia])—attach to nuclear receptors in cells to

cause an increase in production of cellular proteins that facilitate glucose transport. Note Avandia has been taken off the market in Europe since fall of 2010 and restricted in the United States to patients who do not respond to other medications due to its associated increase in cardiovascular risk.

- Alpha-glucosidase inhibitors (e.g., Acarbose [Precose], Miglitol [Glyset])—reduce the rate of digestion of carbohydrates by competitive inhibition of enzymes needed to digest carbohydrates.
- Dipeptidyl peptidase 4 inhibitors (e.g., sitagliptin [Januvia])—increase incretin levels that inhibit glucagon, which allows increase in insulin secretion. Incretins are a group of proteins secreted by the GI tract along with glucose that enhance insulin secretion in the pancreas. These include glucagon-like peptide-1 (GLP-1) and gastric inhibitory peptide (GIP). GLP-1 also inhibits glucagon secretion and delays gastric emptying.
- GLP-1 receptor agonist injectables—exenatide (Byetta) and liraglutide (Victoza). Soon to be released is a GLP-1 receptor agonist that is delivered intranasally not requiring injection.
- SGLT2 inhibitors (e.g., canagliflozin (Invokana®) dapagliflozin (Farxiga®))—act by blocking the kidneys' reabsorption of glucose. The result is decreased plasma glucose due to loss in the urine.

Self-monitoring is important for known diabetics. There are many new products that allow better control of this monitoring process. Target levels that are influenced by the type of patient, but in general:

- Before meals—between 70 and 130 milligrams per deciliter (mg/dL), or 4 and 7 millimoles per liter (mmol/L)

- One to two hours after meals—lower than 180 mg/dL (10 mmol/L)
- Fasting at least eight hours—between 90 and 130 mg/dL (5 and 7 mmol/L)

For those using insulin, there are new approaches beyond the traditional approach of injection using a vial. One is a pen that uses an insulin cartridge with disposable needles. This obviates the need of filling a syringe. Another device is a continuous subcutaneous insulin infusion pump, which requires a catheter that must be changed every few days.

**Table 49-1** summarizes the most commonly used medications for diabetes.

Although medical treatment of type 2 diabetes decreases some of the microvascular complications, it does not seem to decrease the risk of macrovascular disease.<sup>12</sup> Treatment of hypertension or hyperlipidemia does appear to decrease this risk.<sup>36,37</sup>

A separate list of medications is utilized for those patients with diabetic neuropathy. These include but are not limited to:

- Some antidepressants including tricyclics (e.g., amitriptyline [Elavil], nortriptyline, desipramine) and selective serotonin norepinephrine reuptake inhibitors (e.g., Cymbalta [duloxetine], Effexor [venlafaxine])
- Anticonvulsants such as Lyrica (pregabalin) and Neurontin (gabapentin)
- Methylcobalamin (mecobalamin, MeCbl, or MeB<sub>12</sub>) or form of B<sub>12</sub> taken orally or injected

Other approaches to peripheral neuropathy include the following:

- Topical or transdermal lidocaine, or in some cases capsaicin

- Cold laser (photo energy therapy) devices—there are a number of different devices and intensities. Those that emit near infrared light (NIR therapy) are typically at a wavelength of 880 nm. NIR is believed to stimulate the release of nitric oxide causing vasodilation of small blood vessels increasing circulation and improving symptoms<sup>38,39</sup>

Physical activity is extremely important for the management of type 2 diabetes. It is also clear that the associated problems of hypertension and obesity are affected by exercise. For patients taking medication, there may be a fall in blood sugar with exercise, leading to hypoglycemia that lasts as long as 12 hours. This affects the injection site for diabetics using insulin. Exercise, though, increases levels of glucagon and catecholamines that may counter these medication effects. Recent studies have demonstrated a decrease in risk for type 2 diabetes in men and women who exercise.<sup>40</sup> A recent study<sup>41</sup> indicated that the level of activity is also important, demonstrating that vigorous activity is more beneficial than mild physical activity.

Following is a summary of new information regarding lifestyle and diabetes:

- Results from a monumental study by the Diabetes Prevention Program Research Group comparing the effect of lifestyle versus metformin versus placebo in the reduction of incidence of type 2 diabetes instigated a recommendation from the American Diabetes Association, among other groups, for change.<sup>42</sup> The surprise was that the reduction of the incidence of diabetes was 58% for those on the lifestyle intervention compared to 31% for those using metformin. Although this is similar to other findings, such as the Finland<sup>43</sup> and China<sup>44</sup> reports, the effects

were more dramatic. The researchers suggest that the primary reason may be the individualized approach used in their study. In addition to a low-carbohydrate, low-fat diet, participants engaged in physical activity of moderate intensity (such as brisk walking) for at least 150 minutes per week. They also participated in a 16-hour curriculum designed to support the changes in diet, exercise, and behavior modification. The goal was to maintain a weight reduction of at least 7% of the initial body weight.

- A 12-year follow-up study of over 42,000 males involved a comparison between two dietary regimens and the relative risk of type 2 diabetes. The researchers concluded that a Western dietary pattern (i.e., high in red meat, fat, refined grains, and sweets/desserts) combined with low physical activity or obesity substantially increased the risk of type 2 diabetes compared to a “prudent” dietary pattern (i.e., high consumption of vegetables, fruit, fish, poultry, and whole grains).<sup>45</sup> Another more recent study estimated the lifetime risk for type 2 diabetes in the United States. The researchers estimated that for individuals born in the United States in 2000, the lifetime probability of being diagnosed with diabetes for males was 33% and for females 39%.<sup>4</sup>
- Among many studies emphasizing the need for exercise in reducing the morbidity of diabetes, some indicate minor lifestyle changes may affect mortality. One such study indicated that if diabetic patients were convinced to walk two hours per week, the rate of death would decrease by one per year for every 61 people.<sup>46</sup> A similar outcome was found with women who performed an eight-week walking program of 10,000 steps/day, with benefits of improved glucose tolerance and a reduction in blood pressure.<sup>47</sup>

In a study<sup>48</sup> comparing physical activity levels with BMI and waist circumference and relationship to diabetes, researchers found that for both lean and obese men or women there was a benefit to physical activity in the reduction of diabetes. A reduction in the incidence of diabetes was found with even a modest increase in daily physical activity. An increase in activity equal to approximately 460 and 365 kJ/day in men and women, respectively, was independently associated with a 13% (HR 0.87, 95% CI 0.80, 0.94) and 7% (HR 0.93, 95% CI 0.89, 0.98) relative reduction. Beginning with general recommendations, the American Diabetes Association recommends a fiber-rich diet with a maximum of 30% fat (primarily mono- and polyunsaturated fats) and 50% to 60% complex carbohydrates. Specifically, foods that improve insulin sensitivity include:<sup>49</sup>

**Table 49-1** Diabetes Medications

Drug Class	Examples	General Mechanism	Interactions/Side Effects
Thiazolidinones	Rosiglitazone maleate  Avandia	An oral medication used as adjunct therapy with diet and exercise for type 2 diabetes. It acts primarily by increasing insulin sensitivity but is not related to sulfonylureas, the biguanides, or the alpha-glucosidase inhibitors.	Not to be used with nitrates. Hypoglycemic symptoms, edema, exacerbation of congestive heart failure (CHF). Note Avandia has been taken off the market in Europe since fall of 2010 and restricted in the U.S. to patients who do not respond to other medications due to its associated increase in cardiovascular risk.
	Pioglitazone  Actos	Attaches to nuclear receptors in cells to cause an increase in production of cellular proteins that facilitate glucose transport.	As thiazolidinones, Actos can worsen CHF. Also reported are stomach pain, nausea, blood in the urine, dysuria, blurred vision, chest pain, and swelling.
Sulfonylureas	Glipizide  Glucotrol Glucotrol XL	A sulfonylurea hypoglycemic agent used in the initial management of type 2 diabetes after dietary management without medication has failed. Has the effects of sensitizing functioning pancreatic beta cells to release insulin, and indirectly, increasing the number and sensitivity of insulin receptors.	May cause hypoglycemia, heartburn, pruritus, nausea/vomiting, hepatic porphyria, hypersensitivity, and visual disturbances.
	Glyburide  DiaBeta Glynase Micronase Euglucon	A sulfonylurea hypoglycemic agent used in the initial management of type 2 diabetes after dietary management without medication has failed. Has an effect of sensitizing functioning pancreatic beta cells to release insulin.	May cause hypoglycemia, heartburn, pruritus, nausea, or vomiting.
Biguanides	Metformin  Glucophage Glucophage XR	Biguanide hypoglycemic agent (not a sulfonylureas). Does not increase insulin production, but helps bind insulin to insulin receptors and potentiate insulin activity. Used in the treatment of type 2 diabetes. Sometimes in combination with sulfonylureas.	May cause abdominal complaints of pain, nausea, or vomiting. May interfere with absorption of folic acid and B <sub>12</sub> or amino acids. Patient may complain of a bitter or metallic taste. Caution for lactic acidosis.
Insulin	Insulin (many types)  NovoLog (RCA) Lantus (RCA) Humulin Novolin Iletin II Humalog (RCA)	These are recombinant human analogs (RCA) extracted from pork, used in the treatment of diabetes. Affects are to lower blood sugar levels by increasing peripheral uptake in muscle and fat, and promoting of conversion of glucose to glycogen (and inhibiting reverse).	Side effects related to hypoglycemia, profuse sweating, hunger, tremors, palpitations; also coma is possible.
Alpha-glucosidase inhibitors	Acarbose [Precose]  Miglitol [Glyset]	Reduces the rate of digestion of carbohydrates by competitive inhibition of enzymes needed to digest carbohydrates	Reported are abdominal pain, bloating, gas, and diarrhea. Caution for patients who have kidney or liver disease.
Dipeptidyl peptidase 4 inhibitor	Sitagliptin [Januvia]	Increases incretin levels which inhibit glucagon which allows increase in insulin secretion	Cough, sore throat, body aches, ear congestion, difficulty breathing, and abdominal pain.

- broccoli, cabbage, Brussels sprouts, cauliflower

- green leafy vegetables, beans, legumes
- vegetable protein (e.g., soy, peas)
- fiber including rice, oat bran, guar gum, psyllium
- foods rich in omega-3s

Complex carbohydrates are slowly digested so that the rise in blood sugar is more gradual. The advantage of vegetable proteins is that they contain soluble fiber, which decreases the insulin response. Also, protein stimulates the release of glucagon.

There are several strategies to help diabetic patients make decisions about which foods to eat. These include the exchange approach, the glycemic index, and the glycemic load. With the exchange approach, foods are grouped into categories such as starches, fruits, milk products, meats, vegetables, and fats. Each “exchange” means that foods and portions listed within each category can be substituted for each other. The substitutions represent generally the same caloric content and similar makeup of carbs, proteins, and fats. For example, each meat “exchange” choice contains 45 to 100 calories, 7 g of protein and 0 g to 8 g of fat. The basic currency of this program is a serving size of carbohydrates, which equals 15 grams. There is also a diabetes food pyramid, which suggests number of servings for each category of food. The glycemic index (GI) is an indicator of how quickly a consumed carbohydrate affects postprandial serum glucose levels. The value is based on a scale of 100, represented by glucose (or white bread). The lower the better. The problem with this approach is that some foods with a high glycemic index are actually in percent of total content low in sugar content, and the portion of the food determines the total glycemic effect. An example would be watermelon, which is primarily water but has a high glycemic index. The glycemic load (GL) attempts to correct for the glycemic index issues and adds in the feature of a “typical” serving portion of the food so that

foods that may have a high glycemic index may have a smaller impact based on the glycemic load, based on portion size, giving a more accurate measure of their glycemic effect in total. By combining these approaches, patients may find it easier to develop meal plans that are healthy and sustainable.

A number of foods have been evaluated for their role in controlling diabetes and hypertension. Although studies on humans are still pending, there is some evidence that these foods have either a high phenol content or have an effect on enzymes involved in glucose metabolism. Foods include yogurt (in particular, soy and fruit yogurts), pumpkins, cranberries, and fenugreek.<sup>50-52</sup> Taken together, this data seem to indicate that a diet including more fruits, vegetables, soy, and perhaps yogurt may be beneficial, especially in substitution for other commonly consumed foods in the traditional American diet. On the opposite end of the spectrum are the concerns of refined carbohydrates which tend to spike blood sugar levels, and more recently, meat intake. In recent studies,<sup>53,54</sup> reducing meat intake decreased the risk of diabetes. In one of these studies,<sup>53</sup> reducing intake by 0.5 servings per day decreased the risk of diabetes by about 14%.

Coffee consumption, up to six cups per day, has been shown in several studies and reviews to have an inverse effect on diabetes.<sup>55</sup> This is likely not related to the caffeine content because in some studies decaffeinated coffee also has an effect. The effects may be due to the high level of antioxidants and chlorogenic acid. One study<sup>56</sup> indicated that timing may be important. The results of this study indicated that coffee ingested at lunch had the largest effect. Tea may have a similar effect. In one study,<sup>57</sup> people who drank at least four cups of tea per day had a 16% lower risk of developing type 2 diabetes than non-tea drinkers.

A study by Norris et al.<sup>58</sup> evaluated the effects of omega-3 polyunsaturated fatty acid intake on islet cell

autoimmunity in children with an increased risk for type 1 diabetes. These included those with the genetic biomarkers, or with parents or siblings with type 1 diabetes. The outcome measures were being positive for insulin, glutamic acid decarboxylase, or insulinoma-associated antigen 2 autoantibodies on two consecutive visits, or diabetes at the last follow-up visit. Based on these outcomes, it appears there is a decreased risk for those children with a high omega-3 diet.

In addition to the recommendations of eating a healthy diet and keeping weight down, some specific dietary supplements and herbs have been suggested in the scientific literature (**Table 49-2**):

- alpha-lipoic acid<sup>59</sup>
- vitamin E<sup>60,61</sup>
- vitamin C<sup>62</sup>
- vitamin B<sub>6</sub> (pyridoxine alpha-ketoglutarate)<sup>63</sup>
- biotin<sup>64</sup>
- chromium<sup>65</sup>
- gymnema<sup>66</sup>
- Asian ginseng<sup>67</sup>
- aloe vera<sup>68</sup>

**Table 49-2** Nutritional Support for Diabetes

Substance	How Might It Work?	Dosage	Contraindications and Possible Side Effects
Vitamins C & E	May improve glucose tolerance in the elderly and in those with non-insulin-dependent diabetes (NIDDM).	900 IU vitamin E daily 1–3 g vitamin C daily	Side effects for vitamin E are rare. Diarrhea may occur at high doses of vitamin C. Also ensure adequate copper intake with high doses of vitamin C.
Specific form of B <sub>6</sub> (pyridoxine alpha-ketoglutarate)	May improve glucose tolerance.	1,800 mg/day	At very high levels, damage to sensory nerves leading to numbness in the distal extremities may occur. Caution patient to stop supplementation if symptoms appear.
Biotin	May improve glucose tolerance and reduce pain from diabetic neuropathy.	9 mg/day	None due to excretion in urine.
Chromium	May improve glucose tolerance.	200 to 800 mcg/day	At very high levels (> 1,000 mcg/day) severe liver or kidney disease is possible. For those using brewer's yeast, some people have allergies.
Magnesium	May improve insulin production.	300–400 mg/day	Some individuals develop diarrhea even at low doses. Individuals with kidney disease should consult physician.
Coenzyme Q10	Assists in carbohydrate metabolism.	120 mg/day	If patients have congestive heart failure, they should not suddenly discontinue taking.
Evening primrose oil	May improve diabetic neuropathy.	4–6g/day	None reported.
Alpha-lipoic acid	Antioxidant that may improve diabetic neuropathies.	600 mg/day	Skin rash and hypoglycemia are possible. Possible interference with biotin.
Inositol	May help improve diabetic neuropathy.	500 mg taken two times daily	None reported; however, individuals with chronic renal failure may have elevated levels.
Gymnema	May assist the pancreas in insulin production.	400 mg of gymnema extract daily	The safety of gymnema with pregnancy and lactation has not been determined.
Asian ginseng	May increase production of insulin and increase number of insulin receptors.	200 mg of ginseng extract per day	May cause overstimulation or insomnia. Patients with hypertension should consult with physician. Long-term use may result in menstrual abnormalities and breast tenderness. Not recommended during pregnancy or lactation.
Aloe vera juice	May lower blood sugar levels.	1 tablespoon twice daily	If used as a laxative, aggravation of constipation is possible.
Capsaicin ( <i>Capsaicin frutescens</i> or <i>annuum</i> )	A cream applied topically to deplete substance P at nerve endings in an attempt to relieve pain.	Cream base containing 0.025% to 0.075% capsaicin applied	Stings when first applied. Apply 4–5 times/day for at least 4 weeks to determine effectiveness.

Note: The above substances have not been approved by the Food and Drug Administration for the treatment of this disorder. None should be used in place of insulin and for those patients on hypoglycemic agents, consultation with prescribing MD is required.

Note: High levels (several grams/day) of niacin may impair glucose tolerance.

There is still debate as to whether supplementation with beta-carotene or magnesium is useful in the management or prevention of type 2 diabetes.<sup>69–71</sup> Refer also to [Chapters](#)

24, 29, and 51 for recommendations related to associated hypertension, weight gain, and hyperlipidemia.

Recent attention has been focused on the relationship between vitamin D and many chronic disorders. With regard to diabetes, a recent meta-analysis<sup>72</sup> published in *Diabetes Care* summarizes the studies to date as of 2013. As a generalized summary, low levels of 25(OH) D, resulted in a relative risk for type 2 diabetes of 0.62 (95% CI 0.54-0.70). Most importantly, this risk occurred regardless of gender, study size, or diabetes criteria. There was a relationship that was linear. For each 10 nmol/L increment in 25(OH)D levels there was associated 4% lower risk of type 2 diabetes (95% CI 3-6; P for linear trend < 0.0001).

For medical doctors managing type 2 diabetic patients, it is important to keep in mind that correction of hypertension may raise lipid levels if diuretics or  $\beta$ -blockers are used, or if, in an attempt to correct hyperlipidemia, a prescription for niacin is given. This could lead to an increased insulin resistance. Niacinamide (Inositol) may be an alternative. Women who are pregnant or on birth control pills may benefit from vitamin B<sub>6</sub> supplementation.

Specific complications of diabetes and their management are as follows:

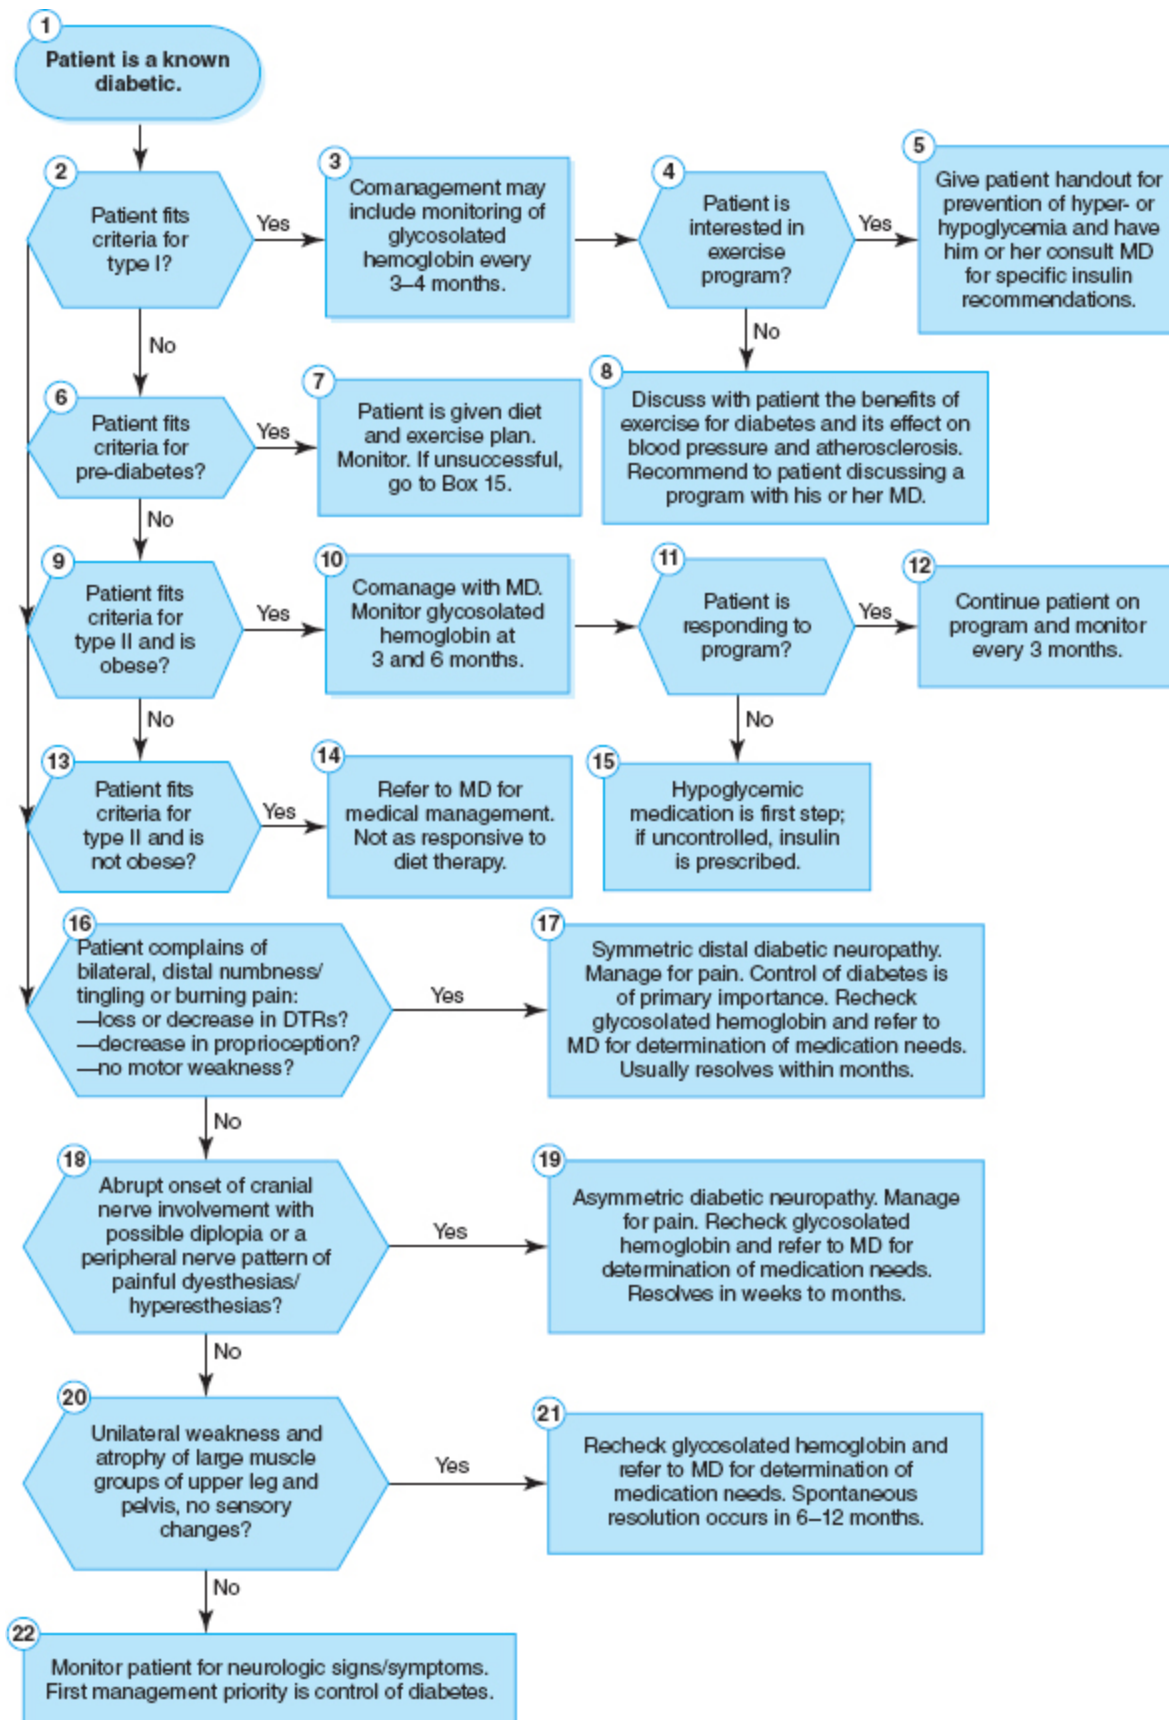

- Diabetic nephropathy—To prevent progressive deterioration, a low-protein diet, combined with hypertension control using an angiotensin-converting inhibitor, has been proven effective.
- Diabetic retinopathy—Good glycemic control, management of hypertension, and avoidance of smoking may help prevent the development of retinal changes. If neovascularization occurs, photocoagulation with an argon laser is sometimes effective.
- Diabetic neuropathy—Good glycemic control and avoidance of smoking are essential. Most of the poly-

and mononeuropathies will self-resolve in 6 to 12 months. Nutritional recommendations include vitamins B<sub>12</sub>, biotin, and inositol.

## Algorithm

An algorithm for evaluation and management of the diabetic patient is presented in **Figure 49-1**.

# CHAPTER 50

## Thyroid Dysfunction

### Context

Patients with thyroid dysfunction often have signs and symptoms that are suggestive of other disorders, including fatigue, depression, or other metabolic problems.

Determination of the appropriate patient to screen for thyroid disease is based on either a clinical presentation of overt disease or high-risk categories for asymptomatic patients. There is a general consensus that screening all patients for thyroid dysfunction is not cost-effective because of the low yield and the difficulty with sorting out small increases and decreases that may reflect a euthyroid state (temporary change with no thyroid pathology).<sup>1, 2</sup> Thyroid dysfunction is found in approximately 1% to 4% of the adult population of the United States with an annual incidence of 0.08% for hypothyroidism and 0.05% for hyperthyroidism.<sup>2</sup>

Epidemiologic studies have determined several groups of patients who are at higher risk. Those patients who are symptomatic often will have a constellation of signs of symptoms; however, there are a number of individuals who are subclinically dysfunctional. A percentage of these patients will progress to overt hypo- or hyperthyroidism. These categories include the following:

- Those with a risk 20 times that of the general population:<sup>3</sup>

- patients who have had radioisotope or radiation therapy
- patients with other autoimmune disorders
- patients with first-degree relatives with thyroid disease
- patients taking amiodarone hydrochloride

Those with a risk eight times that of the general population:<sup>4-6</sup>

- the elderly

Those with a risk four times that of the general population:<sup>7</sup>

- women over age 40 years

Consideration for screening in patients with minor risk:

- psychiatric patients<sup>8</sup>
- those patients taking lithium or who have a quickly fluctuating bipolar disorder

Neonatal testing is required in all states. This is due less to the risk (1 of 3,500 to 4,000 births) than to the devastating effects of not detecting what will become cretinism with its associated mental retardation and other neuropsychological effects.

Although there are a number of thyroid disorders and even temporal sequencing of hyper- and hypothyroidism with the same named condition, the majority of patients fit into two categories: (1) hyperthyroidism—most often due to Graves' disease, and (2) hypothyroidism—most often due to Hashimoto's disease. Hypothyroidism also may be due to treatment for hyperthyroidism with either radioactive iodine therapy or surgery. There are also age-related changes in thyroid physiology, which is why patients over age 65 years, especially women, must be considered for screening.

Thyroid dysfunction may also be due to secondary (pituitary) and tertiary (hypothalamic) disorders. Specific thyroid disorders and how they differ are listed under Selected Thyroid Disorders.

## **General Strategy**

### **History**

- Determine whether the patient has been diagnosed with a thyroid disorder or has had treatment for a thyroid disorder.
- Determine whether the patient has any complaints of fatigue, intolerance to heat or cold, tremors, or eye problems.

### **Evaluation**

- Determine whether a goiter is present.
- Determine whether there are secondary signs of hypothyroidism, including dry skin, loss of outer third of eyebrows, weight gain, slow speech, a decrease in deep tendon reflexes, or the more classic facial appearance of cretinism.
- Determine whether there are secondary signs of hyperthyroidism, including increased pulse rate and blood pressure, increased respiration, increase in deep tendon reflexes, detection of a fine tremor, exophthalmos, or lid lag.
- Screen asymptomatic patients at higher risk based on the above-listed categories.
- Run an ultrasensitive thyrotropin (uTSH) or thyroid panel on patients believed to have a thyroid disorder.

# Management

- Refer patients who fit classic laboratory criteria for overt thyroid disease.
- Educate patients who have subclinical thyroid disease about the pros and cons of treatment and refer to a medical doctor for a second opinion.

## Relevant Physiology

A feedback loop controls thyroid hormone production. When circulating thyroid hormone levels are low, pituitary thyrotroph cells are stimulated by hypothalamic thyrotropin-releasing hormone (TRH). TSH (thyrotropin) is then secreted from the pituitary to initiate several steps in the production of active thyroid hormone. Iodine is trapped and linked to tyrosine by peroxidase. Next, coupling of monoiodotyrosine and diiodotyrosine form  $T_3$  (triiodotyrosine) and  $T_4$  (thyroxine). The thyroid gland then secretes  $T_4$  and a very small amount of  $T_3$ .

$T_3$  is the most active form of thyroid hormone. Most of the circulating  $T_3$  is, in fact, produced via peripheral deiodination of  $T_4$  in the liver. Reverse  $T_3$ , an inactive form, is also produced. Thyroid-binding globulin (TBG) binds 99.95% of thyroid hormones. Therefore, any condition that affects protein levels will affect total thyroid hormone levels. These conditions include liver disease, pregnancy, estrogen levels, starvation, and acute or chronic illness. With severe illness the peripheral conversion of  $T_4$  to  $T_3$  is reduced even though there is no thyroid organ pathology.

## Evaluation

# History

Signs and symptoms suggestive of hyperthyroidism include nervousness, irritability, tremor, muscle weakness, heat intolerance, change in appetite, decreased or dysfunctional menstrual flow, and increased frequency of bowel movements. Many of these complaints are the result of increased metabolism. The patient may also notice a change in appearance, such as a neck mass, enlarged or more prominent eyes and associated eye irritation. Only 5% to 10% develop severe eye changes. Lymphocytic infiltration is the cause of exophthalmos and occasionally diplopia when the extraocular muscles become entrapped by infiltrates.

Patients with hypothyroidism may have complaints similar to those with hyperthyroidism. Complaints include weakness, tiredness, fatigue, depression, weight gain (true obesity is unusual), cold intolerance, dry skin, hoarseness, impaired mental function, joint pains and muscle cramps, and menstrual difficulties such as anovulatory bleeding and infertility. An enlarged gland may be apparent to the patient.

# Examination

The physical examination focuses on possible enlargement of the thyroid gland and the secondary effects of thyroid dysfunction on skin/hair, weight, myxoid deposition, and the cardiovascular system. The first aspect of evaluation of thyroid size and contour is inspection. Viewing the patient from the front and having him or her extend the neck often provides a better visualization of the thyroid. Cross-lighting may be helpful to better delineate contour. Next, viewing from the side, determine if there is any protrusion between

the cricoid cartilage and the suprasternal notch. Palpation of the thyroid has been described many different ways. Some of the variations are whether to palpate from behind or in front of the patient and whether to use the ipsilateral or opposite hand. No studies indicate any specific method as superior. The location of the thyroid gland is determined in relation to the thyroid and cricoid cartilage. Normally the thyroid gland is palpable on either side of the distal half of the thyroid cartilage down to the upper trachea. Palpation is facilitated by relaxing the sternocleidomastoids. This is accomplished by having the patient flex and rotate the head to the ipsilateral side of palpation. It is often recommended that having the patient swallow may assist in determining size and possibly reveal a low-lying gland. It is important to have the patient swallow a sip of water, only because the larger the amount of water, the more the excursion, the more difficult the task of discrimination from other structures.

Some individuals are difficult to palpate. These include the obese, the elderly, and those with chronic pulmonary disease, where the neck is relatively short. Errors may occur due to misinterpretation in the following patients:<sup>9</sup>

- overestimation of size in thin individuals or those with long, slender necks (Modigliani syndrome)
- overestimation due to a more superior location (normal variant)
- misidentification of a fat pad in the anterior and lateral neck as a goiter (pseudogoiter) found in the obese and those of normal weight (in particular young women) (the fat pad does not move with swallowing and the texture is different from that of the thyroid)
- underestimation due to a low-lying thyroid (can be retrosternal)
- underestimation due to sternocleidomastoid interference

Interexaminer agreement on the detection of a goiter and whether individual lobes are enlarged has been demonstrated to be very good.<sup>10, 11</sup>

Additional maneuvers such as measuring neck circumference and determining mobility, modularity, and texture are more subtle and not necessarily consistently rated by examiners. Auscultation for bruits may provide a clue to a hyperfunctioning gland. It is important to remember that a goiter may appear with either hyper- or hypothyroidism and does not help to distinguish between them. It is also possible to have no enlargement and have either disorder.

Patients with hyperthyroidism may have a widened pulse pressure and tachycardia. Approximately 10% to 25% of patients will have atrial fibrillation. Confirmation with an electrocardiogram is needed. In postmenopausal women, bone loss is increased and may be confirmed with dual x-ray absorptiometry.

## **Laboratory Testing and Management**

Laboratory testing for thyroid dysfunction can be extremely confusing. However, in the context of chiropractic practice, most cases of dysfunctional thyroid can be detected by running a uTSH test.<sup>12</sup> The advantages of this test are that it can discriminate between euthyroidism (increased levels due to an underlying disorder/disease), which is transient, and overt thyroid dysfunction. When the TSH is elevated, it should be rerun adding FT<sub>4</sub> and a thyroid autoantibody panel. If the TSH is high and the FT<sub>4</sub> is low, the patient is hypothyroid. If there is an elevation of anti-thyroperoxidase (anti-TPO) antibodies, it is likely the patient has Hashimoto's disease. If the TSH is high and the FT<sub>4</sub> is normal, the patient is considered to be subclinically hypothyroid. Recommendations are to recheck TSH levels every three to

six months for the first year and every six to twelve months thereafter. Referral for medical management is suggested by some practitioners, especially when there is a high level of autoantibodies.

When the TSH is low, rerun with  $FT_4$  and  $FT_3$  with a thyroid autoantibody panel. If the TSH is low and either the  $FT_4$  or  $FT_3$  is elevated, the patient is hyperthyroid. If there is an elevation of thyroid antibodies, specifically thyroid-stimulating immunoglobulin (TSI) antibodies, and activating thyrotropin receptor antibodies (TRAbs), it is likely that the patient has Graves' disease. If the TSH is low and the  $FT_3$  and  $FT_4$  are normal, the patient is considered subclinically hyperthyroid. If the TSH is low, or if it is minimally high or normal with a low  $T_4$ , a search for hypothalamic or pituitary disease is necessary. It is important to note that thyroid function tests are often abnormal in hospitalized and severely ill patients. This may represent a temporary dysfunction and cannot be viewed with the same degree of trust as with the ambulatory patient.

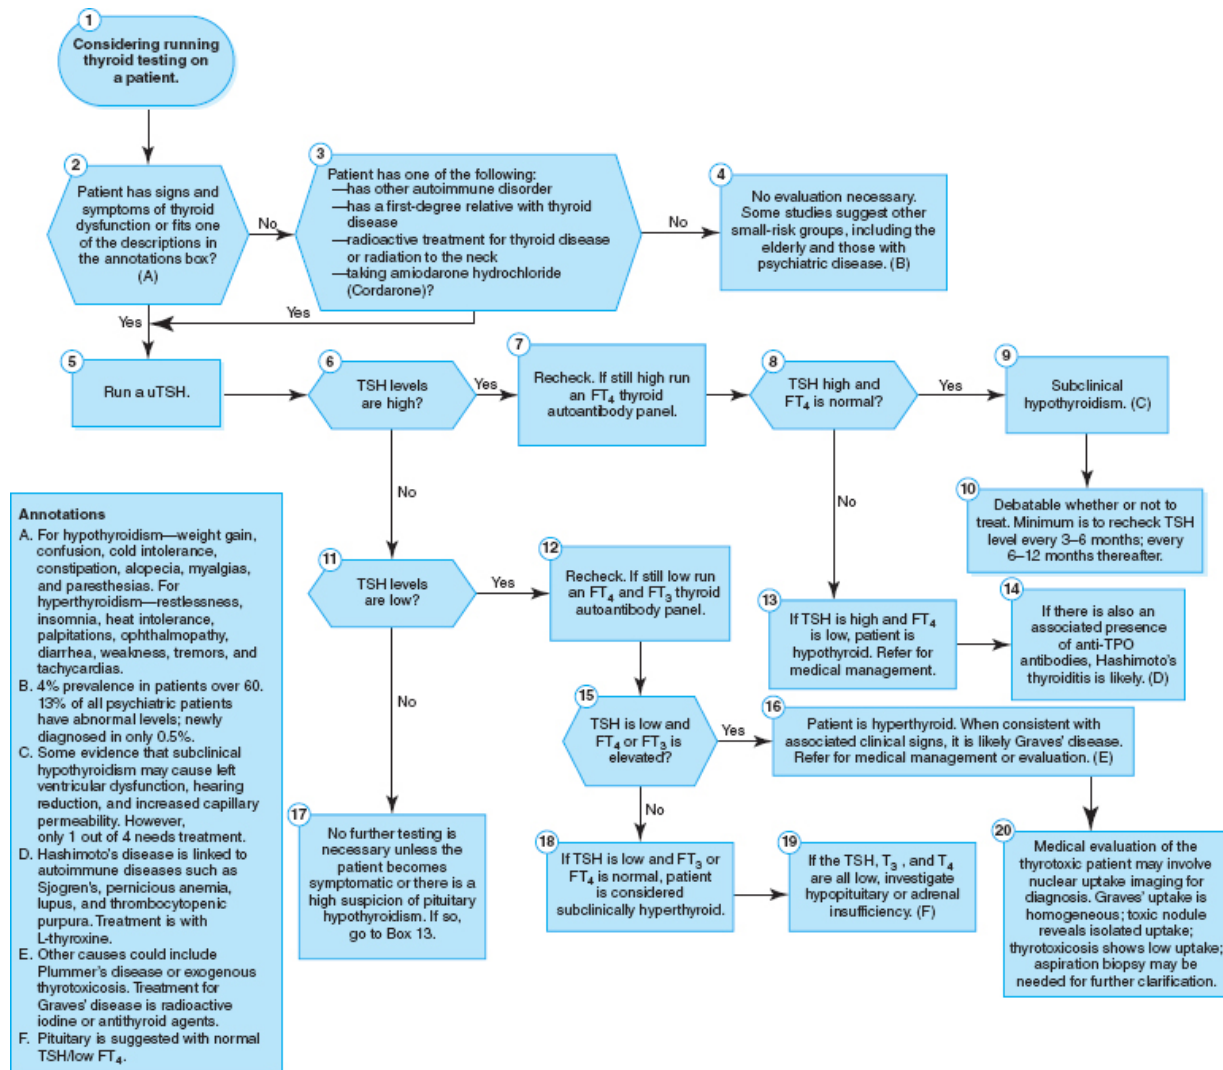

Additional findings with hypothyroidism include macrocytic anemia, increased creatinine phosphatase, and hyperlipidemia. Hyperthyroidism may also demonstrate hypercalcemia, increased alkaline phosphatase, anemia, and decreased granulocytes.

## Algorithm

An algorithm for thyroid lab evaluation is presented in **Figure 50-1**.

**Table 50-1** Thyroid Medications

Drug Class	Examples	General Mechanism	Interactions/Side Effects
<b>Levothyroxine sodium</b>	Eltroxin Synthroid Levoxyl Levothroid Unithroid	A synthetic version of thyroxine ( $T_4$ ) used to treat hypothyroidism and to suppress thyroid hormone release with cancerous thyroid nodules.	May cause similar effects of hyperthyroidism related to increased metabolism including palpitations, hypertension, agitation, insomnia, heat intolerance, weight loss, leg cramps, arrhythmias, headache, menstrual irregularities such as anovulatory bleeding.
<b>Liothyronine (<math>T_3</math>)</b>	Cytomel Triostat	Replaces $T_3$ in hypothyroid patients. Used in the 3 suppression test. Main use is for those patients who do not respond to levothyroxine (Synthroid).	Overdose effects are signs/symptoms of hyperthyroidism.
<b>Methimazole</b>	Tapazole	Blocks transformation of inorganic iodine to organic iodine. Blocks conversion of $T_4$ and $T_3$ . Often used to produce a euthyroid state prior to radiation or surgery. Long-term use may produce euthyroid state in half of patients.	May cause headache, vertigo, nausea, vomiting, hepatitis, myelosuppression, leucopenia, and rarely agranulocytosis. May elevate prothrombin time and liver enzymes.
<b>Propylthiouracil (PTU)</b>	Propyl-Thyracil	Blocks transformation of inorganic iodine to organic iodine. Often used to produce a euthyroid state prior to radiation or surgery. Long-term use may produce euthyroid state in half of patients.	May cause headache, vertigo, nausea, vomiting, hepatitis, myelosuppression, leucopenia, and rarely agranulocytosis. May elevate prothrombin time and liver enzymes.

**Figure 50-1** Thyroid Lab Evaluation—Algorithm

# Selected Thyroid Disorders

## Graves' Disease

### Classic Presentation

A woman (8:1 ratio to men) between the ages of 20 and 40 years presents with complaints of nervousness, weight loss, palpitations, fatigue, heat intolerance, or menstrual irregularities.

### Cause

Graves' disease (also called Basedow's disease) is an autoimmune disorder. Autoantibodies are formed that bind to the TSH receptors, stimulating hyperactivity of the thyroid gland. Thyroid autoantibodies that cause increased secretion of thyroid hormone are thyroid-stimulating immunoglobulin (TSI) antibodies, and activating thyrotropin receptor antibodies (TRAbs). A familial tendency with an association with HLA-B8 and HLA-DR3 has been found.

### Evaluation

Hyperthyroidism is usually evident on examination because of the hypermetabolic state and ophthalmopathy. Tachycardia and atrial fibrillation are possible findings and should be evaluated with an electrocardiogram (ECG).<sup>13, 14</sup> A fine resting tremor, hyperreflexia, fine hair, and moist, warm skin are often found. The eyes may appear protuberant (exophthalmos) and this may be associated with other eye signs, including lid lag and diplopia due to lymphocytic infiltration. The eye changes are not an indication of the severity of the disease.<sup>15</sup> Exophthalmos may be unilateral or bilateral. Pretibial "myxedema" is found in about 3% of patients with Graves' disease. This is an infiltrate on top of the tibia that has the texture of the skin of an orange. The classic pattern found on lab testing includes a decreased TSH with elevated FT<sub>4</sub> with elevated levels of thyroid-stimulating immunoglobulin (TSI), and activating thyrotropin receptor antibodies (TRAbs).

# Management

Treatment involves symptomatic management with  $\beta$ -blockers and the use of drugs that inhibit function, such as methimazole or propylthiouracil.<sup>16</sup> The latter drugs are commonly used in children and pregnant women. Alternatives include radioactive iodine treatment and surgery. Radioactive iodine treatment is contraindicated in pregnancy. Opponents feel that radioactive iodine will predispose the individual to cancer or damage an individual's genetic pool. Surgery is used less often than radioactive iodine and is more likely offered as an alternative for pregnant women unresponsive to medication.<sup>17</sup> When surgery is performed, the patient must be made euthyroid with medication if possible. Complications with surgery can include recurrent laryngeal nerve damage, leading to vocal cord paralysis, and damage to the parathyroid gland, which may lead to hypoparathyroidism. Post surgery, patients may eventually become hypothyroid requiring prescription of synthetic thyroid medication.

## Hashimoto's Disease

### Classic Presentation

The patient with overt hypothyroidism presents with multiple body complaints including weakness, fatigue, arthralgias, constipation, and cold intolerance. Other complaints may include headache, menstrual dysfunction, thinning hair, dry skin, and mental difficulties. The only helpful differentiation from many other similar presentations is a goiter. The patient may present first with a goiter and no other complaints.

### Cause

Hashimoto's disease is an autoimmune disorder characterized by lymphocytic infiltration of the thyroid. Antibodies to the thyroid that decrease thyroid production with Hashimoto's include those against thyroglobulin called anti-TG antibodies and those against thyroperoxidase called anti-thyroperoxidase, also called anti-TPO antibodies. Hashimoto's disease is more common in women and demonstrates a familial relationship.

### Evaluation

Signs may be subtle. Check for loss of lateral third of eyebrows, bradycardia, an enlarged tongue, and decreased deep tendon reflexes. A goiter may or

may not be palpable due to individual and disease variation. The classic pattern found on lab testing for Hashimoto's is an increased TSH, decreased FT<sub>4</sub> and elevated levels of anti-TG and/or anti-TPO antibodies.

## **Management**

Levothyroxine replacement therapy is used for primary hypothyroidism. Reevaluation is performed at six- to eight-week intervals until the TSH levels have normalized. After normalization of TSH, the level should be checked every six to twelve months.

## **Subacute Thyroiditis (De Quervain's Thyroiditis)**

### **Classic Presentation**

The patient is more likely Caucasian or Chinese and presents with a complaint of anterior neck pain that followed a viral prodrome (myalgia, low-grade fever, sore throat, and tiredness), often in the summer or fall. Associated symptoms may be palpitations, diaphoresis, and tachycardia.

### **Cause**

Apparently viral in origin, subacute thyroiditis is an acute, self-limited inflammatory disorder of the thyroid. There appears to be an autoimmune abnormality and an association with HLA-Bw35 in Caucasian and Chinese patients. Women are more commonly affected (range from 3:1 to 6:1), with an onset between ages 30 and 50 years.<sup>18</sup>

### **Evaluation**

Palpation usually reveals a very tender, nodular goiter, but a goiter is not always found. Thyroid function tests indicate hyperthyroidism; however, a coupled finding of a reduced radioactive iodine uptake is diagnostic. A normal thyroglobulin level generally rules out primary hyperthyroidism.

### **Management**

Referral for medical management is necessary, although many patients are treated with aspirin in the initial stages. Occasionally, patients with dysphagia due to an enlarged gland need prednisone (20% experience rebound swelling when drug is withdrawn).<sup>19</sup>  $\beta$ -blockers are occasionally used for the

hypermetabolic symptoms. Antithyroid drugs are useless; the disorder has nothing to do with synthesis of thyroid hormone, only release of existing preformed hormones. Recovery is common in three to six weeks; however, 30% of patients develop hypothyroidism due to follicular cell destruction. Ninety percent of these patients recover in four to six weeks. Ten percent are permanently hypothyroid.<sup>20</sup>

## **Silent Thyroiditis**

### **Classic Presentation**

A woman who is four to eight weeks postpartum presents with complaints of nervousness and palpitations.

### **Cause**

Antithyroid antibodies are found in 50% to 80% of patients, suggesting an autoimmune process. Although this entity may occur in men and women, the most common form is found in women (4:1). Thyroiditis may occur sporadically in either gender, but postpartum presentation is common in women. Hormonal shifts postpartum may act as a trigger. The postpartum and sporadic types account for between 5% and 20% of all hyperthyroidism. Six percent of patients may have persistent hypothyroidism.<sup>21</sup>

### **Evaluation**

Thyroid palpation will reveal a nontender goiter in almost 50% of patients. Other findings are secondary to an initial hyperthyroidism for a few weeks, which may be followed by a 4- to 16-week period of hypothyroidism in 40% of patients. There is a low radioactive uptake in this disorder, distinguishing it from true hyperthyroidism.

### **Management**

Generally reassurance is all that is needed. However, in some patients, referral may be necessary for medical management of transient symptoms, including  $\beta$ -blockers. There is no place for antithyroid medication in the treatment of silent thyroiditis.

## **Acute Thyroiditis**

# Classic Presentation

Patients present with an abrupt onset of intense anterior neck pain with associated signs of fever and chills; it occurs more often in women.

## Cause

Sometimes referred to as suppurative thyroiditis, this rare disorder is usually due to *Staphylococcus aureus*, *Streptococcus pyrogens*, or pneumonia, although parasites and fungi are possible causes. Infection is hematogenous, lymphatic, or through a persistent thyroglossal duct. Fifty percent of patients have a history of thyroid disease.

# Evaluation

Acute thyroiditis is usually apparent because of the abrupt onset and a tender thyroid. Laboratory results indicate normal thyroid function, an elevated white blood cell count with a shift to the left, and a normal radioactive iodine uptake.

# Management

Refer for medical management of underlying infection.

## Riedel's Thyroiditis

# Classic Presentation

A middle-aged or elderly woman presents with a slowly enlarging, hard anterior neck mass that is not tender.

## Cause

This extremely rare condition is due to replacement of thyroid tissue with dense fibrous tissue.

# Evaluation

Palpation reveals a very hard thyroid gland. Laboratory tests usually reveal a normally functioning gland. In some patients, complete replacement of thyroid tissue will result in hypothyroidism evident on laboratory tests.

## Management

Generally, the patient is monitored for progression to hypothyroidism, at which time thyroid replacement therapy is necessary. Surgical treatment is reserved for those with compressive complaints due to thyroid enlargement.

## Thyroid Cancer

### Classic Presentation

A patient with a past history of irradiation of the head or neck presents with a painless swelling in the region of the thyroid.

### Cause

Papillary carcinoma or mixed papillary/follicular cancer accounts for 70% of all thyroid cancers, yet it is the least aggressive. Follicular cancer accounts for about 15% of cancers and is responsible for more metastases. Thyrotoxicosis rarely occurs with thyroid cancer.

### Evaluation

Palpation of the thyroid will reveal a hard nodule in an enlarged gland and in some cases, palpable lymph nodes. Fine-needle biopsy is most useful in distinguishing benign (70% of time) from malignant (5%) tumors.<sup>22</sup> Thyroid function tests are usually normal. Occasionally, calcitonin levels are elevated. Radioiodine uptake testing usually demonstrates malignancies as “cold” lesions representing nonfunctioning tissue. Fine-needle aspiration is the test of choice. Metastatic lesions may be visible on radiographs or bone scans.

## Management

Refer to oncologist.

---

# CHAPTER 51

## Hyperlipidemia

### Context

The leading cause of death in the United States is coronary artery (heart) disease (CAD or CHD).<sup>1</sup> It is estimated that by the year 2020 cardiovascular disease will be the leading cause of death and disability.<sup>2</sup> Although there are many contributing factors to the development of coronary heart disease (CHD), a recent study emphasized that 80% to 90% of individuals with CHD have the four “conventional” risk factors.<sup>3</sup> These are cigarette smoking, hypertension, diabetes, and hyperlipidemia. The focus must be on lifestyle changes, including smoking cessation and the control of the other three factors that are interrelated. The second leading cause of death by disease is cancer; the third is diabetes.<sup>4</sup> There is evidence to suggest that some cancers are linked to high-fat diets. Adult-onset diabetes is strongly linked to diet. It would seem that the philosophy of prevention held by the chiropractic profession would dictate that part of a patient’s care must involve intervention in areas such as these that do not require (and may prevent) the use of drugs or surgery and may prevent morbidity and mortality. Realistically, changes in diet and smoking habits are some of the most difficult to effect. Yet, the chiropractor is ideally positioned to provide either a direct or indirect comprehensive “wellness” program for his or her patients. Promotion of healthful eating and exercise should be a

cornerstone in the management of all patients, regardless of current CHD status.

There are at least 10 meta-analysis studies of randomized trials that have attempted to address the effectiveness of cholesterol reduction and its effect on CHD.<sup>5-7</sup> It appears that for each 1% decrease in serum cholesterol, there is a 2% to 3% reduction in risk for CHD. This occurred in trials using drugs or diet. There is some controversy regarding the use of drugs in patients without CHD regarding cost, and an interesting increase in noncoronary mortality.<sup>8</sup> However, most agree that symptomatic men unresponsive to diet will benefit from drug intervention if it is monitored and reduced when appropriate. The reduction of serum cholesterol and decrease in CHD risk is not as clear in women. Women statistically have their onset of CHD approximately 10 years later than men, beginning at age 45 years. This delay is probably related to the protective effects of estrogen.<sup>9</sup> However, 49% of all CHD-related deaths in the United States are women.<sup>1</sup>

## General Strategy

- Do not screen all individuals. Men aged 35 years and over, women aged 45 years and older, those with CHD or more than two risk factors, and children with a familial predisposition should be screened. Further testing is based on baseline results.
- Determine an individual's risk factors for CHD, including age, gender, physical activity/inactivity, smoking, obesity, hypertension, and diabetes.
- Order a lipid panel that includes total cholesterol, high-density lipoprotein cholesterol (HDLc), low-density lipoprotein cholesterol (LDLc), and triglycerides if the patient is at risk for CHD or has known CHD.

- Combine findings from the lipid panel with risk factors and make treatment/referral decisions.
- Order lipoprotein electrophoresis if patients have an isolated elevation of triglycerides that is suggestive of a familial disorder.
- Remember that for those patients without CHD or less than two risk factors, diet and exercise are the main approach; for those with CHD or two or more risk factors, a trial of diet therapy is usually attempted for three to six months; when not responsive, drug therapy may be indicated.

## Relevant Physiology

Cholesterol is not in and of itself bad. It is, in fact, essential to the body for the production of bile and the construction of cell membranes, myelin, and steroid hormones. The liver produces half the body's cholesterol; the remainder is acquired through the diet.<sup>10</sup> There are two main fats carried in the blood: cholesterol and triglycerides. They are packaged with proteins (apoproteins) into lipoproteins. The lipoproteins are classified based on density. The higher the triglyceride content, the less dense they are. The three main lipoproteins are HDLs, LDLs, and very-low-density lipoproteins (VLDLs). Therefore, LDLs contain about 75% lipid and 25% protein, whereas HDLs contain about an equal ratio. The general sequence of interaction is that VLDLs produced in the liver transport triglycerides to cells. When the VLDLs have lost a sufficient amount of triglyceride, they become LDL particles. LDL then provides cholesterol to the cells. Any excess of LDL is metabolized in the liver, providing cholesterol for bile. LDLs that are oxidized are potentially more harmful because of the direct effects on the arterial wall, and possibly through antibodies developed against the oxidized LDLs.<sup>11</sup> HDLs are produced in the liver

and assist in transfer of apoproteins among the other lipoproteins. It is well known that HDLs may be protective through a mechanism referred to as reverse cholesterol transport—carrying excess cholesterol to other lipoproteins or to the liver.<sup>12</sup>

Hyperlipidemia is a term used to describe an increase in either plasma cholesterol or plasma triglycerides. These may occur in combination or in pure forms. Generally there are three main causes: (1) dietary, (2) genetic, and (3) secondary to other diseases or drugs. One distinction is that the dietary forms are generally milder than the genetic forms. In effect, hyperlipidemia is the same as hyperlipoproteinemia because there is always a problem with one of the steps in lipoprotein metabolism. For example, there may be a problem with the production, lipolysis, removal, or conversion of VLDL. The diagnosis is usually made when a lipid electrophoresis reveals an abnormally high fraction or combination of fractions of the lipoprotein pool.

One cause of high LDLc is familial hypercholesterolemia.<sup>13</sup> It is believed to be due to a defect in the LDL receptor gene, resulting in a reduced ability to process LDLc particles. This results in an LDLc level that is approximately twice that of normal. Many patients have an additional contribution to high LDLc from high dietary intake. These patients have an increased risk of developing CHD in their 30s and 40s. They are more likely to need drug therapy, especially if their LDLc levels remain above 190 mg/dL. Patients with a rare homozygous (two abnormal genes) form have absent surface receptors for LDLc and have extremely high levels of LDLc, with atherosclerosis development in childhood.

Another condition is called mixed hyperlipidemia, metabolic syndrome X, or familial hyperlipidemia (although these are not always synonymous). Most patients show a central obesity, hyperinsulinemia, hypertension, elevated

triglycerides, low HDLc, and elevation of small LDL subfractions. Because these patients are prone toward diabetes and hypertension, they should be evaluated and monitored for these conditions. Patients with mixed hyperlipidemia respond favorably to even small decreases in weight. One ironic complication is that if total fat is reduced below 30% of total calories, there may be a compensatory increase in carbohydrate intake that may then stimulate the production of verylow-density lipoprotein cholesterol (VLDLc).

Triglycerides are more subject to changes in food consumption prior to laboratory investigation. An isolated increase in triglyceride levels is often due to a patient's not fasting or perhaps drinking coffee with cream prior to giving the laboratory sample. There are a number of lipid disorders that result in isolated triglyceride elevation. Usually the triglyceride levels are 1,000 mg/dL or above while the LDLc levels are often low or normal. Although there appears to be a genetic component, poor diet and lack of exercise seem to make the disorder more obvious. These patients can have a predisposition to pancreatitis, especially if they drink alcohol. Therefore, questioning regarding abdominal pain and counseling against excessive alcohol ingestion are warranted. Exercise and weight loss are the main treatment approaches. If unsuccessful, referral for medical management is necessary. There is disagreement as to the risk for patients with an isolated triglyceride elevation without a concomitant LDLc elevation.

## **Evaluation**

## **History**

The history is important in determining the level of concern with any individual cholesterol level. There are specific risk factors for CHD that significantly affect management decisions. Nonmodifiable, but significant, factors include age (45 years or older in men; 55 years or older in women), male gender, premature menopause (without estrogen replacement therapy), and a family history of premature CHD (myocardial infarction or sudden death before age 55 years in father or other male first-degree relative or before age 65 years in mother or other female first-degree relative). The modifiable risk factors include cigarette smoking (more than 10 per day), obesity (more than 130% of ideal total body weight), hypertension, physical inactivity, an HDLc level below 35 mg/dL, and diabetes mellitus. It is interesting to note that with the exception of smoking, the other risk factors are often interdependent. In other words, a patient who is inactive is more likely to become obese. Being obese is a predisposition for adult-onset diabetes, which is associated with hypertension. The other modifiable factor is diet. Although diet cannot always lower cholesterol levels, a low-fat diet is often instrumental in controlling obesity, diabetes, and hypertension.<sup>14</sup> Therefore, a careful diet history is important in determining the level of daily fat intake and its possible relationship to high levels of cholesterol and LDLc.

## **Laboratory Evaluation**

There is some basic agreement as to who should be screened for high blood cholesterol. Men between the ages of 35 and 65 years and women between the ages of 45 and 65 years should be screened with either a fasting or nonfasting specimen to obtain a baseline reading.<sup>15</sup> The recommendation for how often these individuals should be screened varies. The strictest guidelines are from the

National Cholesterol Education Program (NCEP) Adult Treatment Panel II, which recommends screening of nonfasting total cholesterol and HDLc every five years in all asymptomatic individuals aged 20 years and older.<sup>16</sup> These recommendations are similar to those of the American Academy of Family Physicians and the American College of Obstetricians and Gynecologists.<sup>17,18</sup> Most groups recommend selective screening of children and adolescents based on risk factors.<sup>19,20</sup> Children with a parental history of hypercholesterolemia should be screened with a nonfasting test for total cholesterol. Those with a family history of premature CHD should be screened with a fasting lipid profile. Children with multiple risk factors such as obesity and smoking should be considered for a screening lab test. Most groups agree that screening of individuals over the age of 75 years is not warranted.<sup>21</sup>

Total cholesterol is the sum of HDL-C, LDL-C, and very-low-density lipoprotein cholesterol (VLDL-C). Although total cholesterol and HDL-C and triglycerides are relatively easy and inexpensive to measure, LDL-C and VLDL-C are not.<sup>22</sup> To resolve this issue and provide a practical approach clinically, a formula was developed by Friedewald in the 1970s. Using this formula, VLDL-C can be estimated based on a ratio to the total level of triglycerides. This ratio of triglycerides to VLDL-C (TG:VLDL-C) levels is on average 5:1. Using this observation, the Friedewald formula was created to estimate the LDL-C: This formula is  $LDL-C = (TC) - (HDL-C) - (triglycerides / 5)$  in mg/dL. Several attempts have been made, even as late as 2013, to better this estimate given some known concerns, primarily that the formula is not accurate when triglycerides are high. If the triglyceride levels are above 400 mg/dL, the formula is inaccurate and requires a more costly direct LDL-C measurement be utilized. In addition, the TG:VLDL-C ratio is not constant across the range of triglyceride levels and also varies based on the total cholesterol levels. Newer formulas are

complicated and may not add to the clinical value of this estimation. Many argue that given that higher levels of both LDL-C and VLDL-C are the concern regarding atherosclerosis it may be better to continue to use the approach that has been used for years, which simply divides the total cholesterol into the “good” (HDL-C) and the “bad” (non-HDL-C). In other words, treatment approaches as measures could be based on non-HDL-C instead of those for LDL-C.

Interpretation of laboratory results is not a simple process of using a high cut-off value; for example, all levels above 200 mg/dL are bad. The relationship of cholesterol to risk is multivariable, including modifiable and nonmodifiable factors as discussed above. It is also important to refer to a cholesterol result as fitting into a range as opposed to a specific value. The reason for this caution is that cholesterol levels vary with many “outside” influences such as minor illness, stress, posture, and season.<sup>23</sup> This variation may be as much as 4% to 11% for an individual. In addition, laboratory values may not reflect a “true” cholesterol. Laboratory error and variation in equipment or operation of the equipment may affect readings. Finger-stick methods are biased toward a high range averaging between 4% and 7% more than a venipuncture specimen.<sup>24</sup> New desktop machines have been introduced that produce reliable readings; however, some machines do not meet required standards. Given the possible influences on a specific reading, the variation in an individual can be as high as 14%. It is important to note that reliability for HDLc is less than that for total cholesterol, with an average variation as much as 10% from a reference standard. Triglycerides are even less reliable. Therefore, a single measure is insufficient if high, and rechecking with a second sample is often suggested. If the two measurements (performed on different days) differ by more than 16%, a third sample is recommended.

Generally, if a patient's total cholesterol is 240 mg/dL or above or the level is between 200 and 239 mg/dL with known CHD or two risk factors, a lipid panel (cholesterol LDLc, HDLc, and triglycerides) should be performed. Based on the LDLc levels, decisions regarding diet or medication can be made. For patients with an isolated low level of HDLc (cholesterol, LDLc, and triglycerides are normal), it is important to rule out secondary causes. Investigation for possible thyroid, liver, or renal dysfunction should be included. Other possible causes are medications and acute illness.

Additional testing beyond a standard lipid panel is warranted when a primary (familial) hyperlipoproteinemia is suspected. The suspicion is based on either extremely elevated, isolated levels of triglycerides, or cholesterol, or LDLc, or a history of unresponsiveness to dietary changes. For these patients, a lipoprotein electrophoresis will help distinguish among the five types and their subtypes. Refer to **Table 51-1** for a description of these familial disorders, their associated risk for CHD, and general treatment recommendations.

New biomarkers that are linked to the pathogenesis of atherosclerosis progression may be used to help determine further cardiovascular risk in some patients.<sup>25</sup> Some possible future testing approaches follow:

- Markers of lipoprotein and lipid metabolism such as lipoprotein (a) or apolipoprotein B
- Measures of vitamin B<sub>12</sub> metabolism such as vitamin B<sub>12</sub> levels (possible inverse relationship to homocysteine)
- Homocysteine levels
- C-reactive protein levels (increased in patients prone toward coronary events)
- Infectious agents such as Chlamydia, cytomegalovirus, *Helicobacter pylori*, and herpes simplex have been tied

to increased risk of CHD through involvement in atherosclerotic plaque development<sup>26</sup>

- Increased levels of fibrinogen, fibrinogen beta mutation, plasmin-alpha-antiplasmin complex, plasminogen activator inhibitor I, tissue-type plasminogen activator, and D-dimer may identify high-risk individuals for coronary events
- Increased levels of markers for endothelial function and cell adhesion
- Angiotensin
- Levels of vitamins C and E (antioxidants) and vitamin D
- Markers of oxidative stress such as serum 7 beta-hydroxycholesterol, F2-isoprostanes, and nitric oxide synthase polymorphisms

A recent study indicated that although C-reactive protein, lipoprotein (a), fibrinogen, and homocysteine are clear indicators of risk for atherosclerotic disease, how to use them in routine screening has yet to be determined.<sup>27</sup>

Although a number of lipid measures for prediction of coronary heart disease (CHD) are available, it has been unclear as to their value when matched to standard measures. A study published by Inglesson et al.<sup>28</sup> in 2007 indicates that measurement of apoB/apoA-1 ratio provided no more sensitivity in prediction of CHD than the traditional lipid ratio of total cholesterol/HDLc.

## Management

Using only total cholesterol measurements to make management decisions may lead to unwarranted concern or confidence. As discussed above, high-normal levels may be the result of lab error or variation. Approximately 20% of men with confirmed CHD have a cholesterol level below 200 mg/dL with an HDLc below 35 mg/dL. It is clear that women

with high cholesterol levels, especially those who appear healthy, should not be assumed to be at risk unless confirmed with an associated low HDLc. Men who have a low cholesterol level but either are symptomatic for CHD or have significant risk factors should be tested for a low HDLc. In the past, a simple ratio was used between total cholesterol and HDLc, but this may be misleading. For example, two individuals may have a ratio of 5:1. In one individual the total cholesterol is 240 mg/dL with an HDLc of 48 mg/dL; the other individual has a total cholesterol of 150 mg/dL with an HDLc of 30 mg d/L. The second individual may be at more of a risk than the first based on the low HDLc, especially when other risk factors are added.

Published in 2013 was a new ACC/AHA Guideline on the Treatment of Blood Cholesterol to Reduce Atherosclerotic Cardiovascular Risk in Adults: A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines<sup>29</sup> and an online calculator to determine risk. Immediately criticism arose regarding the implications of adopting this new approach. In particular, the calculator appears to overestimate the risk to the point where individuals using the prior estimation of risk are now double the risk using the new calculator. It appears that this might be an attempt to increase the use of statin drugs. It is conjectured that because the calculator data were collected more than a decade ago, at a time when more people smoked and had strokes and heart attacks earlier in life, that the data do not reflect the current status of the general population. It has been estimated that the calculator may overpredict risk by as much as 75% to 150%, depending on the population.

**Table 51-1** Characteristics of the Primary Hyperlipoproteinemias

Type	Name	Clinical Presentation	Risk of Coronary Heart Disease	Plasma Cholesterol Level	Plasma Triglyceride Level	Genetic Form	Secondary Causes	Treatment
I	Exogenous hypertriglyceridemia Familial hyperglyceridemia Familial chylomicronemia Fat-induced hyperlipidemia Hyperchylomicronemia	Pancreatitis Eruptive xanthomas Hepatosplenomegaly Lipemia retinalis	Risk not increased	Normal or slightly increased	Very greatly increased	Autosomal recessive, rare	Systemic lupus erythematosus; dysgammaglobulinemia; insulinopenic diabetes mellitus	Dietary: low intake of fat; no alcohol
II	Familial hypercholesterolemia Familial hyperbetalipoproteinemia Familial hypercholesterolemia Xanthomatosis	Accelerated atherosclerosis Xanthelasma Tendon and tuberosus xanthomas Juvenile corneal arcus	Very strong risk, especially for coronary atherosclerosis	Greatly increased	Normal Slightly increased	Autosomal dominant; common	Excess dietary cholesterol; hypothyroidism; nephrosis; multiple myeloma; porphyria; obstructive liver disease	Dietary: low-cholesterol, low-fat diet Drugs: cholestyramine, colestipol, niacin, probucol Possible surgery
III	Broad beta disease Familial dysbetalipoproteinemia Floating betalipoproteinemia	Accelerated atherosclerosis of coronary and peripheral vessels Planar xanthomas Tuberoeruptive and tendon xanthomas	Very strong risk for atherosclerosis, especially in peripheral and coronary arteries	Greatly increased	Greatly increased	Mode of inheritance unclear; uncommon but not rare	Dysgammaglobulinemia; hypothyroidism	Dietary: reduction to ideal weight; maintenance of low-cholesterol, balanced diet Drugs: niacin, clofibrate
IV	Endogenous hypertriglyceridemia Familial hyperprebetalipoproteinemia Carbohydrate-induced hyperlipoproteinemia	Possible accelerated atherosclerosis Glucose intolerance Hyperuricemia	Possible risk, especially for coronary atherosclerosis	Normal or slightly increased	Greatly increased	Common, often sporadic when familial; genetically heterogeneous	Excess alcohol consumption; oral contraceptives; diabetes mellitus; glycogen storage disease; pregnancy; nephrotic syndrome; stress	Dietary: weight reduction; no alcohol Drugs: niacin, gemfibrozil
V	Mixed hypertriglyceridemia Combined exogenous and endogenous hypertriglyceridemia Mixed hyperlipidemia	Pancreatitis Eruptive xanthomas Hepatosplenomegaly Sensory neuropathy Lipemia retinalis Hyperuricemia Glucose intolerance	Risk of atherosclerosis not clearly increased	Normal or slightly increased	Very greatly increased	Uncommon but not rare; genetically heterogeneous	Alcoholism; insulin-dependent diabetes mellitus; nephrosis; dysgammaglobulinemia	Dietary: weight reduction; no alcohol Drugs: niacin, gemfibrozil

Modified with permission from D.S. Fredrickson and R.I. Levy, Familial Hyperlipoproteinemia, in *The Metabolic Basis of Inherited Disease*, 5th ed., J.B. Stanbury, J.B. Wyngaarden, and D.S. Fredrickson, eds., © 1983, The McGraw-Hill Companies, Inc.

The guidelines recommend an expanded group of individuals in whom statins should be used and for that group they believe the benefits outweigh the risks. This includes patients with:

- clinically evident atherosclerotic cardiovascular disease
- primary low-density lipoprotein (LDL) cholesterol levels of at least 190 mg per deciliter

- type 1 or type 2 diabetes and an LDL cholesterol level of 70 mg per deciliter or higher, or
- a 10-year risk of atherosclerotic cardiovascular disease of at least 7.5%, according to the new cohort equations, and an LDL cholesterol level of at least 70 mg per deciliter.

The implications for how physicians would change their prescribing behaviors based on these new guidelines include:

- Have patients use a new risk calculator that will target many more individuals for the need for statins.
- Decrease the use of indirect biomarkers of risk such as C-reactive protein or calcium scores.
- Increase the use of statins and avoidance of nonstatin LDL cholesterol-lowering agents in statintolerant patients.
- Eliminate the need for routine checks of LDL cholesterol levels in patients receiving statin therapy, because target levels are no longer considered important.
- In patients older than 75 years of age who have no clinical atherosclerotic cardiovascular disease, become more conservative with the use of statins.

Generally, level of risk is known to increase by approximately 3% for each 1% increase in total cholesterol for middle-aged men. Based on the Framingham study, the level of risk is determined by adding point values for each risk factor and using a conversion table to determine the percentage of risk. These simple calculations may be helpful in defining risk for the patient and illustrate how significant each additional risk factor becomes. In practical application, the level of concern for two patients with a cholesterol level of 240 mg/dL is obviously different. If the patient is a

middle-aged man with any risk factors, monitoring levels while applying intervention with diet or medication is warranted, whereas a woman with the same cholesterol level and a high HDLc would warrant less concern. However, recent evidence suggests that it is not always true that higher HDLc levels are protective. Researchers have found that based on genetic mechanisms that raise plasma HDL cholesterol for these individuals, higher levels do not seem to lower risk of myocardial infarction.<sup>30</sup>

Given the controversy over the newer guidelines, it is important to remember the recommendations from the National Cholesterol Education Program, which publishes an “at-a-glance” quick reference to the Adult Treatment Panel (ATP) III Guidelines.<sup>31</sup> They created an evidence-based, sequential, step-by-step approach to the management of patients with hyperlipidemia, which still appears relevant until the newer guidelines can be further evaluated. More than in the past, lifestyle and dietary approaches are emphasized as initial management in most patient scenarios except those with serious risk factors. There are clear indicators of when medical therapy should be pursued. A summary of these steps follows, and **Figure 51-1** shows an algorithmic representation of the guidelines. A website access address is provided at the end of this chapter.

### **LDL Cholesterol:** Primary Target for Therapy

<100: Optimal

100–129: Near optimal/above optimal

130–159: Borderline high

160–189: High

≥ 190: Very high

## **Total Cholesterol**

<200: Desirable  
200–239: Borderline high  
240: High

## **HDL Cholesterol**

<40: Low  
≥ 60: High

- Step 1: Determine the patient's lipoprotein levels utilizing a complete lipoprotein profile test after a 9- to 12-hour fast.
- Step 2: Identify risk factors for coronary heart disease (CHD) event (CHD risk equivalent) evident by the presence of clinical atherosclerotic disease. These include clinical CHD, symptomatic carotid artery disease, peripheral arterial disease, or abdominal aortic aneurysm. Diabetes is considered a CHD risk equivalent.
- Step 3: Determine any major risk factors (other than LDL), including cigarette smoking, hypertension (BP ≥ 140/90 mmHG or on antihypertensive medication), low HDL cholesterol (<40 mg/dL), family history of premature CHD (CHD in first-degree male relative <55 years; CHD in first-degree female relative <65 years), and men ≥ 45 years old or females ≥ 55 years old. Note that HDL cholesterol >60 mm/dL is a "negative" risk factor, allowing the subtraction of one of the other risk factors from the total count.
- Step 4: If there are 2 + risk factors (other than LDL) without CHD or CHD risk equivalents, assess the 10-year (short-term) CHD risk using the Framingham tables. There are three levels of 10-year risk: (1) >20% CHD risk equivalent, (2) 10% to 20%, and (3) <10%.

- Step 5: Determine the patient's risk category. This includes establishing the LDL goal of therapy, determining the need for therapeutic lifestyle changes (TLC), and determining the need for referral for drug consideration. Following is a summary:
  - 1.** *For CHD or CHD risk equivalents:* The LDL goal is <100 mg/dL and the LDL level to initiate TLC is  $\geq 100$  mg/dL; drug therapy is considered if  $\geq 130$  mg/dL.
  - 2.** *For 2+ risk factors (10-year risk <20%):* The LDL goal is 130 mg/dL, at which point TLC is initiated; drug therapy is considered at  $\geq 130$  mg/dL if the 10-year risk is 10% to 20% and if the 10-year risk is 10% drug therapy begins at  $\geq 160$  mg/dL.
  - 3.** *For 0 to 1 risk factors:* The LDL goal is <160 mg/dL, at which point TLC are initiated; drug therapy is considered if LDL is  $\geq 190$  mg/dL. (For 160–190 mg/dL, drugs are considered optional.)
- Step 6: Initiate therapeutic lifestyle changes (TLC) if the LDL is above the goal level. These include dietary recommendations: saturated fats should equal <7% of calories, cholesterol <200 mg/day, possible use of viscous (soluble) fiber 10–25 g/day and plant stanols/sterols (2g/day) in attempting to reduce LDL, weight management, and increased physical activity.
- Step 7: Consider referring for drug therapy if the LDL exceeds recommended levels (see **Table 51-2** for list of medications and proposed effects).<sup>5</sup>
- Step 8: Identify whether the patient has metabolic syndrome and treat if present after three months of TLC. Risk factors include abdominal obesity indicated by a waist circumference of >102 cm (>40 in.) in males and 88 cm (>35 in.) in females, elevated triglycerides  $\geq 150$  mg d/L, HDL cholesterol <40 mg/dL in males and <50 mg/dL in females, blood pressure  $\geq 130/85$  mmHg, and a fasting glucose 110 mg/dL. Treatment includes weight management and increased

physical activity to treat the underlying causes. Treatment for lipid and nonlipid risk factors is initiated if TLC were ineffective. Hypertension should be managed; aspirin is considered for CHD patients to reduce prothrombotic state; and referral made, if necessary, to decrease triglyceride levels or increase HDL if conservative approaches are not effective.

- Step 9: Treat elevated triglyceride levels. See the algorithmic representation of this step plan for management.

#### *Classification of Serum Triglycerides (mg/dL)*

150 = normal

150-199 = borderline high

200-499 = high

≥ 500 = very high

The primary treatment aim is still to reach LDL goal. Weight management and increased physical activity are emphasized. If triglycerides are ≥ 200 mg/dL after the LDL goal is reached, a secondary goal is set for non-HDL cholesterol (total cholesterol minus HDL) 30 mg/dL higher than LDL goal.

- *For CHD or CHD risk equivalents:* The LDL goal is <100 mg/dL and the non-HDL goal is <130 mg/dL.
- *For 2+ risk factors (10-year risk <20%):* The LDL goal is 130 mg/dL and the non-HDL goal is <160 mg/dL.
- *For 0-1 risk factors:* The LDL goal is <160 mg/dL and the non-HDL goal is <190.

**Table 51-2** Nutritional Support for Hyperlipidemia

Substance	How Does it Work?	Dosage	Special Instructions	Contraindications for Possible Side Effects
Gugulipid	Increases liver's metabolism of LDL; increases uptake of LDLc from the blood; may prevent the formation of atherosclerosis.	25 mg (most extracts contain 5%–10% guggulsterones) 3 times/day.	Best taken with meals. Should be taken with pyridoxal 5 phosphate (included in recommended supplement).	Do not combine with Imitrex or other SSRI or MAOI antidepressants. Taking more than recommended dose may lead to serotonin syndrome. Should not be taken with history of liver disease or inflammatory bowel disease or diarrhea is found. Safety unknown for pregnant or lactating women.
Omega-3s (EPA & DHA)	Lowers triglyceride levels.	3,000 mg/day (add EPA & DHA content to determine omega-3 content).	Omega-3s may raise LCLc levels; taking 900 mg/day of garlic may neutralize this effect.	Cod liver oil is less expensive; however, it contains large amounts of vitamins A and D, which may cause side effects.
Flaxseed oil	Another form of omega-3 but does not lower triglyceride levels; may lower total cholesterol; increases HDL.	1–2 tablespoons daily.	Keep refrigerated; away from light; do not heat.	None at recommended dosage.
Inositol Hexaniacinate (Flush Free Niacin)	Lowers LDLc; fibrinogen (blood protein that causes clot formation); raises HDL level.	650 mg 3 times/day.	Best taken with meals.	Although safest form of niacin, it should be used with caution with diabetics and preexisting liver disease.
Chromium	Reduces LDLc and raises HDLc.	200 mcg/day	None.	At very high levels (>1,000 mcg/day) severe liver or kidney disease is possible. For those using brewer's yeast, some people have allergies.
Pantethine	Inhibits cholesterol production and increases utilization of fats as energy source.	250–300 mg 3 times/day.	Best taken with meals.	Diarrhea with increased dosage. Megadoses (over 6 g/daily) may increase calcium oxalate stone formation in susceptible individuals.
Vitamin E	Protects LDL from oxidation; may increase HDLc.	400–800 IU/day.	None.	Side effects for vitamin E are rare.
Vitamin C	Reduces total cholesterol; protects LDL from oxidation; may increase HDL levels.	350–1,000 mg 3 times/day Ascorbyl palmitate.	Best taken with meals.	Diarrhea with increased dosage. Megadoses (over 6 g/daily) may increase calcium oxalate stone formation in susceptible individuals.
B Complex (B <sub>6</sub> , B <sub>12</sub> , and folic acid)	Lowers homocysteine levels.	Per bottle recommendations.	Best taken with meals.	None
Carnitine	May lower triglyceride levels.	1–3 g/day	L-isomer not DL mixture is more safe and effective.	DL-carnitine has caused weakness in some kidney patients on dialysis. L-carnitine at 1.6 g/day for 1 year has not caused side effects.
Wild yam	May lower triglyceride levels.	2–3 ml of tincture 3–4 times/day.	None	None at recommended dose.

**Note:** The following have not been approved by the Food and Drug Administration for the treatment of this disorder.

Other substances that may benefit a patient with dyslipidemia include soy protein, chondroitin sulfate, beta-sitosterol, octacosanol, and royal jelly. **Key:** SSRI, selective serotonin reuptake inhibitor; MAOI, monoamine oxidase inhibitor;

EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid; DL, dextro/levo (right/left).

If the triglycerides are 200–499 mg/dL after the LDL goal is reached, consider referral for drug therapy to reach the non-HDL goal. If triglycerides are  $\geq$  500 mg/dL, it is important to lower the triglycerides first to prevent pancreatitis. This includes recommendation for a very low-fat diet ( $< 15\%$  of calories from fat), weight management and physical activity, and nicotinic acid (or referral for fibrate). Only after triglycerides are lower than 500 mg/dL should the emphasis switch to lowering LDL.

For patients with isolated low levels of HDLc, nonpharmacologic means should be used first including weight loss, exercise, cessation of smoking, and use of nutritional support.<sup>32,33</sup> Moderate alcohol consumption (two drinks/day for males; one drink/day for females) has also been demonstrated to increase HDLc levels; however, the negative effects probably outweigh the benefits of recommending this to patients.

Grundy et al.<sup>34</sup> published an update of the National Cholesterol Education Group Adult Treatment Panel III Guidelines based on published trials since their implementation. Following are some recommended modifications:

- High-risk patients—the recommended LDLc goal is  $<100$  mg/dL; however, when the risk is very high an LDL of  $<70$  mg/dL is a reasonable clinical option even for patients with a baseline LDLc of  $<100$  mg/dL. If the high-risk patient has high triglycerides or low HDLc, combining a fibrate or nicotinic acid with an LDL-lowering drug should be considered.
- Moderately high-risk persons (2+ risk factors and 10-year risk of 10% to 20%)—the LDLc recommended goal is  $<130$  mg/dL but a goal of  $<100$  mg/dL is a

therapeutic option even if baseline LDLc is <100 mg/dL.

- For both high-risk and moderate-risk persons—goal of therapy is at least a 30% to 40% reduction in LDLc levels and regardless of LDLc level, all of these patients must address therapeutic lifestyle changes.

Recent recommendations by the American College of Cardiology and American Heart Association focus on two general categories including advice to adults wishing to lower LDLc and advice to adults wishing to lower blood pressure (BP).<sup>35</sup> A synopsis of these recommendations for both groups is based on diet and exercise as follows:

- Consume a diet with emphasis on vegetables, fruits, and whole grains including low-fat dairy products, poultry, fish, legumes and nontropical vegetable oils and nuts; decrease sugars and meats. This can be accomplished without a plan or using the DASH diet, the USDA food pattern or the AHA diet. Reduce percent of calories from saturated fats and trans fat.
- For BP lowering they add the advice to lower sodium intake consuming no more than 2,400 mg of sodium/day.
- For both groups, it is recommended to exercise aerobically three to four times per week, 40 minutes per session involving moderate to vigorous activity.

There are a number of named dietary approaches. The NCEP two-step program is a staged approach to this reduction.<sup>36</sup> The step-one diet is to reduce dietary fat to less than 30% of total calories (saturated fat less than 10% of total calories). If after a three-month trial the step-one diet is unsuccessful, the step-two diet is implemented. This diet restricts saturated fats to 7% of total calories and dietary cholesterol to 200 mg/day. It begins with a focus on

healthful choices. A list of foods that are high in fat and a substitute for that food allows for an educated participation by the patient rather than a strict diet menu. The goal of the step-one diet is to reduce the total serum cholesterol by 30 to 40 mg/dL. Reduction from the step-two diet is targeted at an additional 15% of total calories. Reduction in LDLc is based on the baseline measure. Generally, if the level is above 160 mg/dL, a goal is simply to achieve levels below this. For those between 140 and 159 mg/dL, the goal is to reach 130 mg/dL if there are two risk factors or to reach 100 mg/dL if the patient has CHD. Failure to achieve these goals after six months of using the step-one and step-two diet plans may indicate an individual who is noncompliant or unresponsive to diet therapy (e.g., familial hyperlipidemia). Referral for drug management may be appropriate.

Another recommended approach is the Ornish program.<sup>37</sup> Ornish demonstrated that a low-fat diet can reverse some CHD and help prevent development of CHD. His program is divided into a reversal diet and a prevention diet. The reversal diet is for those who have CHD, and restricts fat to less than 10% of total calories; protein, 15% to 20% of total calories; and carbohydrates (complex), 70% to 75% of total calories.<sup>38</sup> Cholesterol is limited to 5 mg/day. The prevention diet is less strict, but it is still more conservative than the NCEP guidelines. Ornish recommends the prevention diet for those with cholesterol levels above 150 mg/dL or if the total cholesterol to HDLc ratio is greater than 3. With the prevention diet, fat is still restricted to no more than 20% of total calories. Ornish also recommends other lifestyle changes, such as avoidance of caffeine and other stimulants and inclusion of exercise and meditation. Some studies indicate that modest dietary fat reduction is as beneficial as more aggressive approaches. A recent study<sup>39</sup> comparing four fat-restriction diets demonstrated that all were effective. The range of restriction in the four diets was 30%, 26%, 22%, and 18% of energy from fat.

There are several specifics regarding dietary recommendations for lowering cholesterol. A Mediterranean diet (MeDi) has been shown to decrease cardiovascular risk factors including blood pressure, C-reactive protein, and lipid profile. One study<sup>40</sup> indicated that a MeDi with a focus on nuts (specifically walnuts) did better than a typical MeDi in decreasing both cholesterol and triglycerides. In fact, contrary to intuition given the fat content of nuts, there is strong and increasing evidence that at least among subjects with higher LDL-C levels, nut consumption improves blood lipid levels in a dose-related manner.<sup>41</sup>

Studies have shown that dietary fiber, specifically barley bran flour and oil, and whole grain consumption in general all assist in decreasing cholesterol and perhaps CHD risk.<sup>42-44</sup> One study<sup>45</sup> indicated no additional benefit for children taking psyllium fiber who already follow a low-fat, low-saturated-fat, low-cholesterol diet. A new product line of foods marketed under the name Benecol is available. This product uses plant sterol mixtures (campestanol/sitostanol) to decrease serum cholesterol through increased absorption and decreased synthesis.<sup>46</sup> There are some concerns that the use of plant sterols will lower serum vitamins D and E, retinol, and alpha- and beta-carotenes. Recent evidence<sup>47</sup> suggests that only the carotenes were decreased.

There is increasing evidence<sup>48,49</sup> that the original excitement regarding the lipid-lowering effects of garlic may have been premature. Several large studies<sup>50,51</sup> using various types of garlic supplementation including garlic powder and garlic oil indicated no significant effect at lowering plasma lipids or lipoproteins. A study by Gardner et al.<sup>52</sup> tested several standard approaches to garlic use in attempting to lower cholesterol. Their study indicated that regardless of the type of administration there was no significant decrease in LDLc or plasma lipid concentrations in patients with moderate hyperlipidemia after a six-month trial and follow-up. This conflicts with earlier reports.

Gugulipid has been recommended for many years as a potentially effective herbal treatment for hypercholesterolemia. Some studies have indicated that this may occur because guggulsterones (the bioactive components) are antagonists for farnesoid X receptor and bile acid receptor, two hormone receptors that contribute to bile acid and cholesterol regulatory function. A recent study done through a randomized controlled trial concluded that, although there is evidence for a bioactivity model for the effects of gugulipid, there was no improvement in serum cholesterol over a two-month period.<sup>53</sup> Some concerns from this study were the potential for raising LDL cholesterol and a dermatologic hypersensitivity reaction in some patients.

Other nutritional factors that may be of benefit include diets high in or supplemented with vitamin E and omega-3 fatty acids. Vitamin E supplementation at 200 to 400 IU/day may be beneficial ([Table 51-2](#)).<sup>54</sup> The benefit is derived mainly from prevention of free-radical damage that may lead to atherosclerosis. There appears to be no additional benefit for using tocotrienols versus the standard alpha-tocopherol form.<sup>55</sup> Other antioxidants include vitamin C and bioflavonoids.<sup>56</sup> For omega-3 fatty acids, 8 mg of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) have been demonstrated to have a protective effect.<sup>57</sup> This protective effect is believed to be due to several actions. First, it is believed that omega-3 fatty acids prevent oxidation of LDL. Second, they may protect against CHD by reducing clot formation and coronary artery spasm through a reduction in production of thromboxane and an increase in prostacyclin and tissue plasminogen activator production. Foods high in omega-3s are fish (salmon, herring, mackerel, sardines, anchovies, albacore tuna, and black cod), whole grains, beans, seaweed, and soybean. Adler and Holub<sup>58</sup> suggested that omega-3s may increase LDLc levels and that adding garlic (900 mg/day) to the diet may mitigate this effect, lowering cholesterol, LDLc, and

triglycerides. Chromium supplementation (600 mcg/day) increases serum HDLc in men taking beta-blockers.<sup>59</sup>

Exercise has increasingly been demonstrated to be effective in reducing cardiovascular risk. A recent study by Johnson et al.<sup>60</sup> indicates that a modest amount of moderate intensity exercise even without dietary changes improves metabolic syndrome, supporting the recommendation of 30 minutes of moderate intensity exercise every day for adults. It appears that there is a dose-dependent effect in that a high amount of exercise had greater benefits regardless of whether it was moderate intensity or vigorous intensity. Specifically, a study by Slentz et al.<sup>61</sup> indicates that significant increases in LDLc occur with inactivity while a modest amount of exercise prevents this increase. Moderate intensity results in a sustained reduction in VLDL, whereas a high-intensity group had significant improvements in HDLc maintained at 15 days after exercise has stopped.

In one study,<sup>62</sup> subjects who performed an individualized exercise program for six months showed a 58.3% decrease in mononuclear cell production of atherogenic cytokines and a 35% decrease in serum levels of C-reactive protein. It has also been shown that exercise increases HDLc levels.<sup>63,64</sup> This effect may be less dramatic in women.<sup>65</sup> It is still unclear how much of the effect on HDLc is due to the exercise itself and how much is attributable to the related weight loss. A recent study<sup>66</sup> indicated that moderate-intensity exercise is just as effective as high-intensity exercise at improving HDLc levels. There is evidence<sup>67</sup> that a program of resistance training for 45 to 50 minutes a day, three times per week, may yield an average 10% reduction in total cholesterol, increased HDLc levels, and decreased LDLc levels. An enormous data pool indicates that exercise has effects on weight reduction, risk and degree of diabetes, and hypertension, among other benefits. The debate that is still being resolved is the degree of exercise needed to achieve these results. A recent study evaluated the level of

exercise that tended to predict risk for death from CVD by comparing men with no evidence of CVD and following them for 11 years.<sup>68</sup> This study indicates that those classifying their leisure exercise as heavy or vigorous had an associated reduced risk for death from CVD.

## Medications

There are several classifications of drugs used to lower lipids.

- 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibitors (“statins” such as lovastatin)—inhibits the conversion of HMG CoA to mevalonic acid, which is needed for cholesterol production; this leads to an increase in LDLc receptors, lowering LDLc levels
- bile acid-binding resins (cholestyramine [Questran] and colestipol [Colestid])—combines with bile acids and salts and then is excreted in feces; removal of bile acids causes conversion of cholesterol to bile acids, which reduces blood levels of cholesterol
- nicotinic acid (niacin)—decreases hepatic production of LDLc and increases levels of HDLc (significantly lower doses are needed to increase HDLc)
- fibric acid derivatives (gemfibrozil [Lopid])—decreases triglycerides, raises HDLc, does not have much effect on LDLc
- probucol (Lorelco)—may inhibit the absorption of cholesterol and decrease LDLc levels
- estrogen replacement therapy—estrogen raises HDLc levels, lowers LDLc; however, may increase triglyceride levels; progestogens typically lower HDLc levels

The use of these drugs is somewhat controversial given that there are, as with most drugs, contraindications to their use, side effects, and cost considerations. In general, in patients with isolated LDLc elevations, bile acid-binding resins or statins are used first. For those with mixed hyperlipidemia, nicotinic acid (if tolerated) is the first drug used; if not effective, gemfibrozil or one of the statins is used. For isolated triglyceride elevation, niacin is used. However, niacin can unmask or increase the risk of developing diabetes. **Table 51-3** is a summary of commonly used medications in the management of hyperlipidemia.

Comanagement with a team including the chiropractor, dietitian, and medical doctor is recommended when a patient is noncompliant or does not seem to respond to individual provider recommendations with diet and exercise.

## Algorithm

An algorithm for hypercholesterolemia management is presented in **Figure 51-1**.

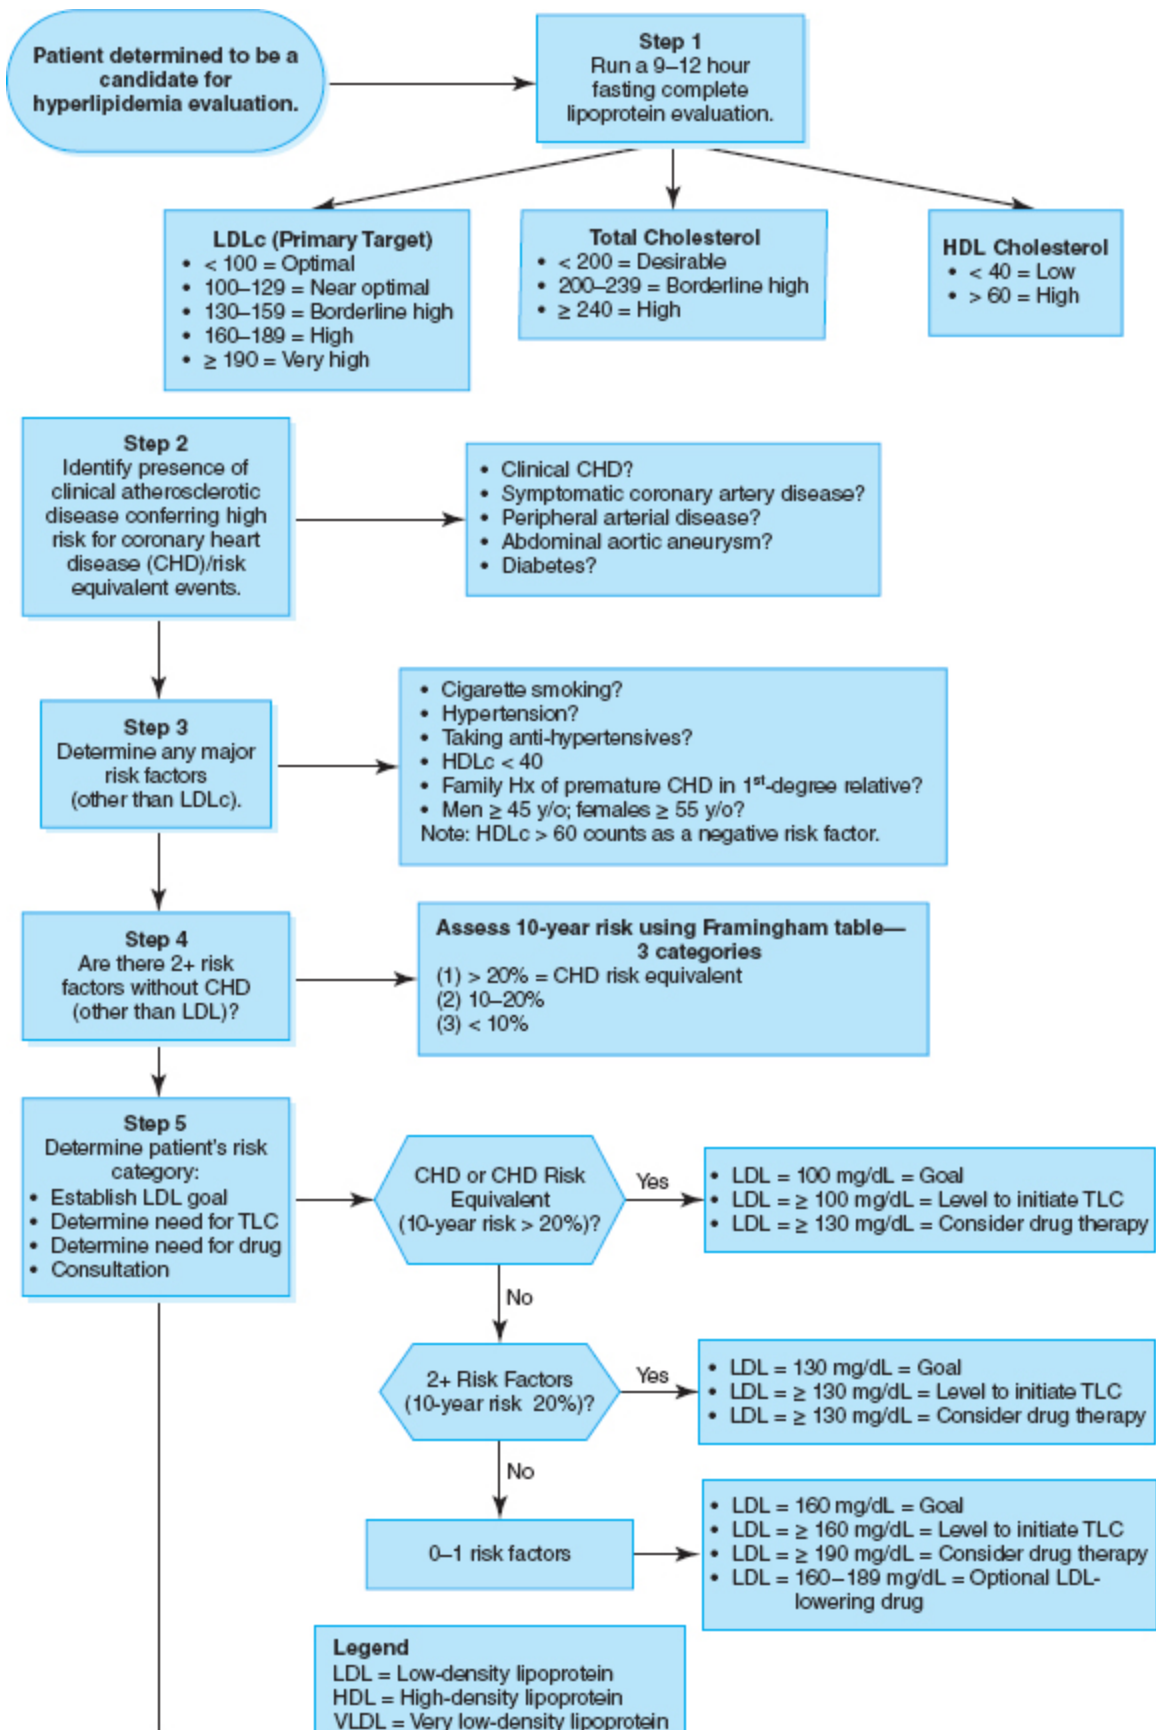

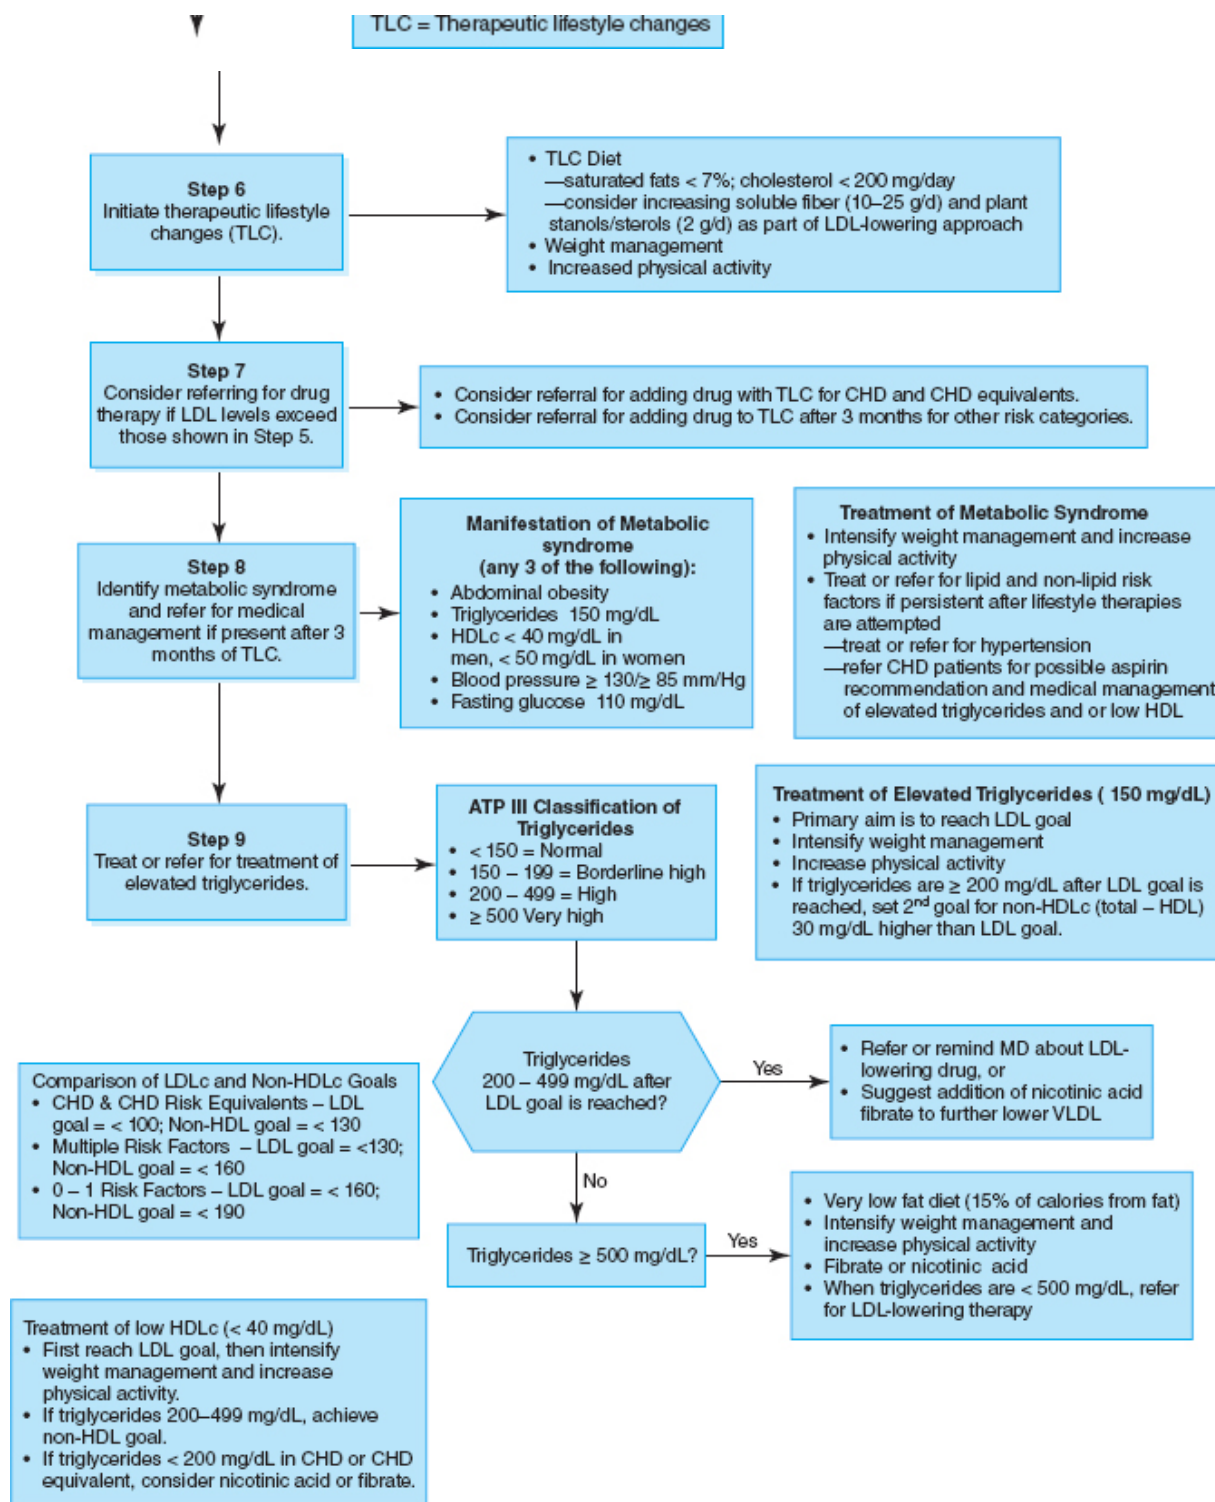

**Table 51-3** Hyperlipidemia Medications

Drug Class	Examples	General Mechanism	Interactions/Side Effects
HMG CoA reductase inhibitors (statins)	Atorvastatin	A statin: a HMG CoA reductase inhibitor. This blocks the enzyme that controls production of cholesterol in the liver. Therefore, used in the treatment of hyperlipidemia. Lowers both total cholesterol and LDL cholesterol while increasing HDL cholesterol. Atorvastatin is different from other statins in that it reduces triglycerides. These effects may retard or reverse coronary artery disease.	GI upset, headache, myalgia, weakness, rhabdomyolysis, ocular and liver toxicity. Should have liver enzymes monitored.
	Lipitor		
	Lovastatin	A statin: a HMG CoA reductase inhibitor. This blocks the enzyme that controls production of cholesterol in the liver. Therefore, used in the treatment of hyperlipidemia. Lowers both total cholesterol and LDL cholesterol while increasing HDL cholesterol.	May cause GI upset, headache, myalgia, weakness, rhabdomyolysis, ocular and liver toxicity. Should have liver enzymes monitored.
	Mevacor		
	Pravastatin	A statin: a HMG CoA reductase inhibitor. This blocks the enzyme that controls production of cholesterol in the liver. Therefore, used in the treatment of hyperlipidemia. Lowers both total cholesterol and LDL cholesterol while increasing HDL cholesterol.	GI upset, headache, myalgia, weakness, rhabdomyolysis, ocular and liver toxicity. Should have liver enzymes monitored.
	Pravachol		
Statins combined with other medications	Simvastatin	A statin: a HMG CoA reductase inhibitor. This blocks the enzyme that controls production of cholesterol in the liver. Therefore, used in the treatment of hyperlipidemia. Lowers both total cholesterol and LDL cholesterol while increasing HDL cholesterol.	GI upset, headache, myalgia, weakness, rhabdomyolysis, ocular and liver toxicity. Should have liver enzymes monitored.
	Zocor		
	Amlodipine/atorvastatin	A combination antihypertensive (selective calcium channel blocker) medication with a statin (5 reductase inhibitor) used as an adjunct to diet in the treatment of primary hypertension.	Back pain, myalgia, constipation, diarrhea, flatulence, palpitations, tachycardia, facial edema, postural hypotension, headache, sexual dysfunction
	Caduet		
	Ezetimibe and simvastatin	Used for patients with primary (heterozygous familial and nonfamilial) hypercholesterolemia or mixed hyperlipidemia. Ezetimibe is a selective inhibitor of intestinal cholesterol and phytosterol absorption combined with simvastatin an HMG CoA reductase inhibitor.	Urticaria, arthralgia, myalgias, angioedema, anaphylaxis, elevated liver transaminases, hepatitis, pancreatitis, cholelithiasis, thrombocytopenia, GI signs/symptoms, such as nausea, abdominal pain, constipation, diarrhea, etc. rare cause of rhabdomyolysis/myopathy.
	Vytorin		
Bile acid-binding resins	Ezetimibe	Used alone or in combination with statins (HMG CoA reductase inhibitors) for the treatment of primary hypercholesterolemia. At the lining of the small intestine, inhibits absorption of cholesterol but does not inhibit cholesterol synthesis in the liver.	Fatigue, arthralgia, myalgia, dizziness, headache, abdominal pain, angioedema, rhabdomyolysis (monitor liver enzymes when used with a statin)
	Zetia		
	Ezetrol		
Bile acid-binding resins	Cholestyramine	By combining with bile acids in exchange for chloride ions, an insoluble complex is formed which is excreted in the feces. Used in the management of hypercholesterolemia with reductions in both total cholesterol and LDL cholesterol.	May cause constipation, weight loss or gain, deficiencies in vitamins A, D, and K, and decreased erythrocyte folate levels, nausea, vomiting and other GI disturbances.
	Questran		
	Lo-CHOLEST Prevalite		

	<b>Colestipol</b>	By combining with bile acids in exchange for chloride ions, an insoluble complex is formed which is excreted in the feces. Used in the management of hypercholesterolemia with reductions in both total cholesterol and LDL cholesterol.	May cause constipation, weight loss or gain, deficiencies in vitamins A, D, and K, and decreased erythrocyte folate levels, nausea, vomiting and other GI disturbances.
	Colestid		
	Lestid		
	Cholestabyl		
<b>Fibric acid derivatives</b>	<b>Gemfibrozil</b>	Through blocking lipolysis of stored triglycerides and inhibiting uptake by the liver of fatty acids, there is a reduction in VLDL, LDL, total cholesterol, and triglycerides synthesis and an increase in VDL. Used in the management of patients with high triglyceride levels including familial hypercholesterolemia (type IIa and IIb).	May cause GI upset, headache, dizziness, musculoskeletal pain, rash, or hypokalemia.
	Lopid		
<b>Nicotinic acid</b>	<b>Niacin</b>	Vitamin B <sub>3</sub> is used in the management of hypercholesterolemia. It has vasodilation effects on vascular smooth muscle and inhibits hepatic synthesis of VLDL, cholesterol and triglycerides, and LDL. May also be used in the treatment of pellagra.	May cause a generalized flushing sensation of warmth, transient, headache, tingling in the extremities, increased sebaceous gland activity, hyperuricemia, hyperglycemia, abnormalities of liver function, and jaundice.
	Nicobid		
	Nicolar		
	Novo-Niacin		
<b>Other</b>	<b>Probucol</b>	May inhibit the absorption of cholesterol and decrease LDLc levels	
	Lorelco

# CHAPTER 52

## Anemia

### Context

Although the *Job Analysis on Chiropractic* report from the National Board of Chiropractic Examiners<sup>1</sup> indicates that few chiropractors order laboratory studies on their patients, all chiropractic colleges teach students that laboratory studies are a diagnostic tool to be used when appropriate. This discrepancy probably occurs for several reasons. One is that students often feel that they have not had enough exposure in the college setting to feel comfortable ordering labs. There is often the concern of reimbursement. This is easily defended (as for any procedure) with an explanation of why the test was ordered. Also, the vast majority of patients are probably being seen by a medical doctor (MD); it is often the assumption of the chiropractor that the MD will order any appropriate laboratory work and, in fact, the chiropractor refers the patient to the MD for the lab work and follow-up. Yet there is a significant group of patients who request and/or need laboratory work for screening of certain values such as cholesterol/triglyceride levels, urinalysis with symptoms of a urinary tract infection, and a cross-check of possible causes with complaints of fatigue. These are easy tests to order and generally easy to interpret. It is important to remember that the patient population seen by chiropractors is ambulatory—not hospitalized; therefore, the types of disorders seen are already restricted. From a cost-effectiveness perspective, it may be less expensive for the patient within the context of the smaller chiropractic setting.

There is often an assumption that all patients with anemia will present as pale, fatigued, clay-eating individuals. It is far more common for a patient to be unaware of an underlying anemia. The

absence of pallor and other physical signs of anemia as a diagnostic rationale for ruling out anemia has a false-negative value of between 45% and 55%.<sup>2</sup> If fatigue is present, it is initially felt only with exertion. If the patient is not in a position to exert himself or herself, anemia may remain silent. It is also crucial to regard anemia as a sign of disease rather than as a disease in itself. In other words, the doctor is only half finished with the evaluation process when anemia is discovered on laboratory testing. The next step in the process is to determine why. Anemia, in general, is due to one of three processes: (1) decreased production, (2) increased breakdown, and (3) blood loss. With each there is a limited number of common causes, and significant associated laboratory findings usually aid in the diagnosis. (See [Table 52-1](#) for less common anemias.)

## General Strategy

### History

- Determine whether there are any clear historical clues of anemia such as blood loss, dietary deficiencies, ethnic or familial predispositions, pregnancy or alcoholism, or past history of anemia; obtain a thorough drug history.
- Determine whether there are any secondary clues such as tiredness with exertion, gastrointestinal (GI) pains (GI bleeding source), heavy menstrual flow, pallor, pica (dirt/clay eating, ice eating, or starch eating), or bone pain (sternal pain in particular).

### Examination

- Examine the patient for signs of tachycardia, systolic flow murmurs, a loud S1 and S2, a widened pulse pressure, a venous hum, and pale conjunctivae.
- If screening for a specific anemia, order an anemia panel that best demonstrates that anemia; if screening the patient

generally, order a complete blood cell (CBC) count, blood chemistry, and urinalysis.

- Interpret the lab with a focus on the size (combined findings of mean corpuscular volume [MCV] and a morphologic description such as microcytosis or macrocytosis) and shape of the red blood cells (RBCs), the RBC distribution width (RDW), and a search for signs of hemolysis (increased bilirubin, lactate dehydrogenase [LDH], and/or potassium), or blood loss (increase in reticulocytosis).
- Combine the laboratory and historical findings to determine a working diagnosis.

## Management

- Iron-deficiency anemia (IDA) requires a further determination of a bleeding source (and more rarely a dietary source); if not an occult process, use iron supplementation for two weeks; a recheck for response is necessary.
- Thalassemia minor is usually asymptomatic and not in need of intervention except to counsel parents who both have the same thalassemia (trait or minor) about risk for their children and also prenatal counseling.
- A patient with macrocytic anemia due to pernicious anemia is referred for cyanocobalamin (vitamin B<sub>12</sub>) injections or other approaches; temporary deficiencies not associated with a loss of intrinsic factor may be managed nutritionally.

**Table 52-1** Some Less Common Anemias

Type	Findings	Management
<b>Heredity Spherocytosis</b>	An autosomal dominant disease with variable presentation. An abnormality of spectrin, an important protein used in the structure of the RBC membrane results in	Patients are supplemented with folic acid (1 mg/d). Splenectomy is usually performed to decrease the degree of hemolysis (does not correct the disorder).

	<p>a spheroid cell rather than the normal biconcave cell. As a result, the cell is destroyed earlier than normal RBCs, leading to a chronic hemolytic anemia. Findings include:</p> <ul style="list-style-type: none"> <li>• Reticulocytosis</li> <li>• Spherocytes on peripheral blood smear</li> <li>• Microcytosis with an increased MCHC</li> <li>• Hematocrit may be normal</li> <li>• May have an increase in indirect bilirubin (common with hemolytic anemias)</li> <li>• Negative Comb's test</li> </ul>	
<b>Glucose-6-Phosphate Dehydrogenase Deficiency</b>	<p>An X-linked recessive disorder affecting approximately 10–15% of American black males. The defect in this enzyme leads to episodic hemolytic anemia to oxidative disruption of the RBC. Many drugs can exacerbate this anemia, such as sulfonamides, quinine, and quinidine, among others. The blood is normal when there is no hemolytic event. During hemolytic events, lab findings may include:</p> <ul style="list-style-type: none"> <li>• Reticulocytosis</li> <li>• Increased indirect bilirubin</li> <li>• May have “bite” cells (looks like a</li> </ul>	<p>No treatment. Avoid drugs known to increase hemolytic events.</p>

	bite was taken out of cell) • Heinz bodies enzyme assay may reveal a low level of G6PD	
<b>Sickle Cell</b>	<p>An autosomal recessive disorder causing a single DNA base change of valine for glutamine in the sixth position of the <math>\beta</math> chain. This leads to hemoglobin S formation and "sickle-shaped" cells. The hemoglobin S gene is found in 8% of American blacks. One out of 400 American blacks will have sickle cell anemia. Onset is within the first year of life. Clinical presentation includes jaundice, pigment gallstones, splenomegaly, and poorly healing ulcers of the lower tibia. Hemolytic "crises" occur when viral infection or folate deficiency is present. Vaso-occlusive crisis may occur after infection, dehydration, hypoxia, or spontaneously. This leads to hours/days of extremely painful bone or organ pain with associated low-grade fever. Patients are at risk for delayed puberty, infections of bone, stroke, and infarction. Prenatal diagnosis is available. Laboratory findings include:</p>	<p>No treatment or cure for the disease. Patients remain on folic acid supplementation. Exchange transfusion is used, especially during painful crises.</p>

	<ul style="list-style-type: none"> <li>• Hemtrocrit is 20-30%</li> <li>• Sickle cells compose 5-50% of RBCs</li> <li>• Reticulocytosis (10-25%)</li> <li>• Nucleated RBCs</li> <li>• Howell Jolly bodies and target cells</li> <li>• WBC count is elevated and thrombocytosis may occur</li> <li>• Indirect bilirubin is high</li> <li>• Abnormal electrophoresis pattern indicating hemoglobin S</li> </ul>	
<h2>Autoimmune Hemolytic</h2>	<p>An acquired hemolytic anemia that is idiopathic in half of cases. Causes include systemic lupus erythematosus, chronic lymphocytic leukemia, and some lymphomas. IgG autoantibody if directed against mainly the Rb system. IgG antibodies coat the RBC, which is turned into a spherocyte to spleen macrophages. Must be differentiated from drug-induced hemolytic anemia. The onset of the anemia is acute, with the patient presenting with fatigue, jaundice, and splenomegaly. Laboratory findings include:</p> <ul style="list-style-type: none"> <li>• Hematocrit may be &lt;10%</li> <li>• Reticulocytosis</li> <li>• Spherocytes on peripheral smear</li> </ul>	<p>Patients are treated initially with prednisone. Immunosuppressive agents may be used. Splenectomy is considered in some cases. High-dose intravenous immunoglobulin is also used.</p>

	<ul style="list-style-type: none"> <li>• Indirect bilirubin is increased</li> <li>• May have nucleated RBCs</li> <li>• May have coexisting immune thrombocytopenia (Evan's syndrome)</li> <li>• Direct Comb's test is positive; indirect may/may not be positive</li> </ul>	
<b>Cold Agglutinin Disease</b>	<p>An acquired hemolytic anemia with the IgM autoantibody attaching to 1 antigen on RBCs. Most cases are idiopathic. Some are associated with Waldenstrom's macroglobulinemia. Cold agglutinin disease may also occur after mycoplasma pneumoniae or infectious mononucleosis. Symptoms may occur on exposure to cold with findings of mottled skin or numbness in fingers and toes. Lab findings include:</p> <ul style="list-style-type: none"> <li>• Reticulocytosis</li> <li>• Spherocytosis</li> <li>• Comb's test positive for complement only</li> <li>• A micro-Comb's test may be used</li> <li>• A bedside cold-agglutinin test demonstrates small clumps of blood on an iced glass slide</li> </ul>	<p>Treatment is primarily symptomatic with avoidance of exposure to cold.</p>

# Aplastic

Aplastic anemia is due to damage to the hematopoietic stem cell in the bone marrow. As a result, all components are affected including RBCs, WBCs, and platelets. Causes include radiation therapy, chemotherapy, SLE, toxins, drug induced (mainly RA and anti-epileptic medications), posthepatitis, pregnancy, and paroxysmal nocturnal hemoglobinuria. Anemia symptoms include fatigue and weakness; neutropenia predisposes the individual to infections; bleeding tendencies result from the decrease in platelets. Splenomegaly, hepatomegaly, pallor, and lymphadenopathy may be present. Lab findings include:

- Pancytopenia without changes in RBC morphology
- Bone marrow aspirate and biopsy appear hypocellular with small amounts of normal hematopoietic progenitors

High-dose immunosuppressants are most often used. Bone marrow transplant may be necessary.

# Sideroblastic

A group of refractory disorders that may be either hereditary or acquired (e.g., drug-

Dependent on cause, erythropeitin may be used. Transfusion is usually avoided.

induced) or idiopathic (myelocytoblastic syndromes). Erythroid hyperplasia of bone marrow is the characteristic that unites these disorders. Iron utilization is impaired.

- Hypochromic, microcytic RBCs (although macrocytes may prevail, making the MCV normal or high)
- Often there is basophilic stippling
- Serum iron and ferritin levels are normal or high
- The serum total iron-binding capacity is normal or low with a high percent saturation
- Free erythrocyte porphyrin levels may be high
- Bone marrow evaluation reveals increased iron and ringed sideroblasts

- Folic acid deficiencies are usually dietary and respond to supplementation; a trial of 100 mg for 10 days and a check for a reactive reticulocytosis may help distinguish between vitamin B<sub>12</sub> and folate deficiency. A cross-check for indicators of a B<sub>12</sub> deficiency is necessary given these do not respond to folic acid supplementation and the consequences of long-term B<sub>12</sub> deficiency include irreversible neurological dysfunction.

## Relevant Physiology

Anemia is an indication of an underlying disorder, not a disease itself. Anemia indicates a decreased ability of oxygen-carrying capacity and will usually result in attempts by the body to compensate. These compensations may be an increase in heart rate and/or an increase in RBC production. Anemia has been described several ways. However, anemia usually involves a decrease in hematocrit, hemoglobin, or RBCs. All of these are not necessarily decreased when anemia is present. In adult women a hemoglobin of less than 12 g/dL is considered anemia; in men, less than 13.5 g/dL is considered anemia. Hematocrit values indicating anemia are less than 36% in adult women and less than 39% in adult men. These values, which were established by the World Health Organization (WHO), are guidelines, not absolutes.<sup>3</sup>

## **Decreased Production**

Although a decrease in production is idiopathic 50% of the time, there are some common identifiable reasons. Many of these aplastic anemias are pancytopenic, meaning there is a concomitant decrease in white blood cells (WBCs) and platelets. Chemotherapeutic agents and other drugs are often the cause. A distinction between blood loss and decreased production is determined through the reticulocyte count. The reticulocyte count (or index) is a reflection of new RBC production in response to a loss of blood. This does not occur with aplastic disorders.<sup>4</sup>

## **Increased Breakdown**

Breakdown of RBCs is either intravascular or extravascular (within the cells of the reticuloendothelial system [RES]). Intravascular hemolysis is rare in the ambulatory patient, usually due to a transfusion reaction, extensive burns, aortic valve prosthesis, or acute glucose-6-dehydrogenase deficiency. Intravascular hemolysis leaves a trail of clues. With RBC breakdown there is an increase in the released constituents such as bilirubin (indirect), LDH, and potassium. These same findings may occur if there was mishandling of the blood sample with consequent hemolysis but to

a lesser degree. Urine hemosiderin may be found several days after intravascular hemolysis has occurred. Extravascular hemolysis, not occurring within the vascular system but within the cells of the RES, leaves few clues. However, most causes can be determined by an abnormality in the hemoglobin or shape of the RBC. Other causes are autoimmune. These are determined by the Coombs' test. A history of transfusion or pregnancy is often found.

## **Blood Loss**

When blood is lost, a historical report of a bleeding source is not always obvious. Abortions, childbirth, stab wounds, and surgeries are obvious causes, but the majority of patients in an ambulatory setting have less obvious causes. The most common cause is heavy menstrual flow in women. Occult sites of bleeding are often GI. GI bleeding may be frank, as with hemorrhoids; however, higher GI bleeding is often not evident in the stool without guaiac testing. Associated GI symptoms such as upper GI pain associated with meals or lower GI pain with a change in bowel habits may be the only clues.

## **Laboratory Evaluation**

The distinction among the various major types of anemia begins with an evaluation of size. This is done two ways: (1) indices, mainly the MCV, and (2) RBC morphology. These two values often coincide. For example, small cells are morphologically described as microcytic and are usually associated with a decreased MCV. Conversely, large cells are referred to as macrocytes and are accompanied by an increased MCV.

## **Microcytic Anemia**

Microcytic anemia is mainly due to IDA and thalassemia minor. Anemia of chronic disease may present as normocytic or microcytic. IDA has some characteristic associated findings that

often will clinch the diagnosis. RDW is the coefficient of variation of RBCs. This is determined by dividing the standard deviation of the erythrocyte volume distribution by the MCV. The result is then multiplied by 100 and expressed as a percentage. RDW is either normal or increased. An RDW increase often precedes changes in the MCV because the MCV is sensitive to large RBC population changes only. The sensitivity of RDW in diagnosing IDA is between 87% and 100%.<sup>5</sup> The RDW is normal with thalassemia minor (except in rare cases of severe anemia).

Serum ferritin is highly specific for IDA (99% to 100%). Therefore, IDA is diagnosed by finding a microcytic anemia with a combination of a decrease in RBCs and an increase in RDW that is confirmed by a concomitant decrease in serum ferritin. Other supportive findings are a decreased hemoglobin, an increased total iron-binding capacity (TIBC), and a decreased transferrin percent saturation.

Patients with thalassemia minor are usually asymptomatic. Although the anemia is microcytic and sometimes hypochromic, the serum ferritin is usually normal or slightly elevated, distinguishing it from IDA. More important, an elevated RBC count is virtually diagnostic, being 75% sensitive and 97% specific for thalassemia syndromes. RDW is normal. Further confirmation may be necessary with hemoglobin electrophoresis.

Anemia of chronic disease (ACD) may present in a pure form or associated with IDA. ACD is microcytic in only 25% of cases.<sup>6</sup> When microcytic, the MCV rarely is below 78 fL. When ACD is pure, the distinction between IDA is clearer. A decrease in TIBC, an increase in ferritin, and often an increase in the erythrocyte sedimentation rate (ESR) are found with pure ACD. Serum ferritin is often increased because it is an acute-phase reactant; it is increased in inflammatory diseases. Total serum iron is low in both ACD and IDA. IDA and ACD may coexist for various reasons. One possibility is that patients with rheumatoid arthritis, for example, may be taking medications that cause GI bleeding and an associated IDA. The serum ferritin will then be low or borderline.

## **Macrocytic Anemia**

The most common causes of macrocytic anemia are vitamin B<sub>12</sub> deficiency, folate deficiency, alcoholism, hypothyroidism, and liver disease. A distinction is made between megaloblastic and nonmegaloblastic anemia. This requires a bone marrow aspirate. This is rarely needed, however, because of the sensitivity and specificity of other laboratory values, coupled with the history. When the MCV is greater than 130 fL the probability is 100% for vitamin B<sub>12</sub> or folate deficiency (megaloblastic).<sup>7</sup> Levels below 95 fL equal a 0.1% probability. Antimetabolite or antifolate drugs may also cause a megaloblastic anemia. A mild elevation in the range of 100 to 110 fL is suggestive of other causes, such as alcoholism, liver disease, or hypothyroidism. Further laboratory testing for liver enzymes and ultrasensitive thyrotropin (TSH) will differentiate these possibilities.

Some lab values are elevated in both vitamin B<sub>12</sub> and folate deficiencies, such as RDW. Also, RBC folate concentrations are low and serum homocysteine levels are elevated with both vitamin B<sub>12</sub> and folate deficiencies.

A differentiation between vitamin B<sub>12</sub> deficiency and folate deficiency is important because of the potential neurologic consequences of vitamin B<sub>12</sub> deficiency. In other words, folate supplementation will not correct the neurologic abnormalities of vitamin B<sub>12</sub> deficiency. Also, vitamin B<sub>12</sub> deficiency is less often a “nutritional” deficiency (only 2% of all cases) and more often either a malabsorption consequence or due to a lack of intrinsic factor. Pernicious anemia is differentiated from dietary B<sub>12</sub> deficiency by testing for anti-intrinsic antibody titers. The Schilling test is rarely used but is an option.

Serum levels of vitamin B<sub>12</sub> and folate may be measured. In addition, serum methylmalonic acid (MMA) and total homocysteine levels are high in patients with vitamin B<sub>12</sub> deficiency (95% sensitive).<sup>8, 9</sup> Folate deficiency will usually raise the homocysteine level only and not MMA. RBC folate is less valuable in distinguishing between the two anemias because it is often found to be low in both vitamin B<sub>12</sub> and folate deficiency. RBC folate is better used as an indicator of tissue stores.

A therapeutic trial may be acceptable as an initial attempt to differentiate between vitamin B<sub>12</sub> and folate deficiency; however,

most authors warn against this approach due to the possibility of misinterpretation and the result of neurologic deficits in patients who actually have pernicious anemia. The approach involves oral folate at 100 mg/day for 10 days. The patient's reticulocyte response is then measured. If the underlying cause of macrocytic anemia is folate deficiency, there will be an increase in reticulocytes; however, there will be no increase in patients with a vitamin B<sub>12</sub> deficiency. Although likely to differentiate between folate and vitamin B<sub>12</sub> deficiency, there are many factors that influence test results and the inadvertent misdiagnosis in a patient with pernicious anemia as the cause of B<sub>12</sub> deficiency may result in irreversible neurologic damage.

## Management

Dietary management of anemias through supplementation must be preceded by a thorough diagnostic search that provides sufficiently convincing information that there is not an underlying cause that needs comanagement or referral. For example, IDA may be a dietary issue in pregnant women, infants, and adolescent or adult athletes. Dietary supplementation (or an iron-enriched formula for infants) is appropriate. However, in the case of occult GI bleeding, heavy menstrual flow, and urinary loss, referral for determination of underlying pathology is needed prior to institution of dietary correction. ACD also requires at the minimum a consultation with the physician treating the primary disorder. Vitamin B<sub>12</sub> deficiency that is due to a strictly vegetarian diet is responsive to a change in diet or supplementation; patients with pernicious anemia should be referred for lifelong treatment with injectable or intranasal vitamin B<sub>12</sub>. There is some evidence from Swedish studies, however, that daily supplementation of 1,000 mg (2,000 mg twice daily for the first month) is sufficient to cover the variable absorption rate in some individuals. There are no toxic effects known.<sup>10</sup> The main reasons given for not using this approach are compliance and cost. The cost currently is not a consideration.

Some basic recommendations for dietary supplementation, when appropriate, follow.<sup>11</sup>

## **Iron-Deficiency Anemia**

- For adults, ferrous sulfate (or ferrous forms of lactate, fumarate, gluconate, glycine sulfate, or glutamate), 200 mg to 325 mg two to three times per day, is given for 6 to 12 months after hemoglobin levels are normal (the dose is dependent on patient tolerance).
- Side effects such as constipation may be decreased by starting with a lower dosage and slowly increasing gradually over several days or by taking the supplement in three divided doses.

Dietary recommendations include the following:

- Avoid substances that may affect iron absorption, including tea, coffee, milk or dairy products, calcium, and some medications at least for one hour before and after ingestion of iron supplementation.
- Include a source of vitamin C at every meal.
- Include foods rich in iron, such as dried beans and peas, poultry, seafood, and red meat.
- Increase dietary fiber moderately to offset the possible side effect of constipation associated with iron supplements.

## **Folate Deficiency**

- Oral folic acid at 1 to 5 mg/day for two to three weeks is necessary to replenish tissues.
- Maintain levels with 50 to 100 mg/day.
- Remember that orange juice, asparagus, beef liver, wheat germ, red beans, and peanut butter are high in folic acid.

## **Vitamin B<sub>12</sub> Deficiency Anemia—Pernicious Anemia**

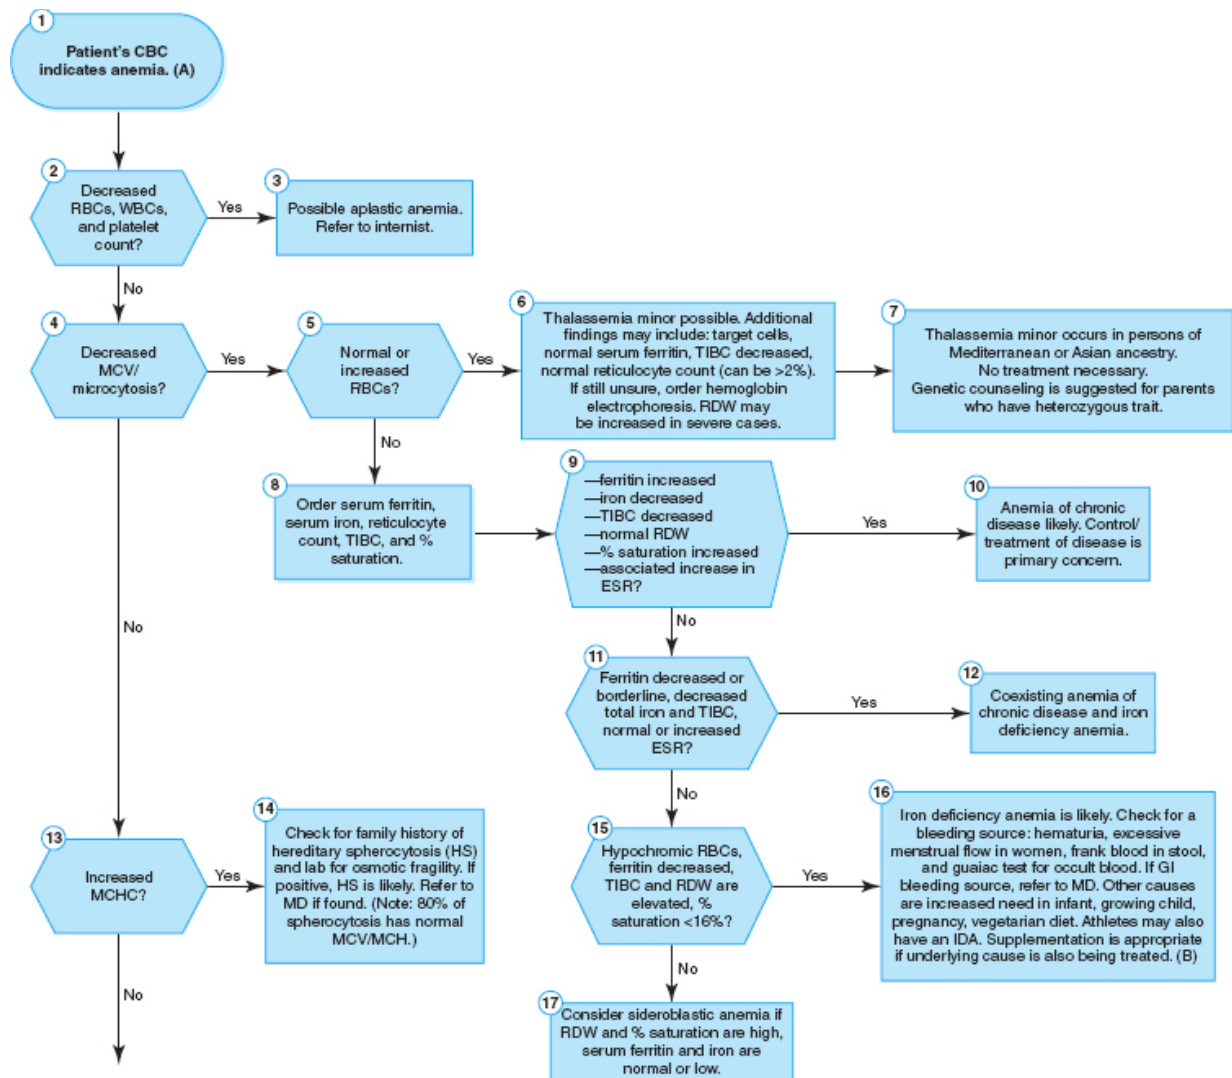

- Very large doses are necessary to attain a high enough level that 1% to 3% of vitamin B<sub>12</sub> that does not require intrinsic factor equals therapeutic levels; doses at 1,000 mg/day are necessary.
- Increase sublingual B<sub>12</sub>.

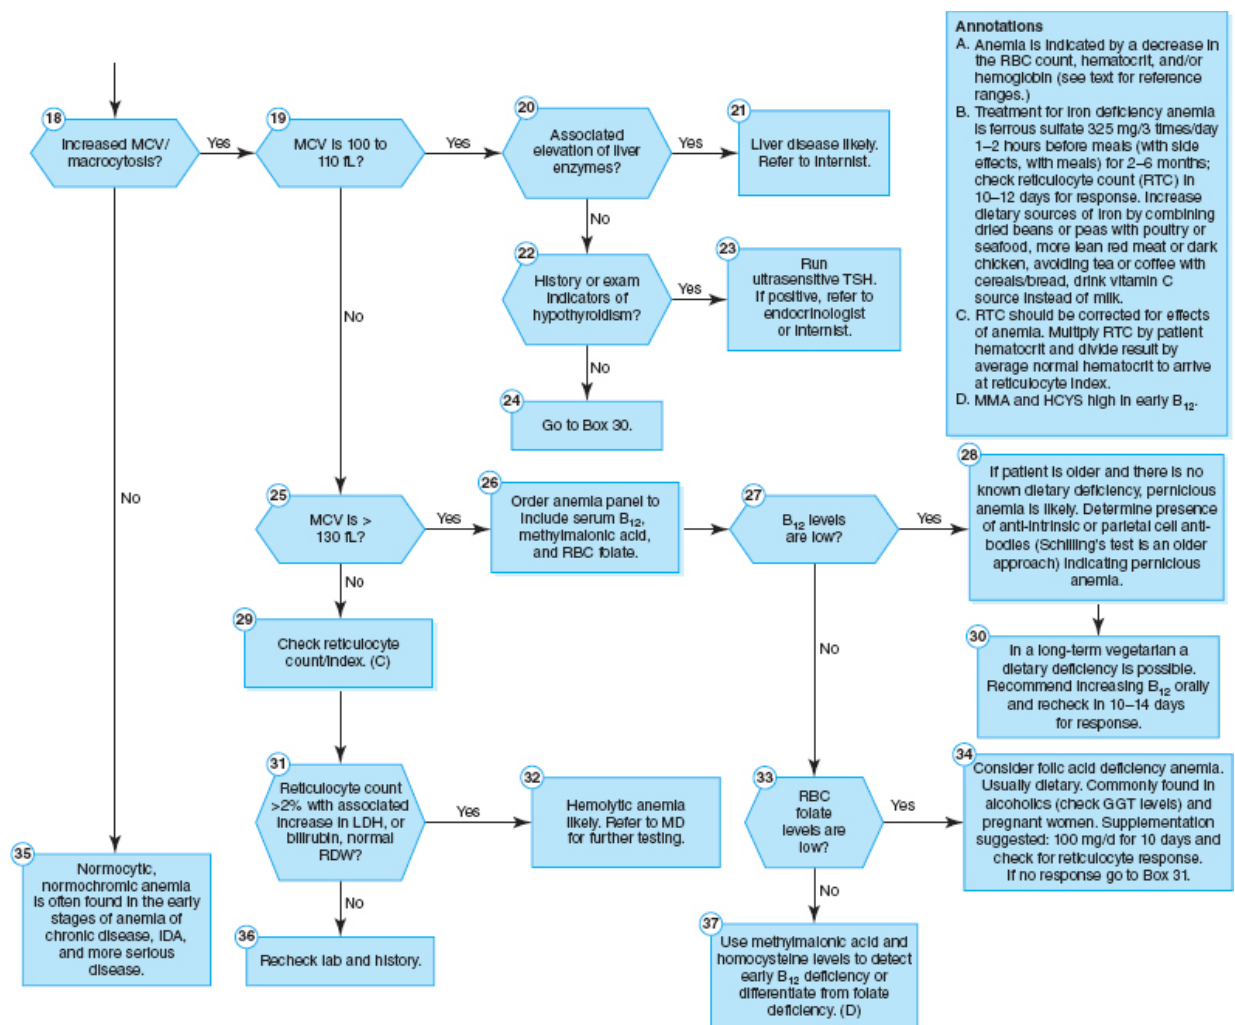

## **Vitamin B<sub>12</sub> Deficiency Anemia—Nutritional**

- Supplementation with B<sub>12</sub> is best achieved through a B-complex formula to avoid imbalances.
- Dietary sources include liver, beef, pork, eggs, and milk and milk products.

## **Algorithm**

An algorithm for microcytic anemia is presented in **Figure 52-1**.

**Figure 52-1** Anemia—Algorithm

## Selected Anemias

### MICROCYTIC AND NORMOCYTIC ANEMIAS

#### Iron-Deficiency Anemia

#### Classic Presentation

Most patients are initially asymptomatic. When symptomatic, the patient may present with symptoms related to a decreased oxygen-carrying capacity of the blood, such as fatigue (mainly on exertion), orthopnea, headaches, dizziness, learning disability/decreased attention span (in children), syncope/presyncope, or angina (if predisposed with coronary artery disease).

#### Cause

IDA is the most common hematologic disorder, affecting as many as 30% of the world's population. However, in the United States, it affects 0.2% to 2% of adult males and 2% to 10% (one study<sup>12</sup> indicated up to 20%) of adult females.<sup>13</sup> The likelihood of IDA development is increased in certain patient populations: pregnant women (increased demand), 60%; heavily menstruating women, 80%; and individuals with pica symptoms, 90%. Other groups at risk include infants (especially those infants fed unfortified cow's milk and/or those who substitute with juices) to age 4 years, adolescents who exercise heavily, long-distance runners (malabsorption, megaloblastic anemia), and patients with chronic diseases (i.e., rheumatoid arthritis, cancer).<sup>14</sup>

Anemia is not the first sign of iron deficiency. There are generally five stages: (1) depletion of storage iron, (2) decreased serum iron, (3) anemia with normal cells, (4) microcytosis, then hypochromia, and (5) symptoms and signs of IDA. The main cause of IDA is blood loss. When IDA is diagnosed, a search for a bleeding source is a requisite prior to treatment. However, a factor for individuals without blood loss is nutritional demand for and availability of iron at varying stages of life.

#### Evaluation

In the early stage of iron deficiency, there are no signs or symptoms. When a patient has reached the later stages, patients with chronic IDA often will have an unusual craving 50% of the time, referred to as pica (craving for ice, clay/dirt, or starch); pagophagia (ice eating) is most common.<sup>15</sup> Chronic, severe IDA may have signs,

including spoon-shaped nails (koilonychia), brittle nails, skin cracking at the corners of the mouth (angular stomatitis), a smooth tongue (atrophic glossitis), or blue sclerae.<sup>16</sup> Remember that these signs and symptoms are the last clinical indicator of IDA. Laboratory evaluation can detect anemia prior to the development of these indicators. The classic laboratory presentation is a decrease in RBCs and hemoglobin, microcytosis, and a decreased MCV with an increase in the RDW. Specific indicators include a decrease in serum ferritin (<10 ng/mL), an increase in total TIBC, and a decrease in transferrin saturation (<16%). Other indicators are due to blood loss, such as increase of blood or RBCs in the urine, or a positive guaiac test for occult blood. If IDA is discovered, a thorough search for a source of blood loss must be made. The most common will be heavy menstruation, GI loss from ulcer or cancer, and urinary/renal pathology.

## Management

The first decision to make before treatment is whether IDA is caused by nutritional need due to increased demand or due to blood loss. Blood loss from heavy menstruation should be managed with a gynecologist to determine whether there is an underlying hormonal imbalance. If occult blood is found, referral for medical evaluation should occur. Nutritional causes may be managed with dietary supplementation. Between 200 and 325 mg of ferrous sulfate two to three times per day for 10 to 14 days should be prescribed (higher doses may be necessary in some individuals).<sup>17</sup> Calcium supplementation may interfere with iron absorption, and therefore should be staggered. At about two weeks, the reticulocyte count is checked to determine a response (increase). The hemoglobin concentration should increase to normal in six to eight weeks. If responsive, continue for a total of six months. If not, consider another cause. Remember to counsel and possibly screen high-risk individuals (or their parents). In a recent preliminary study,<sup>18</sup> individuals who had IDA had no finding other than infection by *Helicobacter pylori*. These same patients did not respond well to iron supplementation. Eradication of the infection led to a cure of the anemia. At one-year post-treatment, 90% of patients were free of anemia. The authors note that many of the patients were women who were told that the anemia was due to menstrual blood loss.

## Thalassemia Minor

### Classic Presentation

The patient is usually asymptomatic.

### Cause

Thalassemia (TS) is the second most common anemia in humans and the most common genetic disorder. The thalassemias are characterized by a reduction in globin chains that results in reduced hemoglobin synthesis. There are different types with varying degrees of severity.  $\alpha$ -Thalassemia trait and  $\beta$ -thalassemia minor (heterozygous) are by far the most common.  $\alpha$ -TS is more common in individuals from

Asia/China and in blacks.  $\beta$ -TS is more common in persons of Italian or Greek ancestry and less common in blacks and Asians/Chinese. Thalassemia major is quite rare in the United States, representing less than 1,000 cases. These patients are homozygous and develop severe life-threatening problems within the first year of life.

## Evaluation

An elevated RBC count with a low MCV is 75% sensitive and 95% specific for thalassemia syndromes. This combination distinguishes TS from IDA in most cases. Other findings may include microcytosis, target cells (basophilic stippling with  $\beta$ -TS), a normal serum ferritin, TIBC normal or decreased, and a reticulocyte count that is normal or slightly elevated. It is important to recognize that a patient suspected of having IDA yet is unresponsive to iron supplementation may have an underlying TS.

## Management

Patients with  $\alpha$ -TS trait or  $\beta$ -TS minor need no treatment. It is important to note that both parents who are heterozygous for a specific TS (i.e., both parents have TS minor or both parents have  $\alpha$ -TS trait) are at risk of producing a homozygous (TS major) child. Given the severity and poor prognosis for a TS child, genetic counseling should be suggested and the option of prenatal diagnosis should be discussed with those already pregnant.

## Anemia of Chronic Disease

### Classic Presentation

Patients with ACD usually have rheumatoid arthritis (RA), cancer, chronic infection or inflammation, or liver disease.

## Cause

The cause is unknown. Several theories have been proposed: (1) impairment of protein synthesis (decrease in transferrin, albumin, and erythropoietin), (2) activation of macrophages or reticuloendothelial (RE) cells, and (3) an impaired ability to recirculate iron from phagocytosed RBCs. Iron deficiency often coexists with ACD. A distinction is made between ACD and that caused by chronic renal failure; however, the mechanisms may overlap.

The iron deficiency seen with ACD is thought to be due to several mechanisms centered around the release of inflammatory cytokines that result in a disruption of iron homeostasis, impaired erythropoiesis, and RBC destruction. The inflammatory cytokines cause an increased uptake and decreased release of iron from the reticuloendothelial system creating a deficiency for heme biosynthesis. This is reflected in the often-found decrease in total iron on a general lab screen. The same mediators increase the release of hepcidin from hepatocytes. Hepcidin is a major negative iron regulator decreasing iron absorption from the duodenum. Erythropoiesis

is down-regulated by inflammatory cytokines due to a decrease in erythropoietin (EPO) precursors, and cells that produce these precursors go through apoptosis. The net result is a decrease in EPO production leading to a decrease in RBC production. Finally, RBC destruction is facilitated by the inflammatory cytokines by increasing phagocytosis of RBCs and increasing free radical destruction of RBCs.

## Evaluation

Coexisting indications or diagnosis of an underlying chronic disease help in the diagnosis. Laboratory diagnosis is sometimes confusing because values are similar for ACD and IDA. This is often due to the fact that they coexist (especially in patients with RA). ACD is usually normochromic and normocytic (75% of the time). Twenty-five percent of the time ACD is microcytic with an associated decrease in the MCV. Classically, the hematocrit is rarely below 25% and there is a decreased TIBC. While serum iron may be decreased, RDW is usually normal unless there is coexisting iron depletion that would lead to an elevated RDW. The likelihood of ACD is strong when there is a normal or increased serum ferritin and a decreased TIBC.

## Management

Usually treatment of the underlying disease is mainly what is necessary. If there is an associated IDA, iron supplementation may be beneficial. In severe cases, transfusion or erythropoietin injection may be necessary.

### MACROCYTIC ANEMIAS

#### Vitamin B<sub>12</sub> Deficiency

### Classic Presentation

In the early stages, most patients are asymptomatic. In later stages, the patient may complain of general weakness, shortness of breath, numbness and tingling, difficulty walking, or a swollen tongue.

### Cause

Vitamin B<sub>12</sub> (cyanocobalamin) is a water-soluble vitamin that requires a glycoprotein, intrinsic factor for absorption in the terminal ileum. Vitamin B<sub>12</sub> stores in the liver are usually sufficient for three to five years. Vitamin B<sub>12</sub> is a coenzyme in DNA synthesis and is important for myelin production. It is found in dairy products and meats. A nutritional cause due to lack of ingestion of appropriate foods is an uncommon cause occurring in only about 2% of cases. Even vegetarians can obtain necessary amounts through the consumption of legumes. With pernicious anemia (PA) and atrophic gastritis, intrinsic factor is unavailable, making vitamin B<sub>12</sub> unabsorbable (except for 1% to 3%). PA is due to an autoimmune response against the parietal cells and

intrinsic factor, leading to atrophic gastritis. Although the classic presentation of a gray-haired, middle-aged, northern European has been the standard description of a person with PA, PA is found in all ethnic groups; it is found more often in older patients<sup>19</sup> and young (<40 years old) black women.<sup>20</sup>

Malabsorption of vitamin B<sub>12</sub> may be due to lack of intrinsic factor due to atrophic gastritis, an *H. pylori* infection which impairs release of B<sub>12</sub> from protein, malabsorption syndromes including Crohn's disease, medications that decrease acidity and also impair the release of B<sub>12</sub> from protein such as proton pump inhibitors, H<sub>2</sub> antagonists, and antacids, and pancreatic insufficiency that decreases proteases necessary to cleave the B<sub>12</sub>-R factor complex. Other less common causes of vitamin B<sub>12</sub> deficiency include malabsorption from blind loop syndrome, fish tapeworm, and certain drugs. Nutritional deficiency is most common in chronic alcoholics and vegetarians. Vitamin B<sub>12</sub> deficiency in vegetarians is not inevitable if they eat a balanced diet. It would take three to five years of a diet free of dairy products and meat before clinical signs would become evident.

## Evaluation

Differentiation between vitamin B<sub>12</sub> and other causes of macrocytic anemia is necessary. A history of alcoholism, nutritional deficiency, or gastric surgery may be helpful. About 20% of individuals with cobalamin deficiency have no anemia and no macrocytosis.

Laboratory diagnosis is based on several classic findings: an MCV greater than 130 fL is 100% sensitive for vitamin B<sub>12</sub> and folic deficiency. Further distinction is that vitamin B<sub>12</sub> deficiency is usually associated with a low serum vitamin B<sub>12</sub>, and a high serum or urine methylmalonic acid (MMA; 95% sensitive).<sup>21</sup> Total homocysteine levels are also elevated. MMA is not elevated with folic acid deficiency. Currently the standard for PA is to test for anti-intrinsic antibodies. The Schilling test is rarely used but is an option.

It is possible to take these values and create a couplet of findings that help negotiate the differential for macrocytic anemia. Using MMA and homocysteine levels, if both are normal, B<sub>12</sub> deficiency is ruled out. If both are positive, B<sub>12</sub> deficiency is ruled in (sensitivity 94%; specificity 99%). If MMA is normal and homocysteine is elevated, folate deficiency is likely.

Coexisting IDA and PA occurs 20% to 25% of the time.<sup>22</sup> This or coexisting thalassemia may result in a normal MCV.

## Management

Folic acid replacement will correct the anemia of vitamin B<sub>12</sub> deficiency; however, there will usually be no reticulocyte count increase in response to folic acid supplementation. Vitamin B<sub>12</sub> deficiency due to PA requires injections (daily injections for one week, weekly injections for one month, monthly injections for life). When correction of the anemia has been achieved based on a normal laboratory investigation, intranasal cyanocobalamin (Nascobal) may then be used. Initial dose is one spray in one nostril once per week. Monitoring will determine effectiveness or need to return to intramuscular injection. Oral supplementation requires very large dosages (1,000 mg/day) and strict patient compliance (1% to 3% is absorbed without

intrinsic factor).<sup>10</sup> Early treatment of PA may prevent or reverse neurologic manifestations. PA patients with neurologic findings less than three months before treatment may have these findings reversed. This may take between 6 and 18 months. Hematologic response is indicated by an increased reticulocyte count in 10 days and correction within six weeks. Patients generally feel physically better almost immediately. It is recommended that because of a higher predisposition to gastric carcinoma, PA patients should be examined with endoscopy every five years.

## **Folate Deficiency**

### **Classic Presentation**

Early folate (folic acid) deficiency is asymptomatic. The patient is often either an alcoholic or a pregnant woman who complains of generalized fatigue.

#### **Cause**

Folate is a water-soluble vitamin needed for DNA synthesis and erythropoiesis. Folate stores last for three to six months. It is found in most fruits and vegetables (especially citrus fruits and green leafy vegetables). There are numerous causes of deficiency. Inadequate intake is found in infants, adolescents, the elderly, and chronic alcoholics. Increased need is found in pregnant women. Malabsorption syndromes and drugs such as oral contraceptives, methotrexate, and phenytoin interfere with absorption. Smoking appears to be a risk factor with folate deficiency. Overcooking foods and a lack of vitamin C may also contribute to a deficiency.<sup>23</sup> It is important to note that low folate levels may be associated with an increased risk of colorectal and cervical cancer.<sup>24</sup> There may also be a relationship to chronic fatigue.<sup>25</sup> Low folate levels during pregnancy may result in neural tube defects in the fetus.

### **Evaluation**

Folate deficiency is difficult to differentiate from early vitamin B<sub>12</sub> deficiency. There are initially no neurologic findings with either. Eventually vitamin B<sub>12</sub> deficiency might develop neurologic manifestations. Laboratory evaluation is helpful. Shared findings include an MCV >130 fL, macrocytosis, and decreased hemoglobin. Specific findings include low levels of serum and RBC folate. Although RBC folate is the better test, it may not indicate folate deficiency for several months. Some authors suggest a trial of oral folate at 100 mg/day for 10 days followed by a check for a reticulocyte count increase helps to differentiate between vitamin B<sub>12</sub> deficiency and folate deficiency. At this level of supplementation there will not be a response with vitamin B<sub>12</sub> deficiency.<sup>26</sup> However, most authors warn against this approach due to the potential of misdiagnosis and subsequent development of irreversible neurologic deficits with patients having pernicious anemia.

### **Management**

When dietary deficiency or increased demand is the cause, supplementation at 1 to 2 mg/day for two to three weeks is needed. Daily supplementation of between 50 and 100 mg is needed. This can be achieved through a diet rich in orange juice, asparagus, red beans, peanut butter, and beef liver. The reticulocyte response occurs within 10 days. Unresponsiveness suggests other causes.

Part IX

## Special Patient Groups

## CHAPTER 53

# The Pediatric/Adolescent Patient

### Context

A survey<sup>1</sup> of patients in Canada evaluated the use of complementary and alternative medicine (CAM) for the pediatric population. The range of use was between 42% to 71% representing wide regional differences. The most common CAM practitioners used were massage therapists and chiropractic physicians.

Data are limited regarding how much of a chiropractor's patient base is pediatric and adolescent. Preliminary studies, primarily done in countries outside the United States, indicate that pediatric visits account for between 4.6% and 10% of daily visits, and adolescent visits account for approximately 15% of daily visits.<sup>2</sup> With adolescents, back pain accounted for about 33% of visits. Neck and headache pain accounted for approximately 40% of visits. Probably unrepresentative of a field practice, a college clinic demonstrated that 33% of pediatric/adolescent patients presented for a general physical examination.

Interestingly, a Canadian study of pediatric visits to alternative care practitioners indicated that the majority of patients presented with nonmusculoskeletal complaints such as respiratory and eyes, ears, nose, and throat (EENT)-related symptoms.<sup>3</sup> In 2012, a review<sup>4</sup> noted that the reason for visits broken down by percentage equaled for skeletal (57.0%), neurologic (23.7%), gastrointestinal (12.4%), infection (3.5%), genitourinary (1.5%), immune (1.4%), and for miscellaneous conditions (0.5%). A review<sup>5</sup> of the literature in 2012 regarding chiropractic management of pediatric complaints revealed there were six clinical trials investigating the effectiveness of spinal manipulative therapy (SMT) for colic, two each for asthma and enuresis, and one each on hip extension, otitis media, suboptimal breastfeeding, autism, idiopathic scoliosis, and jet lag. The authors note that in their review none of the studies evaluated effectiveness of SMT on spinal pain.

Authors of a 2010 review<sup>6</sup> of pediatric care by chiropractors concluded that there is a paradox within the chiropractic profession (similar to the medical profession's use of medication) that although the main reason for pediatric patients (or their parents) to seek a chiropractor is for spinal pain, there are no studies other than case studies for this predominant complaint.

An individual chiropractor's involvement in pediatric/adolescent care is dictated by the chiropractor's pediatric/adolescent focus, expertise, and his or her involvement in school examinations, scoliosis screenings, and sports preparticipation examinations.

Generally, the pediatric/adolescent patient presents a complex and dynamic challenge based on constantly changing "normals" and milestones of development. Specific issues include:

- musculoskeletal and neurologic development
- prevention of injury issues (e.g., sports, motor vehicle collision, and abuse)

- social/psychologic challenges (e.g., attention-deficit disorder, hyperactivity, depression, eating disorders)

In addition to evaluating the young patient with a specific complaint or complaints, monitoring of normal development and screening for disorders and risk factors specific to a particular age range are responsibilities of the managing doctor. Counseling may be particularly important in the prevention of addictive behaviors (e.g., smoking, alcoholism, gambling), nutrition and exercise, sexually transmitted disorders, and birth control. Regarding unusual patient presentations, a review by Miller et al. evaluated the literature regarding child medication errors over a five-year period. The reviewers estimate that between 5% and 27% of medication errors occur during ordering, which includes prescribing, dispensing, and administering. The majority of these (72% to 75%) occur with administering the medication. Other “errors” include the use of medications designed and tested on adults but not on children. Most of these errors are hospital-based.<sup>7</sup>

Specific challenges arise when eliciting historical information with limitations presented by the inability of the infant or child to verbalize a complaint or the issue of privacy in an adolescent patient. Overreactive responses to physical examination procedures introduce a challenge to interpretation of orthopaedic and palpation positives. Radiologic challenges occur due to the overlap between normal variants and areas of complaint and age-related, and therefore changing, normal radiographic anatomy.

The following discussion is intended as an overview of an extremely broad specialty, focusing on some age-related complaints that are nonmusculoskeletal, but primarily on complaints and concerns of the musculoskeletal system.

## General Strategy

- Consider the purpose and requirements for evaluation in three common scenarios:
  1. The periodic health examination—intended to check for milestones in development, screen for risk factors for a specific age group, and counsel on health-related topics for that age group
  2. The sports preparticipation examination—intended to screen for developmental markers related to the type of sport, screen for risk factors for injury, and determine deficiencies in performance to aid in exercise/training prescription
  3. The child or parent concerned about pain, dysfunction, or cosmetic appearance
- Address vaccination issues.
- Be vigilant with regard to ominous signs suggestive of cancer or tumor.
- Be vigilant with regard to child abuse and have a referral source for suspected cases.
- Be aware of normal variants of growth centers and bony development in children, always considering a bilateral radiographic evaluation if involving an extremity.
- Consider injuries or conditions that are more common or exclusive to the child/adolescent such as developmental asymmetry, epiphyseal and apophyseal injury, and different types of fracture patterns.
- Refer for second opinion in the following settings:

1. signs of abuse
  2. orthopaedic problems that have a tendency to progress without surgical management
  3. ear infections associated with high fever and chills
  4. suspicion or identification of fracture (with the exception of a torus fracture), osteomyelitis, septic synovitis, or tumor/cancer
- When adjusting the pediatric spine, consider anatomic and developmental issues, modifying the degree of force and positioning of the child.<sup>8</sup>

## The Periodic Health Examination

For the asymptomatic patient, many agencies, including the U.S. Preventive Services Task Force (USPSTF), have developed strategies focusing on age-related concerns.<sup>9</sup> The examination components include screening, counseling, and immunization recommendations. General evaluation recommendations include:

- Measure vitals including height, weight, and blood pressure.
- Determine if normal growth and neurologic development are occurring. These signposts are particularly important in the first few years of life (see [Table 53-1](#)).
- Be vigilant regarding signs of physical or sexual abuse.
- Screen for vision between the ages of 3 and 4 years.
- Screen for lead toxicity and hypercholesterolemia in high-risk groups.
- Focus counseling on the risk areas based on age; however, always counsel on a healthy diet and adequate exercise.

A 2007 study by Hansen et al.<sup>10</sup> indicates that there is an underdiagnosis of hypertension in children and adolescents. In a group of 507 children and adolescents, 3.6% had hypertension. Only 26% of those with HTN had an entry in their medical records, while only 11% with prehypertension had an entry in their medical records. Factors related to an increased associated risk were older age, increase in 1% height-for-age percentile, obesity, and frequency of degree of prior abnormal BP readings.

Many conditions due to inborn errors are evident at birth or as the child develops. A short list of some of these conditions is given in [Tables 53-1](#) and [53-2](#). These lists are not comprehensive; rather, they are a reminder that hereditary disease must be considered when neurologic development is abnormal, or when unusual signs or symptoms develop.

**Table 53-1** Developmental Milestones

Age	Observational Activities	Activities Reported by Patients	Language Capabilities
1–2 months	Holds head up Raises head prone 45° Turns head and eyes to sound Acknowledges faces Follows objects through visual fields Drops objects (toys) Is alert in response to voices	Smiles responsively and spontaneously Recognizes parents	Engages in vocalizations (coo)
3–5 months	Smiles, laughs, giggles Holds head high and raises body with hands while in a prone position Reaches for and brings objects to mouth Makes “raspberry” sound Sits with support (head steady) Holds rattle briefly	Anticipates food on sight Rolls from front to back Turns from back to side Excited upon recognizing familiar people	Squeals Babbles, initial vowels Guttural sounds (“ah,” “go”) Consonants: m, p, b Vowels: o, u
6–8 months	Initiates “bye bye” Reaches Sits alone for a short time Some weight-bearing Passes object from hand to hand in midline First scoops up a pellet then grasps it using thumb opposition	Rolls front to back and back to front Is indifferent to the word “no”	Babbles/initiates speech sounds Syllables: da, ba, ka
9–11 months	Sits alone Pulls to stand Stands alone Creeps Initiates pat-a-cake and peek-a-boo Uses thumb and index finger to pick up pellet	Feeds self finger foods Walks supported by furniture Follows one-step verbal commands (e.g., “Come here,” “give it to me”)	MaMa/DaDa nonspecifically Approximates names: babba/bottle
12 months	Walks with support or independently Pincer grasp Gives toys upon request Brings two blocks together; tries to build tower Releases objects into cup after demonstration	Points to desired objects Looks for hidden objects	MaMa/DaDa specific Jargon begins (own language) 2–3 words understandable
18 months	Throws ball Climbs/descends stairs with aid Turns pages Uses a spoon Identifies body parts Seats self in chairs Scribbles spontaneously Builds tower of 3–4 blocks	Feeds self Carries and hugs doll Understands a 2-step command	Says 10–15 words Consonants: t, d, w, h, n 2-word phrases understandable
24 months	Kicks ball Holds cup securely Points to named objects or pictures Jumps off floor with both feet Stands on one foot alone	Verbalizes toilet needs Mimics domestic activities Pulls on simple garments	3-word phrases understandable (contains subject, verb, and object) Use of pronouns: mine, me, you, I

	Builds tower of 6–7 blocks Climbs/descends stairs unaided Turns pages of a book singly		Vowels uttered correctly Approximately 100-word vocabulary
30 months	Refers to self as I Copies a crude circle Walks backwards Begins to hop on one leg Holds crayon in fist	Helps put things away	Counts 3 objects correctly Repeats 3 numbers or a sentence of 6 syllables Carries on a conversation Uses prepositions
36 months	Shares playthings Copies a circle Holds crayon with fingers Initiates a vertical line Builds a tower using 9–10 blocks Gives first and last name	Dresses with supervision Rides tricycle using pedals While looking at picture book, able to answer: "What . . . doing?"	Some degree of hesitancy and uncertainty common Intelligible 4-word phrases Approximately 900 words
3–4 years	Walks on heels Climbs/descends stairs with alternating feet Responds to command to place objects in, on, or under table Draws a circle when asked to draw a person (man, boy, girl) Knows own sex Finger opposition Begins to button and unbutton General knowledge: Full name, age, address (2 out of 3)	Takes off shoes and jacket Feeds self at mealtime	Intelligible 5-word phrases Answers questions using plurals, personal pronoun, and verbs (What do you want to do that is fun?)
4–5 years	May stand on one leg for at least 10 seconds Runs and turns without losing balance Tiptoes Tells a simple story Knows the days of the week Draws a person Counts to 4 by rote Begins understanding rules (right and wrong) Cuts and pastes Gives appropriate answers to: "What must you do if you are sleepy? Hungry? Cold?" etc.	Dressing and undressing without supervision Buttons clothes and laces shoes but does not tie Self-care with toilet needs (may need help wiping) Plays outside for at least 30 minutes	Intelligible 6-word phrases Names 4 colors Repeats sentence of 10 syllables Approximately 1,540 words
5–6 years	Skips Catches a ball Copies a + that is already drawn Tells own age Knows right and left Draws a recognizable person with at least 8 details Understands the concept of 10 (is able to count out 10 objects) Describes favorite television program or video in some detail	Goes to school unattended or meets school bus Helps with simple chores at home (taking out the garbage) Good motor capability, but little aware of dangers	Intelligible 6–7 word sentences Approximately 2,560 words

## Focused Concerns (Not Covered in Other Areas of This Text)

# Sudden Infant Death Syndrome

Sudden infant death syndrome (SIDS) is death in an infant younger than 1 year old that cannot be explained after complete autopsy, death scene investigation, or review of the family history. SIDS is the leading cause of death between 1 month and 1 year of age. In the United States the incidence is about 1.5 per 1,000 live births.<sup>11</sup> Although rare in the first month of life, there is a peak incidence in months two through four. Although there are no clear explanations as to the pathophysiology, there are identifiable risk factors including maternal smoking, prematurity, and perhaps bottle-feeding as compared with breastfeeding. The most successful modifiable risk factor,

though, is the prone sleeping position.<sup>12</sup> SIDS rates decrease dramatically when parents are educated to the safer sleeping position of side-lying or supine.<sup>13</sup>

**Table 53-2** Chromosomal Abnormalities with Examples of Each

<b>Type with Example</b>	<b>Overview</b>
<b>Structural</b>  WGAR syndrome (Deletion of short arm of chromosome 11) Retinoblastoma (Deletion of long arm of chromosome 13)	Stands for congenital Wilms' tumor of the kidney, anidia (lack of iris), general malformations, and mental retardation. This condition results in tumor due to loss of a Wilms' tumor suppressor gene.
<b>Numerical</b>  Trisomy 21 (Down's syndrome)	1 in 800 births. Common combinations of characteristics in varying degrees of severity, including mental retardation, wide face, low-bridged nose, closely set slanted eyes with epicanthus (medial fold of the upper lid), macroglossia (large tongue), short limbs, simian crease across palms, clinodactyly (fifth finger shorter and crooked), heart defects, gastro defects (atresia and stenosis), infertility in males and most females, possible mild anemia, and predisposition to leukemia. Down's syndrome affects longevity mainly due to cardiac problems; average age of death is 55 years. Prenatal diagnosis for Down's syndrome includes chorionic villus biopsy or amniocentesis.
<b>Sex chromosome</b>  <b>Turner's syndrome</b>	Monosomy X (45 XO) occurs in 1 in 3,000 births. Abnormal segregation of sex chromosome during meiosis in female or male gonads. Characteristics include short stature, increased valgus angle at the elbows, webbed neck, barrel chest, and sometimes heart defects and coarctation of the aorta. Normal female genital organs except ovaries transform into "streak" gonads. Females do not develop secondary sexual characteristics and are generally infertile. Hormonal replacement may help body image but not the infertility.
Klinefelter's syndrome	Trisomy of sex chromosomes (47 XXY) occurs in 1 in 700 births. Abnormal segregation of sex chromosome during meiosis in female or male gonads. Phenotypically male and infertile. Puberty does not develop. Patients typically have a small penis, scant pubic hair; generally tall and effeminate with possible gynecomastia (enlargement of breast tissue).
<b>Single gene disorders</b> <b>Autosomal dominant</b>  (over 1,000 disorders total)	Trait is apparent in heterozygotes with a 50% chance of passing on the gene to offspring with expression in every generation. Unaffected offspring of a symptomatic carrier do not transmit gene.
Marfan's syndrome	Occurs in 1 in 10,000 births. Dysfunction of the gene that codes for fibrillin, a connective tissue protein involved in the structure of many organs. Features

	include a tall, slender stature with elongated head (dolichocephalic) and prominent frontal bosselation, scoliosis and kyphosis, aortic aneurysm and other dissecting predisposition, valvular insufficiency, subluxation of the lens in the eyes, retinal detachment, cataracts, and sometimes blindness. Must be distinguished from anorexia nervosa, and in tall athletes diagnosis may affect participation.
Achondroplastic dwarfism	A type of osteochondrodysplasia dwarfism (many other types). Short limbs, bulky forehead, saddle nose, lumbar lordosis, and bowlegs. Parents are not affected by dwarfism in 90% of cases. Spinal stenosis is common as is basilar impression and stenosis of the foramen magnum. This may lead to apnea and sudden death.
Osteogenesis imperfecta	There are two main types, and some subdivisions, of this disorder that is characterized by abnormal maturation of collagen due to an ATPase enzyme deficiency. The clinical features include osteoporosis with resulting fragility of the skeleton, blue sclerae (90% of individuals), abnormal dentition (dentinogenesis imperfecta), and premature otosclerosis. Fractures, bowing of the extremities, dislocations, kyphoscoliosis, basilar impression, ligamentous laxity, and deafness are all found. The tarda form usually allows a normal life expectancy.
Polycystic kidney disease	Occurs in 1 in 400 to 1 in 1,000 births. The abnormal gene is (in most cases) located on the short arm of chromosome 16 (sometimes 4). In addition to kidney cysts development, cysts may be found in the liver (most common), pancreas and spleen (less common), and CNS arachnoid. Individuals are more prone to cerebral aneurysms. Diagnosis is made by a positive family history of polycystic kidney disease and three or more cysts in both kidneys detected on renal ultrasound or abdominal CT. Medication treatment for associated hypertension. If end-range kidney disease occurs, dialysis or renal transplantation is considered.
Spherocytosis	The membrane defect is found in the protein spectrin (there are two structural proteins for the red blood cell: spectrin and actin). The result is a round cell instead of a biconcave disk, making the cell vulnerable to lysis in the spleen. As a result, the individual will develop splenomegaly. The diagnosis is based on a positive family history, general signs of anemia, and a finding of spherocytes and increased reticulocytes on peripheral blood smear. Treatment includes splenectomy and daily dose of folic acid.
Huntington's disease	A trinucleotide repeat problem located on the short arm of chromosome 4. Occurs in 33.1-35.4 out of 100,000 births. Initially small oculomotor dysfunction and choreiform movement problems that progressively worsen. Usually the onset is in ages 30 to 40 years; however, may occur at any age. Progression to full neuropsychiatric instability (insanity) with associated neuronal loss in the caudate nucleus.
Neurofibromatosis	May also occur as a new mutation and not autosomal dominant. Of two types, characteristics include peripheral nerve tumors (neurofibromas) and pigmented skin lesions (café au lait spots).
Familial hypercholesterolemia	Occurs in 1 in 500 births. One of several familial hyperlipidemias. Involves the receptor for low-density lipoprotein (LDL). Gene for the receptor is mutated, which results in dysfunctional cholesterol removal. Deposition of lipids occurs, resulting in accelerated atherosclerosis, xanthomas (made up phagocytized cholesterol in macrophages that deposit in skin, especially around eyes). Requires low-fat diet and medical management.
<b>Autosomal recessive</b>	Only homozygotes have the gene effect, with both parents of the homozygote as asymptomatic carriers of the trait. The children of the homozygote are not symptomatic but 50% carry the gene for the trait. In siblings of the affected zygote, 25% are symptomatic homozygotes, 50% are asymptomatic carriers for the trait, and 25% are unaffected and do not carry the gene.
Cystic fibrosis	Occurs in 1 in 2,500 births in U.S. with an estimated 1 in 25 individuals being asymptomatic carriers. Seen primarily in Caucasians. Results in a more viscid glandular secretion (mucoviscidosis) from all exocrine glands, leading to obstruction, in particular in the pancreas, bronchi, and intestines. This is due to a defect in the gene for the protein that is involved in the chloride transport

	<p>channel in the cell membrane. Fetal effects can include meconium peritonitis and meconium ileus. The primary concern is accumulation of viscid mucus makes breathing difficult and allows for the development of bronchiectasis and the development of life-threatening infection (the usual cause of death). Testing of sweat indicates increased salt content (pilocarpine test). Management includes antibiotic therapy for prevention of fulminant infection coupled with daily clearing of airways and some dietary manipulation.</p>
Sickle cell	<p>Sickle cell disease is a hemolytic anemia occurring primarily in blacks (0.3% of blacks in the U.S.) characterized by abnormally shaped red blood cells (sickled) due to homozygous inheritance of hemoglobin S. Hepatosplenomegaly is common. Growth retardation with associated radiographic findings are salient features. Individuals are prone to infections. Upon exposure to acute infection (often viral) an aplastic crisis occurs due to a decrease in erythropoiesis. This results in bone infarcts and vascular occlusions causing severe pain in the hands, feet, and lower legs. Abdominal pain also occurs due to the vascular occlusion. Life expectancy is greater than 50 years old. Death is usually due to infection, pulmonary emboli, and renal failure.</p>
Thalassemia	<p>A group of hereditary disorders that involve decreased synthesis of globin chains (alpha or beta). The result may either be the trait for alpha or beta (heterozygous) or the full-blown beta thalassemia major (homozygous). The result is a microcytosis out of proportion to the degree of anemia. Individuals with the traits are mildly anemic and generally require no treatment, but should be given a recommendation for genetic counseling. Those with the beta trait have Mediterranean (e.g., Greek or Italian) or Chinese ancestry. Those with the alpha trait are either from southeast Asia or China; less commonly black. Those with full-blown beta thalassemia major usually require bone marrow transplantation with a relatively high degree of success in selected individuals (80%).</p>
Tay-Sachs (hexosaminidase A deficiency or gangliosidosis GM2)	<p>Found in Ashkenazi Jews, this gangliosidosis results in accumulation of sphingolipids in the brain. There is an early onset, with progressive retardation leading to death at ages 3 to 4 years. Indicators are progressive paralysis associated with dementia and cherry-red retinal spots seen ophthalmologically. Prenatal screening is available.</p>
Niemann-Pick	<p>There are three types (A, B, and C) of this lysosomal accumulation disorder. Types A and B involve defective sphingomyelinase activity leading to accumulation of sphingomyelin in the reticuloendothelial cells. Type C allows lysosomal accumulation of unesterified cholesterol. Prenatal diagnosis may be done through amniocentesis or chorionic villus sampling. Diagnosis in the infant or child is prompted due to hepatosplenomegaly. Treatment is supportive and nonspecific.</p>
Hurler's	<p>A mucopolysaccharidosis, involves primarily the skeletal system and central nervous system leading to body deformity (gargoylism), neurological dysfunction, and mental retardation. Urinary excretion finding of dermatan sulfate and heparin sulfate. Death occurs usually before age 10 years.</p>
Hunter's	<p>A mucopolysaccharidosis, with iduronate-2 sulfinate similar to but milder than Hurler's. No corneal clouding. Associated skeletal dysplasia, mental deficiency, and hepatosplenomegaly. Death at early age is still common before age 15 years.</p>
Albinism	<p>The enzyme tyrosinase defective affecting tyrosine and leading to an absence of pigment in the skin, hair, and eyes. Management involves protection from actinic radiation for skin and eyes.</p>
Phenylketonuria (PKU)	<p>This is an enzyme defect disorder that involves a deficiency of the enzyme that metabolizes phenylalanine into tyrosine (phenylalanine hydroxylase [PAH]). The result is an accumulation of dietary phenylalanine in the blood and body tissues and a shift in breakdown leading to the formation of phenyl pyruvic acid and other phenylketones excreted in the urine (reason for the term PKU). This disorder is screened for at birth in the U.S. If undetected, leads to pigmentation problems due to deficient melanin production and, more importantly, impairs nervous system development leading to slow, progressive mental retardation. If detected, a specific diet is prescribed.</p>
<b>X-linked recessive</b>	<p>Gene defect evident primarily in males, transmitted via asymptomatic mother (unaffected brothers do not carry the gene; sisters of affected males are</p>

	asymptomatic). Sons of a female carrying the gene have a 50% chance of being affected; however, affected males do not pass on gene to sons but all daughters are asymptomatic carriers.
Hemophilia	Leads to bleeding disorder due a defect in gene (inherited or through mutation) that codes for coagulation factors VIII (hemophilia A; most common) or IX (hemophilia B; less common). Hemophilia A can exist anywhere from a mild to a severe form. Hemophilia B is always severe. Internal bleeding into joints (hemarthrosis) is common, which leads to deformity; cerebral hemorrhage is rarer than in the past. Genes for each hemophilia are available as recombinant clotting factors.
Muscular dystrophy	Several types: Most common are Duchenne (1 in 3,300 males) and Becker's (1 in 20,000 males) muscular dystrophy DBMD. Affects primarily males. Gene located to the midportion of the short arm of X chromosome for coding of dystrophin. Dystrophin is needed as a structural protein for the integrity of cell form. With Duchenne there is severe muscle wasting. Gower's sign may be evident, indicating proximal muscle wasting. Most confined to wheelchairs and die in teens. Becker's is less severe.
Fragile X syndrome	A trinucleotide repeat disorder (cytosine, guanine, and guanine [CGG triplet repeat]) in the chromosomal area Xq27. Eighty percent of males have mental retardation. It is the most common form of hereditary mental retardation (deficiency) in males. Even children of normal mental function carriers of Fragile X may be mentally retarded.

## Infantile Colic

Infantile colic is a relatively common condition that usually occurs within the first weeks after birth. The incidence reported is quite variable (8% to 40%) due to the existence of several definitions of what infantile colic is and the reliance on parental interpretation of these definitions.<sup>14</sup> Probably the most accepted criteria are crying for three hours a day for more than three days a week for a minimum of three weeks.<sup>15</sup> Given that newborns have a tendency to cry with a reported average of about 2.75 hours/day, it is not surprising that the reported incidence can be so high.<sup>16</sup> The stress on the parents of infants with colic may lead to abuse (i.e., shaken infant syndrome) or feelings of guilt by the parents due to a feeling of being unable to meet the needs of their new child. Although the cause would seem to be gastrointestinal based on the reports of increased flatulence and association with onset after feeding, there is little evidence to support this theory. Radiologic studies have not shown any more air in the intestines of infants with colic compared with infants who do not have colic.<sup>17</sup> Other investigations of intestinal origin including measure of intestinal hormones, fecal analysis, and occult blood analysis have not shown abnormal findings.<sup>14</sup> Studies regarding mode of delivery (e.g., breech versus normal, those with epidurals, those with oxytocin) have not demonstrated any clear connection. One plausible theory is that due to an immature nervous system the infant is neurolabile with an overreaction to normal negative (e.g., hunger, gas, fatigue) or positive (e.g., music, voices, handling) stimuli.

The medical management of colic is primarily with dimethicone (Simethicone, Mylicon). However, it appears to be no better than placebo.<sup>18</sup> The new trend of physicians prescribing proton-pump inhibitors for colic should be discouraged due the potential effect on absorption of important minerals and a reduction in immune response. Studies<sup>19,20</sup> from Denmark seem to indicate that chiropractic manipulation is effective at improving or resolving infantile colic. The most recent study<sup>21</sup> compared manipulation to dimethicone as a treatment strategy. Generally, improvement in the

manipulation group was a 2½-hour reduction in crying time compared with a one-hour reduction in the dimethicone group at one week.

## Abuse and Neglect

Childhood abuse is divided into physical abuse, mental abuse, and sexual abuse. Given the common musculoskeletal focus of most chiropractors and given that 50% to 70% of physical abuse results in skeletal trauma, it is likely that the chiropractor will see signs of abuse.<sup>22</sup> The most commonly injured area is the face. More than half of abused children are in the age range of birth to 4 years. In one large, hospital-based study,<sup>23</sup> the percentage of childhood maltreatment cases relating to physical abuse was 41%, sexual abuse 35.4%, and neglect 23.6%. A recent study<sup>24</sup> indicates that approximately 20% of all head injuries seen at a metropolitan children's hospital were due to abuse. Given that even a suspicion of childhood abuse is a reportable event in some jurisdictions, it is a difficult task to weigh what may be circumstantial evidence against what may appear to be reasonable explanations in deciding whether to report. For chiropractors, it may be appropriate to refer for second opinion, voicing concerns to the medical physician.

There are some potential risk factors that, when taken together with physical evidence, suggest the possibility of abuse. Factors may include an early or unwanted pregnancy, foster care, poverty and/or unemployment, history of family psychologic problems (including a parent's childhood experience of separation or abuse), and postpartum depression. The infant/child who is premature, colicky, hyperactive, handicapped, sick, or biologically unrelated to the abuser is at higher risk.

Suspicion of abuse is supported by multiple bruises of areas not usually exposed to trauma (such as the back or trunk area); fractures of the skull, face, or spine; or pattern-shaped burns. Interestingly, children may report the abuse, but more commonly will lie to protect themselves. The child may demonstrate fear of the parent/caregiver or may even demonstrate a closeness to the abuser fostered by the need to be loved and not abused. One of the most serious injuries is the "shaken infant" or "shaken impact" syndrome where the caregiver violently shakes the infant, usually holding onto the shoulders while the head and neck are whipped back and forth.<sup>25</sup> Without evidence of outside trauma, intracranial injury including subarachnoid hemorrhage, subdural hematoma, and cerebral edema may occur. Shaken infant syndrome is suspected when any of the following are present:<sup>26</sup>

- There is a decreasing level of consciousness or lethargy, orbital or lid ecchymosis, retinal hemorrhages, disconjugate eye movement, bulging fontanelle, or focal or generalized motor weakness.
- There is an uncertain or illogical explanation offered by the caregiver. Common caregiver reports are no causative event, a minor fall, a seizure, or respiratory arrest.
- A new onset of seizures is reported associated with retinal hemorrhages and intrathecal hemorrhages seen on computed tomography (CT) scan or magnetic resonance imaging (MRI).

Radiographic clues to physical abuse include:<sup>27</sup>

- Evidence of multiple fractures that have healed or are in a healing stage without appropriate orthotic support.

- Multiple or bilateral skull fractures; linear fractures of the parietal bone may be due to an unintentional fall off of a bed but are rare.
- Fractures that are shaft or metaphyseal suggest abuse; supracondylar fractures of the humerus would typically indicate a fall with hyperextension and are not suspicious.
- Femoral fractures in children under 1 year of age are suspicious given the child is not yet weight-bearing in most cases; the most common fractures in abuse cases are subtrochanteric and distal metaphyseal chip fractures.

**Table 53-3 Dysplasias**

<b>Dysplasias</b>	<b>Diagnostic Features and Considerations</b>
<b>Achondroplasia</b>	<p>This is the most common cause of dwarfism. Although it may be transmitted as a single-gene abnormality, most new cases are due to new mutation. There is an abnormality in endochondral ossification with intramembranous bone formation normal. This short-limb dwarfism is recognized at birth as an enlarged head, frontal bossing, a low nasal bridge, and generalized hypotonia. Head and motor control milestones are delayed. All patients have foramen magnum stenosis that is associated with an increased incidence of sleep apnea and sudden infant death syndrome. Forty-four percent of neurologically intact achondroplasts demonstrate abnormal somatosensory evoked potential. Cervicomedullary compression is common enough to warrant extreme concern with cervical adjusting. A thoracolumbar kyphosis is seen at birth. There are two forms, with the fixed type caused by a triangular-shaped vertebral body with anterior wedging (seen on lateral radiograph). The more common flexible type extends over several levels. It appears that it may resolve over time. If persistent past age 3 years, a brace is recommended. Those with a kyphosis &gt; 40° should have surgery. Spinal stenosis due to a congenitally small canal is common, with more than half of achondroplasts developing symptoms. Symptoms generally appear in the 20s or 30s. There are mixed results with surgical decompression. It is particularly worse in those with a thoracolumbar kyphosis. Extreme care should be taken when adjusting the spine. Hyperlordosis is common in the lumbar spine due to a heavy, larger head, lax ligaments, and vertebral malformation. Flexion deformities of the hip are also common.</p>
Pseudoachondroplasia	<p>This short-limbed dwarfism is an autosomal dominant disorder characterized by normal facies, joint laxity, and abnormalities in epiphyseal and metaphyseal development. There is abnormal proteoglycan accumulation in the chondrocyte rough endoplasmic reticulum. The disorder is not apparent at birth, with the first findings appearing within the first years of life. The spinal abnormalities that are of concern are atlantoaxial instability, a thoracic kyphosis (with anterior vertebral body wedging), and scoliosis. Hip deformities are also more common with achondroplasts.</p>
Osteogenesis imperfecta	<p>A large number of inherited connective tissue disorders are classified under osteogenesis imperfecta. The most common features are small, triangular faces, fragile bones with associated multiple and recurrent fractures, abnormal teeth, deafness, and blue sclera and tympanic membranes. Defects in or the quantity of type I collagen accounts for most of these findings. In addition to the frequency of nontraumatic fractures, the other orthopaedic/neurologic concerns are basilar impression and scoliosis. Scoliosis is common and progresses most in patients with a biconcave type of thoracic vertebrae. Compression fractures also factor into the development of kyphosis and scoliosis. Treatment for scoliosis is generally ineffective. Spinal or extremity</p>

	adjusting should not be performed on these patients due to the brittleness of their bone.
Spondyloepiphyseal dysplasia	This form of dwarfism is a short-trunk type with involvement of the vertebrae and long bone epiphysis. An autosomal-dominant condition, it is usually seen at birth with a clinical appearance of a flat face with wide-set eyes, short neck, cleft palate, retinal detachment, barrel-chest, and shortening of the limbs with hip flexor contractures. A later form seen first in adolescence is the X-linked form only appearing in males. The first signs are osteoarthritis in a major joint and delay in the appearance of ossification centers. The major concerns are atlantoaxial instability seen in 40% of patients, often due to os odontoideum or odontoid hypoplasia. As a result, cervical myelopathy may develop, signaled by regression of motor milestones, respiratory problems, or simply fatigue. Kyphoscoliosis is not uncommon due to flattening of the vertebral bodies and other abnormalities in development. Radiographs for atlantoaxial instability are a requirement in making decisions regarding spinal adjusting.
Diastrophic dysplasia	This is a short-limb dwarfism, autosomal-recessive disorder associated with severe clubfeet, "hitchhiker thumb," cleft palate, and eventually in most patients, a cauliflower ear. Spinal concerns center around a cervical spine kyphosis associated with spina bifida and anterior wedging of apical vertebrae. Spontaneous resolution occurs in many cases by age 5 years; however, some cases may progress to spinal cord compression and death. Atlantoaxial instability is not a common feature. Kyphoscoliosis commonly develops with walking. The most rapid progression is between ages 8 and 12 years. Early bracing is recommended.
Ehlers-Danlos syndrome	A group of related disorders characterized by abnormal collagen production and structure. Although there are ten types listed, they generally have three common clinical manifestations: (1) hypermobile joints, (2) fragile blood vessels, and (3) various cutaneous abnormalities including hyperelasticity. Other areas that may be affected are the eyes (may have blue sclerae), bronchopulmonary (higher incidence of bronchiectasis and spontaneous pneumothorax), cardiovascular (tetralogy of Fallot, aortic and other aneurysms), gastrointestinal (spontaneous rupture or hemorrhage of the bowel), among others. Clinically the patient often is tall and exhibits a gait of hyperextension at the hips and genu recurvatum (hyperextended knees). Redundant skin folds around the eyes, hyperelastic skin, and joint hypermobility are evident upon examination. Radiographically, small "spherules" of subcutaneous fat may be seen (mainly pretibial and at forearms). Musculoskeletally, these patients are more prone to dislocations and early degenerative changes.
Marfan's syndrome	An autosomal dominant disorder of connective tissue, Marfan's is a condition associated with abnormal collagen organization with defects in cross-links leading to problems in three distinct organ systems (1) musculoskeletal, (2) ocular, and (3) cardiac. The condition is not all that rare, with a prevalence of about 1 in 10,000. Patients are often tall with long legs and hypermobile joints. The major musculoskeletal concerns are an enlarged concavity of the superior and inferior endplates of spinal vertebrae with widening of the spinal canal and dural ectasia. There is thinning of the cortex, dilation of the neural foramina, and dura protrusion outside the canal. There is some concern for both atlantoaxial instability and basilar invagination found in one-third to one-half of patients. Although spondylolisthesis is not seen more often than in general population, slippage is twice as common. Scoliosis is seen in three-fourths of patients with a single thoracic, thoracolumbar, and double major curve most common. Hyperkyphosis is also common. Scoliosis progression is more common, and therefore early bracing is recommended. Surgery is more likely with these patients. Ocular concerns are ectopia lentis (subluxation of the lens). Other orthopaedic concerns are pectus carinatum/excavatum and ligament laxity. Acetabular protrusion is seen in half of patients, and a higher incidence of slipped capital femoral epiphysis is also seen. Dissecting aortic aneurysm, valvular insufficiency, and mitral valve prolapse are all concerns for these patients, and a cardiovascular evaluation should be performed frequently.
Morquio's syndrome	Although not technically a dysplastic disorder, Morquio's syndrome represents one of several lysosomal storage diseases characterized by specific enzyme deficiencies resulting in accumulation of mucopolysaccharide

glycosaminoglycan (GAGS) in different tissue, resulting in disease. Clinically the patient is of short stature. Normal at birth, there is progression to short-trunk dwarfism, corneal opacities, hearing loss, and generalized laxity. Of particular concern is atlantoaxial instability (due to odontoid abnormalities) and the abnormal shape of thoracolumbar vertebrae. They are typically flame-shaped with flattening and an anterior projecting central tongue. Also, an increase in soft tissue anterior to the spinal cord may cause neurologic injury.

- Chip fracture or bucket-handle fracture indicates an injury caused by sudden twisting of a limb; metaphyseal ligaments are stretched to the point of fracturing and avulsing bone at their insertion point at either one or both metaphyseal corners; a specific distinction between acute injury versus healing fractures is localized radiolucent extension of the growth plate into the metaphysis indicating hypertrophic cartilage extension found more often with past abuse.
- Rib fractures in young children are rare and should raise the suspicion of abuse, especially if associated with head trauma.

Sexual abuse should be suspected when there is vaginal bleeding in a child, persistent vaginal discharge, infection in the genital area and associated recurrent urinary tract infections, and genital/anal trauma with questionable explanation.<sup>28</sup> Pregnancy in adolescents should also be investigated for possible abuse. Behaviors suggesting abuse are sexual knowledge or behavior inappropriate for age, inappropriate sexual activities or game-playing with adults, fear of having diaper changed or being bathed, or sudden avoidance of being left with familiar adults or in familiar places. Later signs are depression, suicidal behavior, "night terrors," drug and alcohol abuse, and prostitution or promiscuity.

Neglect may be subtle. It is a generalized term including not only abandonment/desertion, but also medical, environmental, nutritional, safety, and emotional neglect. Signs of malnutrition, fatigue, poor hygiene, or inadequate clothing may indicate neglect. Emotional growth may be severely impacted by neglect. This may lead to problems in school performance or relationships with peers. Suspicion of neglect should be referred to the appropriate social services or welfare department.

## Lead Toxicity

Although the prevalence of elevated blood lead levels has decreased dramatically over the last 20 years, it is still as high as 17% of preschool children in the United States ( $> 15 \mu\text{g/dL}$ ).<sup>29</sup> More than 3 million children under age 6 years had blood lead levels greater than  $10 \mu\text{g/dL}$  based on a 1990 estimate. It is recommended that all children at risk of exposure be screened for blood lead levels at age 12 months or in all children in communities where high environmental lead exposure is likely. Risks include minority race/ethnicity, central city living environment, low income and educational level, and living in the northeast United States. Sources include lead-based paint in pre-1950 housing, lead-soldered pipes, and lead dust from areas of heavy traffic and industry. Suspicion of lead intoxication should be raised and tested when there are indicators of either developmental delay, learning disabilities, convulsions, autism and other behavioral disorders, speech and hearing problems, or recurrent abdominal pain or vomiting. The effect on development and on central nervous system (CNS) function is due to the incomplete development of the blood-brain barrier before age 3 years, which allows accumulation of lead in the CNS.

The American Academy of Pediatrics recommends that intervention occur for children with blood lead levels greater than 10 µg/dL:<sup>30</sup>

- investigate and eliminate lead sources, including removal of lead-based paint
- use cold tap water, let water run for one to two minutes to rinse out pipes
- wash and clean toys frequently
- change shoes and clothing before returning home from work if there is potential lead exposure
- do not store food in inverted bread bags (printed with colored ink)

Children deficient in calcium, iron, zinc, and ascorbate more readily absorb lead. For those with levels 25 to 45 µg/dL, more aggressive attention to environmental exposure should be made and monitored. Levels above 45 µg/dL require chelation therapy; however, there is no indication that this can reverse any existing neurotoxicity.

---

## Attention Deficit-Hyperactivity Disorder

Although there is little debate about the existence of attention deficit-hyperactivity disorder (ADHD), there are grave concerns about the overlap between normal childhood activity (especially in boys) and the diagnostic criteria for ADHD resulting in misdiagnoses and subsequent inappropriate prescription of medication. Although the incidence is reported to be between 3% and 5%, in one report, the proportion of children taking medication for ADHD is as high as 10% in second through fifth grades and 20% in fifth graders.<sup>31</sup>

The hallmarks of ADHD are a decrease in attention span, hyperactivity, and poor impulse control that spans across developmental norms and situations (e.g., occurs both at home and school). The signs of ADHD generally occur before age 7 years. The *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-V)<sup>32</sup> currently divides ADHD into three categories: (1) predominantly inattentive, (2) predominantly hyperactive/impulsive, and (3) a combination of both. The categories use the following signs/symptoms as indicators of ADHD, if six or more are present:

- Inattentive
  1. Has difficulty following instructions
  2. Has difficulty keeping attention on work or play activities at home and at school
  3. Loses things needed for activities at school and at home
  4. Appears not to listen
  5. Does not pay close attention to details
  6. Seems disorganized
  7. Has trouble with tasks that require planning ahead
  8. Forgets things
  9. Is easily distracted
- Hyperactive/Impulsive
  1. Fidgety
  2. Runs or climbs inappropriately
  3. Cannot play quietly
  4. Blurts out answers
  5. Interrupts people
  6. Cannot stay in seat

7. Talks too much
8. Is always on the go
9. Has trouble waiting turn

It would strike most parents that these are common in most children, in particular boys. The concern is that given the easy out of medication, parents and schools encourage and steer the diagnosis to obtain what many feel is a medical form of behavioral therapy. With such a broad criteria overlap with “normal” behavior, it is not surprising that numerous suspected causes have been identified. These include inheritability, family environment, culture, lead poisoning, fetal anoxia, maternal smoking or use of alcohol, and many others. In those who do truly have ADHD there appears to be a processing dysfunction in the motor cortex that results in inappropriate motor response to stimulus.<sup>33</sup> The inattentive type may be due to parietal lobe dysfunction with an impairment in stimulus detection. In addition, specific defects have been found including reduced blood flow to the basal ganglia, small right hemispheres, and dopamine transporter density imbalance. Because ADHD is associated with comorbid conditions such as dyslexia and other learning disabilities, the diagnostic waters are muddled by potential overlap findings in patients with other conditions.

The primary medical approach to ADHD is methylphenidate (Ritalin) and amphetamine/dextroamphetamine (Adderall). Common side effects are a decrease in appetite, increased pulse and blood pressure, nervousness, mood lability, and sleep disturbance. Some of these side effects may be mediated by how and when the drug is administered. The biggest concern is the potential of growth retardation. **Table 53-4** summarizes the medical management of ADHD. Although recommended management opportunities include behavioral therapy, cognitive therapy, family counseling, and collaborative management with a team composed of the parents, physician, and school personnel, many rely on the medication to control the condition. Parental recommendations include:

- Present an organized schedule for the child.
- Set up house rules.
- Make sure directions are understood.
- Be consistent and positive.
- Help with homework and praise effort, not grades.
- Talk to school and child’s teachers.

There are no chiropractic studies on ADHD at this time. However, it would seem prudent to aid in the parental need to obtain a valid diagnosis without reliance only on meeting symptom criteria. This would include an evaluation of diet, exercise, home environment, and the child’s self-appreciation. For an accurate diagnosis, a referral to a specialist, preferably a psychologist who specializes in ADHD, is needed. The psychologist specialist is trained in the administration and interpretation of neurocognitive tests and is less likely to rely on the drug solution to ADHD.

**Table 53-4 ADHD Medications**

Generic Drug	Examples	General Mechanism	Interactions/Side Effects
Methylphenidate	Concerta	A central nervous system stimulant used in the management of attention deficit-hyperactivity disorder (ADHD).	Slowing of growth height, seizures (in patients with Hx of seizures), blurred vision, GI blockage, heart racing, headache, stomach ache, decreased appetite, dizziness, nervousness, difficulty sleeping, anaphylaxis
Atomoxetine	Strattera	Strattera is a selective norepinephrine reuptake inhibitor used for the treatment of attention deficit-hyperactivity disorder (ADHD).	Decreased appetite, sleeping problems, constipation, dry mouth, nausea, allergic reactions, dizziness, tiredness, mood swings, are the most common reported side effects.
Methylphenidate	Ritalin	Causes the release of norepinephrine, dopamine, and serotonin from storage vesicles resulting in CNS stimulation. This causes an increase in performance, coordination, and energy. There is a decrease in appetite with an increase in blood pressure. Used for narcolepsy and attention deficit disorder.	May cause restlessness, insomnia, dizziness, anorexia, psychic disturbances, and arrhythmias
Pemoline	Cylert	Causes the release of norepinephrine, dopamine, and serotonin from storage vesicles resulting in CNS stimulation. This causes an increase in performance, coordination, and energy. There is a decrease in appetite with an increase in blood pressure. Used for attention deficit-hyperactivity disorder.	May cause restlessness, insomnia, dizziness, anorexia, psychic disturbances, and arrhythmias
Amphetamine and dextroamphetamine	Adderall	A combination of amphetamine and dextroamphetamine used for the management of ADHD; also used for narcolepsy.	High potential for abuse. Weight loss, dry mouth, nausea, dizziness, headache, diarrhea, nervousness, irregular or rapid heart rate, increased blood pressure, and allergic reactions

## Childhood Cancer

Unfortunately, childhood cancer is a major cause of death in U.S. children. For children ages 1 to 14 years, cancer is second only to accidents as a cause of childhood mortality.<sup>34</sup> Although the survival rate has increased dramatically for some cancers, many types are still resistant to treatment or are clinically evident too late in the course of the illness to apply effective treatment. It is crucial that the chiropractor be vigilant in watching for red flags in a child's presentation that suggest cancer. Some of these red flag indicators follow:<sup>35</sup>

- unexplained weight loss
- bone pain that is resistant to analgesics or accompanied by recurrent or relapsing fever
- sternal tenderness, with recurrent nosebleeds
- lymphadenopathy that is persistent for more than 3 weeks and lymph nodes that are hard, rubbery, fixed, and nontender
- occult or frank blood in the urine or stool
- abdominal masses
- recurrent or severe (unbearable) headache associated with nausea and vomiting or persistent headache

It is important to remember that childhood cancer presents differently than adult cancer. By the time of diagnosis, approximately 80% of pediatric cancers are in their advanced stage. Pediatric cancers more commonly involve white blood cells

(leukemias), brain, bone, lymphatic system (Hodgkin’s and non-Hodgkin’s), muscle, kidney, and the nervous system. A summary of the most common pediatric cancers is given in **Tables 53-5** and **53-6**.

**Other Specific Concerns**

Some of the following conditions or concerns are discussed in this chapter, but please consult the related chapters listed:

Table 53-5 Cancers and Tumors More Common in Childhood and Adolescence		
Tumor	Diagnostic Features and Considerations	Management Considerations
Leukemias	Leukemias are the most common malignancy in children, with an age of onset of between 2 and 10 years (peak onset at age 4 years). There is a slightly increased incidence in boys, whites, and in siblings of children with leukemia. Signs and symptoms include hepatosplenomegaly (60% of patients), fatigue, bone pain (commonly in the pelvis, vertebral bodies, and legs), easily bruised, and other signs of vascular fragility such as petechiae or purpura, fever, lymphadenopathy, and, in boys, testicular enlargement. Laboratory testing includes a complete blood cell (CBC) count, which usually shows at least one cell type deficiency. A white blood count (WBC) above 50,000 is a strong indicator of leukemia. Radiographic findings may include diffuse osteopenia, radiolucent metaphyseal bands, new periosteal formation, and signs of osteosclerosis and bone destruction. Chest x-rays may reveal a mediastinal mass. Bone marrow	Acute lymphoblastic leukemia (ALL) is the most common. Acute myelogenous leukemia (AML) has the poorest cure rate. Various drug regimens and chemotherapy are the treatments of choice, with localized radiation treatment when necessary. Bone marrow transplantation is reserved for unresponsive cases. Prognosis is best for children diagnosed between ages 3 and 7 years, with a more favorable outcome for patients with a total WBC count of 25,000 or less and no central nervous system (CNS) involvement at the time of diagnosis. The overall cure rate for ALL is 75%, with initial remission seen in 75%. Generally, girls have a more favorable prognosis than boys.

	aspiration and biopsy are needed for a definitive diagnosis.	
<b>Brain tumors</b>	25% to 30% of all childhood cancers are found in the CNS. The age of onset is generally between ages 5 and 10 years. Signs and symptoms include headaches, nausea and vomiting, seizures, cranial nerve dysfunction, or cerebellar signs such as dysarthria and ataxia; precocious or delayed puberty or a personality change may also occur. Referral for computed tomography (CT) and magnetic resonance imaging (MRI) is required for the differential diagnosis.	One-half of pediatric brain tumors occur above the tentorium and the other half in the posterior fossa. The most common type of brain tumor in children is astrocytomas. The ten-year survival rate with surgical excision is approximately 80%; however, central astrocytomas carry a less than 25% two-year survival rate. Most brain tumors are treated with a combination of surgery, radiation, and chemotherapy.
<b>Hodgkin's</b>	Hodgkin's is a malignancy of the lymphatic system. 60% of Hodgkin's lymphoma occurs in children 10 to 16 years old. Signs and symptoms include fatigue, fever, chronic cough, night sweats, weight loss, painless cervical or supraclavicular lymphadenopathy, pruritus, and pain worse with alcohol ingestion. Radiographically, it is important to x-ray the chest in a search for a mediastinal mass (seen in 50% of patients). Further evaluation is based on staging defined by the Ann Arbor classification system. CT scans, lymphangiography, bone marrow aspirate, and biopsies are all used to determine spread of the disease. The presence of malignant Reed-Sternberg cells is pathognomonic for Hodgkin's. The CBC is often normal with a possibly increased erythrocyte sedimentation rate (ESR).	Those patients with early stages at time of treatment have an 85% to 90% five-year survival rate, while those with more advanced disease (stages III and IV) have a 50% to 80% five-year survival rate. Radiation therapy and chemotherapy are used in treatment.
<b>Non-Hodgkin's</b>	Mainly occurs in children ages 15 years or older. Accounts for only 7% to 13% of all childhood malignancies. Symptoms and signs include fever, chills, night sweats, loss of appetite, chronic cough, abdominal pain, headaches, hepatosplenomegaly, and lymphadenopathy, among others. Medullary destruction or pathologic fracture may be seen radiographically. The diagnosis is based on biopsy and subsequent typing of the cells. CT, bone scan, abdominal ultrasound, and bone marrow are also used.	Chemotherapy is the standard treatment with 90% survival rate if only localized disease is found. Poorer prognosis is expected with advanced disease, in particular to the CNS or bone.
<b>Neuroblastoma</b>	Neuroblastoma is the most common solid neoplasm outside the CNS, accounting for 7% to 10% of all pediatric malignancies. They occur at an early age with 50% occurring before age 2 years and 90% before age 5 years. Signs and symptoms are fever, weight loss, failure to thrive, neurologic signs, bone and	Chemotherapy is the standard treatment, with 90% survival rate if only localized disease is found. Poorer prognosis is expected with advanced disease, in particular to the CNS or bone.

	abdominal pain, swelling around the eyes, and bowel and bladder dysfunction. Radiographically, widened skull sutures with “sunburst” spiculations and diffuse, multiple, osteolytic lesions are seen. CT and MRI are needed to detect spread and extent of lesions. Bone scans are used for peripheral sites.	
<b>Wilms’ tumors (Nephroblastoma)</b>	Wilms’ tumor is an embryonal tumor of the kidney seen mainly in children under age 5 years. A palpable abdominal mass, fever, anorexia, and abdominal pain are commonly seen. When hematuria is present, invasion of the collecting system has occurred. Hypertension may also occur. Abdominal ultrasound and CT are used to diagnose. Chest x-rays are needed to evaluate pulmonary metastasis.	Combined approaches of surgery, radiation, and chemotherapy are used. The Wilms’ tumor study group has established criteria for staging and prognosis.
<b>Neurofibromatosis (NF)</b>	NF is an autosomal dominant disorder classified as type 1 or peripheral NF (von Recklinghausen’s disease) and type 2 or central NF (characterized by bilateral acoustic neuromas) seen usually in the over 20-year-old patient. One-third of type 1 patients are asymptomatic, yet carry physical characteristics that allow clinical diagnosis by cosmetic or neurologic signs. Café-au-lait spots (brown spots) are seen as freckle-like macules in the flexor creases of the elbows and knees (found in 90% of patients at birth or in infancy). Various cutaneous tumors, subcutaneous nodules representing Schwann cell tumors (plexiform neuromas), are seen less often initially; more often after puberty. Varying types of skeletal involvement may occur including vertebral scalloping, scoliosis, and the absence of the greater wing of the sphenoid bone. Neurofibromas of the nerve roots grow in the intervertebral foramina (iVFs) (dumbbell tumors) and may grow intra- or extraspinally resulting in related dysfunction or pain. Optic gliomas and acoustic neuromas are common, with related loss of function.	Surgery and radiation therapy are the treatments of choice. When neurofibromas are removed, loss of function of the involved nerve is common. Genetic counseling is recommended.

**Table 53-6** Bone Tumors More Common in Childhood and Adolescence

<b>Tumor</b>	<b>Diagnostic Features and Considerations</b>	<b>Management Considerations</b>

<b>Benign tumors</b>		
<b>Fibrocartilagenous defects</b>	Fibrous lesions of bone that have a cortical location and are small and well delaminated with sclerotic margins. There are no symptoms; therefore, these are found incidentally on x-ray.	Resolve over 1-2 years.
<b>Nonossifying fibroma</b>	A larger version of the fibrocartilagenous defect. Metaphyseal and large. Concern is the possibility of pathologic fracture.	If the lesion is large or fractures, curettage and bone grafting are used.
<b>Fibrous dysplasia</b>	Neoplastic fibrosis replaces bone, weakening it and predisposing it to pathologic fracture. Two types are monostotic or polyostotic. In the proximal femur, it may result in the "shepherd's crook" deformity.	The weakened area is strengthened with intramedullary rods that are left in indefinitely.
<b>Osteochondroma</b>	Endochondral ossification under a cartilage cap results in pedunculated or sessile lesions that often grow to the extent that they protrude enough to be seen. The multiple form is common and is an inherited, autosomal dominant condition. Standard radiography of the area reveals the characteristic lesion; therefore, biopsy is not needed. Osteochondromas may become symptomatic if there is direct trauma or they grow large enough to protrude against pain-sensitive structures.	Only symptomatic lesions need excision. Rarely there is transformation to a chondrosarcoma; prophylactic removal is not recommended. When transformation does occur, it is usually in the adult and around the pelvic area.
<b>Enchondroma</b>	These tumors calcify in bone and are often multiple, occurring in the fingers and long bones. Radiographically, speckled calcification can be seen within the lesion.	Usually do not require surgical excision.
<b>Chondroblastoma</b>	Rare tumor of the epiphysis. Aggressive and recurrent, these lesions may be confused with infection or arthritis.	Curettage and bone grafting are needed.
<b>Osteoid osteoma</b>	These are highly vascular, bone-producing tumors. They often appear in the spine and result in a characteristic patient presentation of night pain relieved by aspirin. There is often an acute-angle scoliosis if found in the spine.	Excision is necessary.

	Radiographically, there is a small radiolucent nidus surrounded by sclerosis.	
<b>Unicameral bone cysts</b>	These solitary bone cysts are more commonly found in the proximal humerus and femur. They are metaphyseal and have well-defined margins. They are usually symptomatically silent until there is a pathologic fracture.	If found before fracture, treatment involves steroid injection.
<b>Malignant tumors</b>		
<b>Osteogenic sarcoma</b>	Most common malignant tumor occurring in the second decade, often around the knee. Patient complains of night pain. A mass is sometimes palpable. Radiographs demonstrate osteolytic or osteogenic lesions of the metaphysis. Bone scans, computed tomography, and magnetic resonance imaging (MRI) are useful in determining other sites and the extent of the lesion.	Surgical elimination through resection or amputation is followed by chemotherapy. Limb salvage may be possible with allograft or metallic implant, yet creates a higher risk for the patient. The five-year survival rate is about 75% with aggressive treatment.
<b>Ewing's sarcoma</b>	The second most common malignant tumor of childhood. This round-cell tumor is often diaphyseal and osteolytic, creating large soft tissue masses. The child is febrile with an increased erythrocyte sedimentation rate. Bone scan and MRI help differentiate the cause and reveal the extent of involvement; biopsy confirms the diagnosis.	Chemotherapy and resection result in a five-year survival rate of 50%-60%.

- Otitis media—[Chapter 44](#)
- Specific joint complaints—See chapter specific to joint

For the special-abled child, please refer to a brief overview presented in [Table 53-7](#). Check the index for conditions or problems not described in detail in this chapter.

## Sports-Related Issues in the Young Patient

Sports-related injuries in children and adolescents are relatively common. Chiropractors should be aware of specific aspects of the young athlete's anatomic and physiologic uniqueness and how they affect participation in sports activities. As always, prevention is the major goal in working with athletes; when injured, the goals are proper diagnosis and rehabilitation. An overview of the more common concerns with children and adolescents follows.

**Table 53-7** Selected Special Needs Children

--	--

Disorder	Diagnostic Features and Considerations
<b>Autism spectrum disorder (includes autism, Asperger's, childhood disintegrative disorder, and pervasive developmental disorder)</b>	<p>A syndrome characterized by deficits in social communication, and restricted repetitive behaviors and activities (RRBs). Social communication disorder is diagnosed if RRBs are absent. Autism usually manifests itself within the first year, often misinterpreted as deafness or mental retardation. The diagnosis is fairly clear by age 3 years. Abnormal behaviors include aloofness (detached, not making eye contact, not answering questions, avoiding physical contact), attachment to sameness (resists changes in environment or routine, develops rituals, repetitive behaviors), and speech/language problems (ranges from muteness to other idiosyncratic behavior such as echolalia [repeating words spoken by others], and pronoun reversal ["you" instead of "I"]). Other manifestations are with play, spinning objects or repetitive activity often demonstrating hyperactivity. Many autistic children demonstrate bursts of violent behavior. Some children will demonstrate remarkable skills in music or mathematics (savant). The cause is unknown, although the brainstem is shorter than normal and structures are closer together, especially at the lower medulla, with the appearance that a band of tissue is missing. A subgroup of patients has enlarged ventricles visible on computed tomography or hypoplasia of the cerebellar vermis on magnetic resonance imaging. Other isolated cases have been associated with congenital rubella and other infections. Behavioral therapy has mixed results dependent on the technique and the uniqueness of the child. Many "fringe" approaches are suggested including certain forms of music therapy, diets, and other approaches. The use of sign language has also been advocated as an alternate means of initial communication. None seems consistent in the results obtained. Speech therapy is recommended based on the severity of the child's case. Some children need medication to control violent or aggressive behavior. Some children have to wear protective headgear to protect against banging their head during repetitive or violent outbursts. In dealing with treatment of these children it is important to be almost ritualistic in the sameness from treatment to treatment, with an emphasis on avoiding disturbances such as loud noises. If the child is being treated chiropractically, distraction during adjusting is necessary.</p>
<b>Cerebral palsy syndromes</b>	<p>A group of nonprogressive motor disorders that affect approximately 2 out of every 1,000 children in the United States, that results in involuntary movement. The etiology is unclear and may range from in utero problems to perinatal and neonatal factors. Birth trauma, asphyxia (15% of cases), abnormal birth position, prematurity, and central nervous system trauma or systemic disease have been identified as causes. There are four types: (1) spastic, (2) athetoid or dyskinetic, (3) ataxic, and (4) mixed. Seventy percent to 80% are the spastic type characterized by stiffness, weakness, muscle hypertonicity, and a tendency toward contractures; a "scissors" gait; toe-walking; and increased deep tendon reflexes (DTRs). Milder forms may affect lingual/palatal movement resulting in speech disorders. With basal ganglia involvement, the athetoid/dyskinetic type (20% of cases) occurs. Either slow writhing movements of the extremities (athetoid) or the proximal muscle groups of the trunk (dystonic), or abrupt jerking type movements (choreiform) are found. Dysarthria is quite common and often severe. Due to the large variation in presentation, it would be difficult to outline all the options for patients with cerebral palsy. The goal is to develop as much independence as possible. This is accomplished mainly through physical therapy training, bracing, occupational therapy, orthopaedic surgery, and speech therapy. When possible, children who are not severely affected should attend school and develop social interaction skills.</p>
<b>Down's syndrome</b>	<p>Down's syndrome is due to an abnormality of chromosome 21 (trisomy 21). It occurs rather frequently; 1 out of every 800 births. This varies based on maternal age, with a much higher incidence in mothers over 40 years (1/40 births). The need for prenatal screening is necessary for mothers who would consider abortion. Characteristics of Down's children are low-set ears, almond-shaped eyes with persistent epicanthus, short physical size, mental retardation, shallow palate, Simian crease in palms, short fifth digit, Brushfield spots on the iris (peripheral spots that disappear during year 1), and heart defects. Like many disorders, there are varying degrees of expression. The biggest concern for the chiropractor is the common finding of atlantoaxial instability. Although it has been a requirement to screen all Down's children with flexion/extension views prior to participation in the Special Olympics, recent changes have not required this screening procedure. It is important to note that in addition to cardiac abnormalities, thyroid dysfunction is also common in these children.</p>

# Statistics

- Seven million individuals are involved in high school sports.<sup>36</sup>
- Twenty million individuals between the ages of 8 and 16 years are involved in non-school community athletic programs.
- Another 20 million participate in unstructured, relatively unsupervised recreation.<sup>37</sup>
- Fifty percent of all boys and 25% of all girls present as patients due to involvement in competitive sports.
- Approximately 79% of middle and junior high schools have sports programs.

## Motivational Factors

Generally, all children initially participate in an activity for the purpose of fun. Other considerations are to (1) attain self-confidence, (2) avoid boredom, (3) socialize, and (4) further life goals. Health is not usually a motivational factor for children.

## Characteristics of Young Athletes

- Physical growth affects exercise as well as the reverse; exercise may affect physical growth. Only one of the three growth spurts in life occurs while major physical activity is possible: puberty. The first is in utero during the fourth month. The second bridges on possible athletic interest: between 48 and 60 months. Minimum amounts of exercise may stimulate growth, while excessive exercise may retard growth.
- Exploration. Children and adolescents are interested in investigating new experiences. Sports may provide this experience for them.
- Maturation. At puberty there is an increase in strength, agility, and endurance that allows the individual to participate at a higher level than previously attainable.
- Body proportion changes. There is a gain of 15% of adult height and an increase in skeletal mass of 48% during puberty.
- Body composition. The male body fat decreases 11% on average through adolescence. Females increase body fat on average 25% during this same period. Prepubescent males and females are equal in body fat composition.<sup>38</sup> Exercise habits carry over into adulthood. The percentage of body fat of adults who exercised as adolescents is lower.

### **Predisposing Factors to Injury in the Skeletally Immature Athlete**

Children's response to injury is often different from an adult's given the same mechanism and severity. Some of the factors involved include:

- *Weakness of epiphyseal and apophyseal areas.* A child is more likely to injure these areas than the surrounding or attaching ligaments or tendons; the reverse is true for adults.
- *Differential growth rate between bone and muscle.* Soft tissue lengthening lags behind skeletal growth. Therefore, during growth spurts a relative tightness

occurs around the joint. This tightness may predispose the individual to overuse injury.

- *Malalignment of the pelvis, hip, and lower extremity.* Conditions affecting version (i.e., angle of alignment) of the hips and lower extremity are common. Differences in leg length due to growth alterations are also common.
- *Imbalance of muscle strength.* The most common example is a ratio of quadriceps to hamstring strength of 2:1 versus the adult ratio of 3:2.
- *Ligament laxity.* This finding is more common in females; although it allows flexibility, there is a predisposition to certain types of injuries such as patellar dislocation or subluxation.

### Specific Concerns with the Young Athlete

## Thermoregulatory Capacity

Children have less thermoregulatory capacity than adults.<sup>39</sup> This is more apparent in extremes of heat and cold. There are three factors:

1. larger surface area per kilogram of body weight
2. lower cardiac output at a given oxygen uptake level
3. lower sweating rate

## Fractures

Generally there are four important differences between children and adults when considering fractures:<sup>40</sup>

1. A long bone fracture may heal in 3 weeks in a neonate; 6 weeks in a 7-year-old; 8 to 10 weeks in an adolescent; and up to 12 weeks in an adult.
2. In a child, a “sprain” is more likely to be a skeletal injury because bones (growth centers in particular) are weaker than ligaments.
3. Bone is more resilient than in the adult. Therefore, a full fracture in an adult would more likely be a “greenstick” fracture in a child.
4. Skeletal injury in children is usually at the growth plate, and therefore may have consequences regarding bone growth (although this sequela is uncommon).

## Epiphyseal Injury

Growth plate fractures are generally classified according to the Salter-Harris system (see **Figure 53-1**).

- Type I—The type I injury is due to a shearing force applied to the junction of the epiphysis and metaphysis. It usually occurs during early childhood or infancy (occasionally due to a difficult labor). The perichondrium on one side remains intact as does the blood supply. Reduction is rarely necessary, and resolution is usually uneventful.
- Type II—These injuries are also due to a shearing force; however, in addition to separating the epiphysis from the metaphysis, there is a triangular avulsion of the metaphysis. This usually occurs falling on an outstretched hand or other

similar injury between the ages of 6 and 12 years. The growth spurt period is when the physis is weakest. Again, the perichondrium on one side is intact as is the blood supply. Occasionally reduction is necessary; however, healing is uneventful.

- Type III—The forces here are directed both transversely and longitudinally across the physis and epiphysis, resulting in epiphyseal separation. The type of mechanism involves a lateral or rotational component. Prompt restoration is necessary to prevent the major complication: a bone bridge. The bone bridge is due to intermingling of separate vascular systems forming parallel to the plane of the physis. This effectively arrests cell growth in the physis. Open reduction is usually required.

**Figure 53-1** Salter-Harris type fractures. Type I: split of the growth plate. Type II: split of the growth plate with fracture producing triangular metaphyseal fragment. Type III: vertical fracture through the epiphysis that enters the epiphyseal plate. Type IV: fracture extending across the epiphysis, epiphyseal plate, and metaphysis. Type V: compression of a portion of the epiphyseal plate.

- Type IV—The fracture extends the full thickness of both the epiphysis and physis and additionally splits off a portion of the metaphysis. Again, a bone bridge may form. In the upper extremity this may occur with a fall on an outstretched hand. Reduction, often with pin fixation, is frequently necessary.
- Type V—This is the rarest of growth plate fractures. It is a crushing injury that can severely affect bone growth. Unfortunately, it is not always easy to detect radiographically. A common scenario is a fall from a great height, crushing the distal radius. Again, it may be misdiagnosed as a sprain. Radiographically it may not be readily apparent, and the growth retardation may not be evident for months.

## Apophyseal Injury

Apophyseal injuries are almost always due to sports activity.<sup>41</sup> They occur mainly about the pelvis and occur in the adolescent age group. This is when there is closure but not fusion of the apophyseal ossific nucleus. Common locations include the

ischium, the anterior superior iliac spine (ASIS) or anterior inferior iliac spine (AIIIS), the iliac crest, and the lesser trochanter. Oftentimes these are sudden injuries in track and field. They frequently require oblique films to detect the avulsed fragment (see **Table 53-8**).

**Strength Training** There is a large debate regarding the appropriateness of prepubescent participation in strength training programs. These concerns center on the tendency toward strains, tendinitis, epiphysitis, avulsions, fractures, and vertebral injuries. Most of these injuries are avoidable with proper training, supervision, and progression. It has been demonstrated that prepubescent children do increase muscle strength with training. The American Academy of Pediatrics, the National Strength and Conditioning Association, and the American Orthopedic Society of Sports Medicine have made the following eight recommendations:<sup>42</sup>

1. A mandatory preparticipation examination should be performed
2. Emotional maturity to accept coaching and instruction should be required
3. Adequate supervision should be provided by coaches who are knowledgeable in the area of children's weight training
4. Strength training should be a part of a more comprehensive program
5. Training should be preceded by a warm-up and followed by a cool-down
6. Training should emphasize full range of motion concentric contractions
7. Competition is prohibited
8. No maximum lift should ever be attempted

The prescribed program should be as follows:

1. Exercise sessions should be limited to two to three times per week, 20- to 30-minute periods.
2. No resistance should be applied until proper form is demonstrated.
  - 6 to 15 repetitions
  - 1 to 3 sets per exercise
3. Weight should be increased in 1- to 3-lb increments after the child is able to do 15 reps with good form.

## Preparticipation Screening

With preparticipation examinations, the medical history is fraught with difficulties:

- Athletes may exclude problems they feel might disqualify them.
- They may not recognize the significance of positives in their past histories.
- Only 39% of athletes' histories agreed with their parents'.<sup>43</sup>
- With the written history, it is important to consider illiteracy, which is as high as 30% in some areas.

The specific goals of the examination are:

- To determine information that will exclude or modify an individual's performance in a particular sport and possibly refer for further medical evaluation.
- To determine the musculoskeletal status of an individual compared with the documented requirements for a given sport.
- To provide feedback to the individual about his or her general level of health, and, more specifically, point out areas in which the individual needs to focus to

- better perform the sport or activity and prevent potential injury.
- To act as a general health screen that is reproducible, establishing a baseline assessment for future comparison.
- To meet state or insurance requirements.

**Table 53-8** Disorders of the Skeletally Immature Patient—The Extremities

<b>Regional Disorder</b>	<b>Diagnostic Features and Considerations</b>	<b>Management Considerations</b>
<b>SHOULDER GIRDLE</b>		
<b>Os Acrominale (Bipartite Acromion)</b> <i>Before Age 22</i>	<p>Found in 2% to 8% of individuals (62% of the time bilateral). There are two secondary centers of ossification that enlarge and merge during the adolescent growth period. A third may appear during adolescence that may either represent an ossification center or possibly an avulsed fragment. An incomplete fusion of these centers may be due to a direct blow or repetitive overhead activity resulting in symptoms of rotator cuff irritation and inflammation. It is proposed that when the deltoid contracts it pulls the ununited fragment and any associated spur into the rotator cuff causing tearing. Most often seen on an axillary or Stryker radiographic view.</p>	<p>Limited activity and a balanced, progressive strengthening program are generally all that are needed. Rarely a persistent, symptomatic, nonunion requires surgical intervention such as open reduction and screw fixation.</p>
<b>Acromial Apophysitis</b> <b>Before Age 19</b>	<p>Similar to os acrominale; however, the ossification center is not abnormal, yet irritated. Pain is felt at the lateral acromion, due to repetitive traction by the deltoid attachment to the distal acromion.</p>	<p>Rest from or modification of the inciting activity, protection (i.e., padding) if involved in contact sports will usually resolve the problem over time. Generally, self-resolving; however, may progress to nonunion.</p>
<b>Coracoid “Apophysitis”</b> <i>Before Age 21</i>	<p>The cause is stress due to repetitive upper extremity activity (e.g., baseball pitchers, swimmers, tennis players). Pull of the lower center at the base of the coracoid is most common. This is the anchor site for the pectoralis minor. Tenderness on palpation of the coracoid (compare to opposite side) and a widened physeal line at the base on radiographic examination are the keys to the diagnosis.</p>	<p>Modification of the inciting activity and time will suffice for most cases. The condition is self-limiting and rarely causes functional long-term problems.</p>
<b>Little</b>	<p>Usually seen in young baseball pitchers or sometimes catchers, due to repetitive torque stress placed on the proximal humeral</p>	<p>Healing is usually complete with 4–6 weeks of rest. Prevention is accomplished by following rules set</p>

<b>League Shoulder</b>	epiphyses (type I Salter-Harris injury). Widening of the epiphyseal plate may be evident on anteroposterior and lateral radiographs. It is also important to consider fracture through a unicameral bone cyst in the differential.	by the Little League Association to limit the time of non-relief pitching.
<b>Sprengel's Deformity</b>	Failure of migration of the mesenchyme during fetal growth results in a congenital elevation of the scapula. Seventy percent of cases are unilateral.	Mild elevation that is not cosmetically obvious may be left untreated (except for stretching). More severe deformity must be corrected surgically, usually involving soft tissue release and possible excision of the superior/medial scapula and/or osteotomy of the clavicle.
<b>Clavicular Fracture</b>	The most common skeletal injury during delivery is a clavicular fracture. Risk increases with the size of the infant. The left side is fractured more often than the right. The clavicle is the fourth most common children's fracture (8% to 16%). Middle-third fracture is most common in children. Falls and blows to the clavicle are the most common injury seen in sports and abuse. Radiographs demonstrate the location and extent of injury.	Birth fractures rarely need treatment except to avoid picking the child up by the arms (use waist). Rapid healing occurs. In older children, a figure-of-eight brace is generally all that is needed. Although there may be an initial large deformity, this almost always resolves with time in children. Healing occurs in a few weeks.

## ELBOW

<b>Little League Elbow</b>	A complex of changes seen in the Little League pitcher. Due to distraction forces medially and compressive forces laterally during late cocking phase of pitching and posterior traction and compressive forces at radial-capitellar joint with the quick pronation seen with follow-through. Elbow pain that may localize may be combined with flexion contracture or an increased valgus carrying angle. Radiographically, medial epicondyle hypertrophy or fragmentation, trochlear or olecranon fragmentation, and widening of medial epicondyle and humeral metaphysis space may be seen alone or in combination. These may represent, to some degree, normal variants in response to increased forces at the elbow. However, if symptomatic, the patient should be treated. Osteochondritis dissecans may also be seen as part of this complex.	Management simply involves limiting the activity to allow healing. Strict adherence to the Little League rules for pitching will be helpful. Generally, if caught early the prognosis is good; however, occurrence or persistence in the later stages of adolescence warrants a surgical consult due to the risk of the formation of loose osteocartilagenous fragments that will lead to early degeneration.
<b>Osteochondritis Dissecans</b>  <i>Ages 13-16</i>	Avascular necrosis (local subchondral infarction) of the capitellum or radial head is due to vascular insufficiency and compressive trauma seen most often in Little League baseball pitchers; however, it may occur in gymnasts, basketball players, or any active adolescent. Patient presents with lateral elbow pain. Radiographs should include radial-capitellar view.	Restriction of inciting activity coupled with rest for a number of weeks to months may be successful in some cases. Loose-body formation, failure to heal, or persistent symptoms often require surgical debridement, excision of loose bodies, and occasionally drilling or curettage to vascularize the area to assist healing.
<b>Panner's Disease</b>	An osteochondrosis of the capitellum	Healing occurs over a 2-year

Ages 4–12	distinguished from osteochondritis dissecans by some authors because of the younger occurrence (still primarily male) and that the entire physis is involved (more similar to Legge-Calvé-Perthes) with sequential change of sclerosis, fissuring, fragmentation, collapse, and remodeling. Enlargement of the radial head may occur. Patient presents with lateral elbow pain.	period. Temporary immobilization and avoidance of rapid forearm pronation/supination and activities that increase lateral compressive forces (valgus) may help prevent the complication of loose fragments. A brace to prevent flexion contractures is also used. Loose-body formation, failure to heal, or persistent symptoms often require surgical debridement, excision of loose bodies, and occasionally drilling or curettage to vascularize the area to assist healing.
<b>Medial Epicondyle Fracture/Separation</b>	Due either to repetitive forces of distraction and/or rotation or may be due to an acute injury, such as falling on an outstretched hand, or any valgus loading force. The patient complains of medial elbow pain and possible swelling. Standard radiographs will demonstrate the degree of displacement; stress views may help determine stability of physis.	Displacement less than 5 mm may be managed with a long arm cast for 3 weeks. Radiographs while in the cast will help detect any further displacement that can occur due to the pull of the flexor/pronator group of muscles. Displacement greater than 5 mm requires orthopaedic consult with a surgical attempt at fixation with pins likely.
<b>Olecranon Apophysitis</b>	Repetitive activities that require forceful contraction of the triceps, such as the acceleration phase of throwing, may result in a triceps tendinitis or olecranon apophysitis. The patient complains of posterior elbow pain with resisted extension or occasionally with passive overpressure on extension. Radiographs are not generally helpful, although the late consequence may be hypertrophy or spurring of the olecranon with eventual impingement or loose-body formation (usually seen in the adult).	Primarily an overuse phenomenon; therefore, rest and modification of the activity (i.e., reduction in numbers of throws) coupled with ice and stretching are usually sufficient. Chronic apophysitis may rarely progress to avulsion of the olecranon apophysis.
<b>Regional Disorder</b>	<b>Diagnostic Features and Considerations</b>	<b>Management Considerations</b>
<b>Radial Head Subluxation (Nursemaid's Elbow)</b> <i>Younger than Age 7</i>	Subluxation (medical) of the radial head may occur in the young child due to a traction force that pulls the radial head through the annular ligament and then traps the ligament between the radial head and capitellum. Common descriptions include swinging the child by the arms or sudden tugging or lifting by the arms. The child has sudden pain in the lateral elbow and holds the arm against the side unable to use it (pseudoparalysis).	Reduction may be accomplished with one thumb placed on the radial head while the other hand applies gentle traction through the wrist. This is followed by a quick, gentle supination of the forearm while pressing on the radial head. A click is usually felt when reduction occurs. Ability to move the arm is usually immediate.

<b>Supracondylar Fractures</b>	Hyperextension of the elbow, often seen with falling on an outstretched arm, may result in a supracondylar fracture, whereas in the adult, a dislocation would more likely occur. Displacement of the distal humerus may be palpable. Radiographs will demonstrate the relative posterior displacement of the distal humerus and a positive fat pad sign on the lateral view. Oblique views may be necessary. Neurovascular complication is not uncommon and may result in Volkmann's ischemic contracture and deformity.	Expert orthopaedic attention must be given immediately to avoid Volkmann's contracture. Generally, reduction and percutaneous pinning fixation are used. Malunion will result in a "gunstock" deformity.
<b>WRIST/HAND</b>		
<b>Distal Radial Epiphyseal Injury</b>	Injury to the distal radial (or ulnar) epiphyses may occur due to a fall on an outstretched hand or a twisting injury with the wrist weight bearing. Repetitive changes may occur due to the compressive maneuvers of gymnasts and weight lifters. Radiographs will help differentiate between physeal injury and soft tissue injury through demonstration of characteristic patterns for Salter I-IV fracture.	If the injury is severe, an effect on bone growth may occur. Long-term management should include follow-up radiographs to determine if growth is occurring normally.
<b>Kienbock's</b>	An avascular necrosis of the lunate is usually symptomatically silent without obvious traumatic onset. Hypermobility or an ulna minus (shortened ulna) may contribute to the development of Kienbock's. Even when the patient presents with wrist pain, radiographic changes may not yet be evident. When evident, there is an apparent increased density (i.e., appears brighter) of the bone compared with the other carpals.	If caught early, avoidance of repetitive, compressive activities may help. Recent studies indicate that conservative, nonsurgical care has a good outcome. Surgical options involve osteotomy of the radius and arthrodesis of the carpals.
<b>Torus and Greenstick Fractures</b>	With torus, or buckling, fractures the child usually reports falling on an outstretched hand. The wrist may be swollen and painful. The lateral radiograph may better demonstrate the buckling. The cortical bulge is usually 2 to 4 cm from the growth plate and may take 2 to 4 weeks to become visible. Greenstick fractures are usually due to a longitudinal force. A bowing deformity will be evident and an incomplete break may be seen radiographically. The child will have a definite problem with pronation/supination.	Torus fractures do not usually displace and simply require immobilization for 2-4 weeks. Greenstick fractures are manipulated by an orthopaedist to reduce bowing deformity. They heal in 4 to 6 weeks.
<b>HIP/PELVIS</b>		
<b>Developmental (Congenital) Hip Dysplasia (DHD)</b>	DHD is a generic term that encompasses a wide variety of anatomic abnormalities that are predispositions for dislocation or instability in the infant/child and degenerative arthritis in the adult (especially females). A shallow acetabulum, inverted acetabular labrum, enlarged	0 to 6 months—If caught early, fixation of the hips in a Pavlik brace (position of flexion/abduction) for a minimum of 6 weeks. Other approaches such as the use of double-diapers should be discouraged. The intent is to allow
	ligamentum teres or an iliopsoas tendon interposed between the	sufficient growth in

	<p>femoral head and acetabulum are common features. There is a genetic tendency (10% family history). Breech delivery, neonatal positioning in adduction and/or extension, and neonatal hormonal contributions to ligament laxity all are factors. Examination should be performed at birth and rechecked throughout the first year. Tests include Ortolani's sign (abduction/external rotation of femur produces a "clunk" with reduction), Barlow test (flex/abduct with long axis traction or posterior pressure of femoral head creates "clunk"), and Galeazzi's test (comparing level of knees with infant prone, hips and knees flexed). Ultrasound may be a useful tool for diagnosis (operator dependent); however, radiographic interpretation may be difficult. Radiographic findings are usually found later with a disruption of Shenton's line, femoral head in superior lateral quadrant, and a Skinner angle greater than 35° in newborn, 27° in pre-walking stage, and 25° at 1 year.</p>	<p>the hip to establish stability and to avoid the consequences of early degenerative changes or avascular necrosis.</p> <p>6 to 18 months—Traction to stretch out any hip contractures prior to manipulation under anesthesia is followed by spica casting.</p> <p>18 to 36 months—Surgery is generally necessary with a pelvic osteotomy to correct the acetabular dysplasia.</p> <p>36 months or older—Open reduction, femoral shortening and/or pelvic osteotomy is often necessary to correct deformity.</p>
<b>Transient Synovitis</b>	<p>A transient synovitis of the hip is a relatively common occurrence in children. The cause is unknown; however, over half of children have had a recent previous upper respiratory infection. Trauma and allergic etiologies are also possible. It is difficult or impossible to place weight on the affected hip and the hip is held in abduction. The key is to distinguish between septic and nonseptic synovitis. The erythrocyte sedimentation rate (ESR) is normal, and the hip radiograph is negative for bony pathology with transient synovitis. With septic synovitis, there is often a fever, elevated ESR, and joint aspiration may demonstrate leukocytosis with a positive culture. Bone scans are generally not helpful.</p>	<p>Rest and non-weight-bearing will allow resolution within a few days to a week. Persistence or worsening suggests a septic etiology and requires referral for joint aspiration. Recurrent cases may indicate a tendency toward Perthes' disease (2% to 3% of cases). Residual effects of transient synovitis may include a mild coxa magna or widening of the femoral neck.</p>
<b>Slipped Capital Femoral Epiphyses (SCFE)</b> <i>Between Ages 8 and 15</i>	<p>Progressive or sudden posterior/inferior slippage of femoral epiphysis; 10% to 25% (as high as 41%) bilateral; classified as acute or chronic; acute slippage is a type I physeal fracture occurring in 5% to 10% of children with SCFE (some authors feel that there is a distinction between SCFE and a transphyseal fracture where a single traumatic event is more likely); chronic SCFE designated as symptoms having been present for more than 3 weeks; two types of "typical" patients seem evident: (1) tall, rapidly growing children, and (2) a Frolich-type young male (obese); more common in blacks; pain is usually in the hip but may be referred to thigh or knee; patient may have a limp and inability to bear weight; on physical examination when hip is taken passively into flexion it tends to externally rotate; internal rotation is often limited, although any attempt at hip range of motion may be extremely painful with acute slippage; lateral radiograph is necessary to view slippage; slippage</p>	<p>Never attempt to manipulate back into place due to the high risk of subsequent avascular necrosis.</p> <p>Medical management involves a short period of traction followed by internal rotation to achieve reduction. Good results with operative</p>

	<p>is graded I-III; grade I involves less than 33% displacement, grade II 33% to 50% slippage, and grade III is greater than 50% slippage; computed tomography (CT) may be necessary to demonstrate accurately the degree of slippage.</p>	<p>positioning have been found in 50% of cases without formal manipulation. Percutaneous fixation with cannulated screws is a common approach to management. Newer approaches include bone graft epiphysiodesis. For chronic slips no attempts at closed reduction should be made (i.e., avascular necrosis complication). Percutaneous pinning in situ is usually recommended.</p>
<p><b>Legge-Calvé-Perthes</b> <i>Between Ages 4 and 9 (80% of time)</i></p>	<p>Avascular necrosis of femoral head with associated subchondral fracture; four to five times more common in males; only 17% of patients report an associated traumatic onset; symptoms may be minimal with only a chronic limp and mild pain aggravated by activity during previous several months; pain is often referred to the knee; limited abduction and internal rotation secondary to muscle spasm may be seen; the Trendelenberg test may be positive; leg length inequality and thigh atrophy may be present; radiographs are often initial tool to identify characteristic staging signs such as a crescent sign, fragmentation of the epiphysis, reossification of femoral head shape (flattened), and residual deformity in the later stage.</p>	<p>Bed rest with skin traction are often helpful. Approaches to femoral containment in acetabulum include prescription of an abduction orthosis, femoral osteotomy, and innominate osteotomy.</p> <p>Few asymptomatic hips with normal initial radiographs are at risk for pain or radiographic abnormalities. When the uninvolved hip does become involved, the process is slow and surgical intervention is rarely indicated.</p>
<p><b>Apophysitis (General Comments)</b></p>	<p>Usually the result of trauma, specifically sports activities that involve sudden contraction of muscles causing avulsion at tendon insertions. Sixty percent to 90% involve males. The apophysis is weakest at the time of its appearance. Occurrence is primarily in the adolescent population. Sudden pain and limitation of activity usually accompany the injury. When there is no obvious single traumatic event, radiographs may be difficult to interpret due to variation in the appearance of secondary ossification centers and also may be confused with osteosarcoma, Ewing's sarcoma, or osteomyelitis. Refer films to chiropractic or medical radiologist.</p>	<p>Controversy exists regarding treatment of avulsion.</p> <p>1. Nonsurgical management—Studies indicate excellent results. Five-stage rehabilitation program consists of an initial period of rest for up to 7 days using ice and analgesics; positioning of the leg to decrease tension of involved muscle group. Week 2 begins when acute pain is decreased and consists of protected walking, isometrics, and limited stretching. Week 3 includes a progressive resistance exercise program, and week 4 increases resistance when 50% of anticipated strength is achieved. Sports-specific training usually begins in weeks 5–6. The only concern is bony exostosis formation, which occurs rarely and occasionally requires surgical excision.</p> <p>2. Surgical management—Still recommended by some orthopaedics, especially for displaced avulsions of the</p>

		ischial tuberosity; open reduction and internal fixation are recommended with displacement of more than 2 cm of the avulsed fragment.
<b>ASIS Apophysis</b>  <i>Appears between Ages 13 and 15</i> <i>Fuses between Ages 18 and 25</i>	<p>Caused by sudden contraction of the sartorius with hyperextension of hip with knee in flexion; mainly occurs in sprinters (middle of run), hurdlers, noncontact football players, or runners (running accounts for 75% of injuries). Patient may report a snap at the time of injury; pain at ASIS with passive hip extension or active hip flexion. Avulsed fragment may be palpable. Patient demonstrates antalgia forward and lateral to same side; oblique radiographs of area may be needed to view fragment.</p>	<p>Nonsurgical management is recommended with an emphasis on an initial period of rest, ice, analgesics, and crutch ambulation; follow above general recommendations for apophyseal injury. Average time of return to normal activity is 6 to 10 weeks.</p> <p>Surgical management is recommended only with severe displacement.</p>
<b>AIIS Apophysis</b> <i>Appears between Ages 13 and 15</i> <i>Fuses between Ages 16 and 18</i>	<p>Due to rare injury of rectus femoris overcontraction; mechanism same as ASIS injury (sprinter-type injury) and may also occur in soccer/football with kicking; antalgic gait with pain increased by active hip flexion. Radiographs should include obliques; caution in misinterpreting an os acetabuli (normal variant) as an avulsion (contralateral comparison films may help).</p>	<p>Nonsurgical management recommended; follow general recommendations above; average return to full activity is 6 to 8 weeks.</p>
<b>Lesser Trochanter Apophysis</b>  <i>Appears between Ages 8 and 12</i> <i>Fuses between Ages 16 and 17</i>	<p>Avulsion occurs with forceful contraction of the iliopsoas against resistance (sprinters, jumpers, kickers); may occur in running or football. Antalgic gait on same side; anterior hip pain with radiation occasionally into groin; leg may be held in slight adduction/internal rotation; resisted hip flexion, passive extension, and internal rotation increase pain; positive Ludloff's sign—inability to actively flex hip while seated. Radiographs should include slight external rotation to clearly see lesser trochanter.</p>	<p>Nonsurgical management recommended; follow general recommendations above; average return to full activity is 10–12 weeks.</p>
<b>Greater Trochanter Apophysis</b>  <b>Appears around Age 4</b>  <i>Fuses between Ages 16 and 18</i>	<p>Due to excessive, sudden contraction of the hip abductors (e.g., cutting); sudden pain at greater trochanter with leg held in slight flexion/abduction; trochanteric fragment may be palpable. Patient is unable to perform a single-leg stance on affected side; Trendelenburg's may be positive; active abduction or passive adduction of hip will increase pain. Radiographs usually demonstrate a fragment displaced proximally, posteriorly, and medially; on rare occasions a small accessory ossification may be confused with avulsion and a comparison view assists in the differentiation.</p>	<p>Surgical management recommended if fragment is displaced more than 1 cm.</p> <p>Nonsurgical management for all other cases following recommendations above for general apophyseal rehabilitation. In addition, a hip abduction orthosis with a thigh cuff may assist in the early phases of healing.</p>
<b>Iliac Crest Apophysis</b>	<p>Excessive muscle pull from either abdominal obliques, tensor fascia lata, or gluteus medius anteriorly and latissimus dorsi and gluteus maximus posteriorly. There are three forms (1) acute contact—fall or blow to crest (hip pointer), (2) acute noncontact—due to sudden change in direction, and (3) overuse—often due to torsional strains. Pain and tenderness worse with resisted abduction of hip, contraction of abdominal muscles, or lateral bending of the torso; caution when viewing</p>	<p>Nonsurgical management recommended for most cases; follow general recommendations above; average return to full activity is 4–6</p>

<p><i>Appears between Ages 12 and 15</i></p> <p><i>Fuses between Ages 18 and 25</i></p>	<p>radiographs due to common occurrence of normal variants simulating pathology.</p>	<p>weeks. Surgical management recommended if fragment is displaced more than 3 cm.</p>
<p><b>Ischial Tuberosity Apophysis</b></p> <p><i>Appears between Ages 14 and 16</i></p> <p><i>Fuses between Ages 18 and 25</i></p>	<p>Classified as acute separation (apophyseolysis), chronic apophyseolysis with slow separation, and osteochondrosis (avasular necrosis or Kremser's disease); mechanism in acute injury is forceful eccentric contraction of hamstrings with knee in extension and hip in flexion found primarily with runners and also broad jumpers, hurdlers, and gymnasts/cheerleaders (performing splits). Patient is antalgic; pain is reproduced with passive stretching or active contraction of hamstrings or hip adductors; tenderness at ischial tuberosity or sacrotuberous ligament. Defect or gap may be palpable; diagnosis confirmed with radiographs. Displacement is usually distal and lateral.</p>	<p>Concern with nonsurgical management is fibrous nonunion (up to 68%). If nonunion does occur, excision of fibrous nonunion and reattachment of hamstrings are usually successful. Nonsurgical management is still recommended for most cases. Open reduction and internal fixation is recommended with displacement of more than 2 cm.</p>
<p><b>Adductor Avulsion of Symphysis Pubis</b></p>	<p>Usually a sprinting injury with onset of sudden groin pain; resisted adduction or passive abduction increase pain. Radiographs are difficult to interpret; no avulsed fragments are seen.</p>	<p>Usually conservative treatment is sufficient. Figure-of-eight wrap for assisted walking is beneficial followed by mild stretching and strengthening for several weeks.</p>
<p><b>KNEE</b></p>		
<p><b>Blount's Disease (Tibia Vara)</b></p>	<p>Disruption of growth at the medial proximal tibial growth plate leads to a varus deformity. There is a higher incidence in children who are black, obese, and who have a familial history or live in certain geographic areas. The cause is unknown but may be due to stress or trauma. There is an infantile and juvenile form. Initial radiographs may be negative. Increased uptake on bone scan is diagnostic. There is an associated medial tibial torsion in many cases.</p>	<p>There are six stages. In the first two stages braces are used during play and at night. If there is progression to later stages osteotomy is recommended (especially before the age of 4).</p>
<p><b>Posttraumatic Genu Valgum</b></p>	<p>Although rare, overgrowth may occur as a result of proximal tibial metaphysis fractures. The deformity may be due to soft tissue caught in between the fracture segments or malunion.</p>	<p>Prevention is possible with correct positioning in casting the leg for these fractures. If the deformity develops, osteotomy or hemi-epiphysiodesis may be used dependent on the degree.</p>
<p><b>Osgood-Schlatter's</b></p> <p><i>Age 11-15</i></p>	<p>An apophysitis at the tibial tubercle commonly seen in running/jumping sports, in hockey with boys and gymnastics and figure skating for girls. Pain and swelling over the tibial tuberosity are relatively diagnostic. Radiographs may be misleading due to normal variant of tibial tuberosity fragmentation and should generally be used either to rule out tumor (if suspected) and full</p>	<p>Activity modification (reduction of intensity or frequency), icing, stretching, and strengthening are the mainstay of management. Focus is on hamstring, quadriceps, iliotibial band, and Achilles stretching and eccentrically strengthening</p>

	avulsion (seen generally in patients complaining of pain with activity and rest; <1% of all patients).	the quadriceps. An Osgood-Schlatter brace may provide some limited symptom relief. The condition generally resolves in 6 to 9 months in most cases.
<b>Sinding-Larson-Johannsen Syndrome</b> <i>Ages 10-14</i>	An apophysitis of the inferior pole of the patella, this condition is seen primarily in males. The causes are similar to Osgood-Schlatter's including running and jumping, but also climbing stairs or kneeling may be aggravating. Radiographic appearance is of an irregular calcification at the inferior pole of the patella. Occasionally, this process affects the proximal pole of the patella.	Same as Osgood-Schlatter's.
<b>Bipartite/Tripartite Patellae</b>	Secondary centers of ossification may produce a bipartite or tripartite patella. These centers are connected to the patella by fibrous or cartilaginous tissue (not visible on radiographs). Symptoms are produced with direct trauma to the patella or pull from tight quadriceps (common during growth spurts). The most common location is the superior/lateral patella. Radiographs clearly demonstrate the center; however, bilateral views may be necessary to differentiate from a fracture when direct trauma to the patella has occurred (bipartite patellae are often bilateral).	Rest from any inciting activity and quadriceps stretching are usually sufficient for symptom resolution. On occasion, the pain is resistant to conservative care due to an associated chondromalacia of the affected region. In rare cases, surgical excision or a lateral retinacular release is recommended.
<b>Tibial Eminence Fracture</b>	Tibial spine fractures are more common in children. Causes include avulsion from anterior cruciate ligament (ACL) injury or direct trauma from a fall or direct blow to the area (common in bicycle injuries). ACL-related injuries are due to the fact that the incompletely ossified eminences are weaker than the attached ACL. Tunnel and oblique radiographs will demonstrate the fracture in most cases.	Dependent on the degree of fracture, management may range from closed reduction and cast immobilization to surgical fixation. Although this injury is not usually associated with other damage, it is not uncommon to have some indications of ACL instability after healing has occurred.
<b>Discoid Meniscus</b>	Usually found laterally, this abnormally shaped meniscus has abnormal attachments that allow too much mobility. The patient complains of the knee giving way, or snapping, or sometimes locking and pain. Full extension may not be possible passively, and joint line tenderness laterally may be found. Magnetic resonance imaging (MRI) is usually necessary for the diagnosis.	Meniscectomy should be avoided. Menisco-plasty may help in reshaping the meniscus or a partial meniscectomy may be performed.
<b>Plica</b>	A redundant synovial fold may persist. The most common is a medial shelf plica. Symptoms often appear during the growth spurt when bone grows, yet the plica does not. This tethering may cause erosion pain at the femoral condyle and/or snapping with knee flexion. Also direct trauma may cause irritation. A CT or MRI is necessary for confirmation.	Management may be conservative with rest, ice, and anti-inflammatories. If persistent, surgical release is effective.
<b>Epiphyseal Injury</b>	When a twisting, hyperextension, or valgus injury occurs at the knee, epiphyseal injury is more likely than soft tissue injury in a young patient. Valgus testing will reveal opening that must be confirmed with a stress fluoroscopic study demonstrating epiphyseal opening (usually a Salter type II fracture).	Closed reduction is sufficient for Salter I and II injuries. Open reduction may be necessary for Salter III and IV. Long-term follow-up includes monitoring for any growth disturbances.
<b>Osteochondritis</b>	OCD is partial or incomplete separation of a distal	If the fragment is intact, the

<b>Dissecans (OCD)</b>	femoral osteochondral fragment. The cause is unknown but is likely the result of trauma, ischemia, aberrant ossification, or a hereditary epiphyseal abnormality. The juvenile/adolescent form is probably the result of a combination of these factors. Symptoms usually appear in adolescence and may be bilateral in 20% to 30% of individuals. The most common site is the lateral area of the medial, distal femoral condyle. If the fragment is still attached, symptoms are usually of vague knee pain with swelling occurring in some cases. If the fragment dislodges or hinges into the joint, mechanical symptoms such as locking may then occur. Physical examination may reveal tenderness at the condyle with palpation of the area (knee is flexed 90° or more to access area). Wilson's test may be positive. Radiographs must include a tunnel view. Other imaging tools may be necessary to confirm the configuration and extent of the lesion.	management goal is to support healing. This includes rest and restriction from activity (to the extreme of cast immobilization if necessary). Sequential radiographs must be taken. If the patient is still symptomatic and/or there is no evidence of healing after 3 to 6 months of conservative care, surgical management may be considered. Surgery includes drilling to allow increased vascularization and healing or the use of fixation devices if the fragment is unstable and likely to separate off the condyle. The adult form of this condition has a higher rate of nonunion and need for surgical intervention.
<b>Patellar Dislocation</b> <i>Most Common: Ages 9 and 15</i>	Occurrence is 1 in 1,000 children. Associated osteochondral fracture is approximately 50%. This associated fracture may occur on relocation as the patella hits the lateral femoral condyle. Injury may include hyperextension or twisting injury with femur rotating medially or, less commonly, a direct blow to the medial patella. In unreduced dislocations, the deformity is usually obvious but may be obscured by a swelling (due to tearing of retinacular vessels or osteochondral fracture). If reduced, tenderness is found on the medial patella due to tearing of the retinaculum and other soft tissue.	Management of unreduced dislocation includes a gentle attempt at relocation. If not possible, transport to the emergency department is suggested due to the high rate of osteochondral and lateral femoral condyle fracture seen with aggressive relocation. For first-time dislocators without osteochondral involvement, 3 to 6 weeks of immobilization with knee extension and a lateral compression pad are sufficient. The chance of recurrent dislocation is one in six. If biomechanical predispositions can be determined such as patella alta, an attempt at conservative accommodation may be helpful. Surgical stabilization for recurrent dislocators is recommended.
<b>ANKLE/FOOT</b>		
<b>Snowboarder's Fracture</b>	Although not exclusive to the snowboarder, fracture of the lateral process of the talus is three times more common in snowboarders than in the general population. An "ankle sprain" with a complaint of anterolateral ankle pain, especially if the pain is persistent after a reasonable period of time, should raise the suspicion of this fracture. Although often missed on radiograph, a mortise view with internal rotation might catch the fracture; found just distal to the lateral malleolus. Lateral radiographs at 0° dorsiflexion and 10° to 20° inversion may demonstrate the fragment. If still suspected but not seen on radiographs, a CT scan should be ordered.	Generally it is accepted that nondisplaced fractures can be managed with a short-leg, non-weight-bearing cast for about 4 weeks followed by 2 weeks of walking. Minimally displaced fragments will probably also do well with this treatment. With more displacement there is some disagreement as to whether the above protocol is sufficient or whether surgery is indicated.
<b>Freiberg's</b> <i>Ages 14-18</i>	Avascular necrosis of the head of either the second or third metatarsal. This condition is more common in females. Metatarsal pain in an adolescent would warrant a differentiation between stress fracture and Freiberg's. However, symptoms may appear 6 months prior to radiographic changes. Changes include a sequence of irregular articular surfaces progressing to sclerosing, fragmentation, and remodeling. Bone scans are occasionally used in the differential; however, uptake varies based on the staging of disease.	If caught early, rest, an orthotic designed to relieve metatarsal head stress, and a sole orthotic to reduce motion of the joint may be successful. If not, a short-leg walking cast may be necessary. Advanced changes with fragmentation or overgrowth may require surgical excision and debridement.

<b>Kohler's</b> <i>Ages 3-6</i>	There is still some debate as to whether this represents an avascular necrosis of the tarsal navicular or whether it is a normal variant (may be found bilaterally and unassociated with symptoms). This condition is more common in males. Therefore, patients who are symptomatic should have comparative films taken and the findings correlated to clinical symptoms. A navicular subluxation should be considered.	This condition usually resolves over 3 to 9 months. Arch supports may provide some symptom relief. Adjusting of a navicular subluxation may also prove effective in relieving symptoms.
<b>Sever's Phenomenon</b> <i>Ages 11-12</i>	Irregularity of the secondary ossification center of the calcaneus is often misinterpreted as a cause of adolescent heel pain. The following scenario occurs and should be managed as an insertional tendinitis. Presentation is more frequent in boys. Pain at the heel exacerbated by running activities. Predispositions may include repetitive microtrauma, tight gastroc-soleus, weak ankle dorsiflexors, fast growth spurt, and biomechanical abnormalities including genu varum, or subtalar and forefoot varus. Rarely is there swelling. Tenderness with compression on the medial and lateral calcaneus is suggestive. Radiographs are of little help because of the normal variant of increased density seen at the apophysis.	A self-resolving condition in most cases. Management is conservative with temporary reduction or elimination of inciting activities and stretching of the plantarflexors and strengthening of the dorsiflexors. Orthotics may help compensate for some associated biomechanical predispositions.
<b>Tarsal Coalition</b>	Connections or fusion between tarsal bones with bone, cartilage, or fibrous tissue causing loss of inversion and eversion movement. Often familial, these may be unilateral or bilateral. Pain, flatfoot, and peroneal spasm may be seen. The most common at the calcaneonavicular joint is best seen on an oblique radiograph of the foot. The next most common is the talocalcaneal joint. This type is less visible on radiographs (occasionally seen on a Harris view); best seen on CT scan.	A short-leg walking cast for 4 weeks may provide relief from pain. When symptoms recur quickly after removing cast, surgical resection is used.
<b>Accessory Tarsal Bones</b>	Irritation or disruption of the connection (syndesmosis) between primary and secondary centers of ossification (accessory bones) may be the cause of pain in children and adolescents. There are about 21 accessory bones in the feet; therefore, pain may be localized to many different sites dependent on the involved syndesmosis. Common sites are at the navicular and below the medial or lateral malleolus. It is equally important not to mistake an avulsion fracture for an accessory ossicle. This is most common at the base of the fifth metatarsal, where an inversion injury may occur (through contraction of the peroneus brevis tendon) causing an avulsion fracture.	Short-leg walking cast immobilization may be sufficient for 2 weeks. If unresponsive, surgical excision may be required.
<b>Iselin's</b>	Considered a traction apophysitis of the base of the fifth metatarsal, this condition is considered either rare or nonexistent by some authors. The consideration is whether there is actually a fracture versus an apophysitis. Lateral pain at the site of irritation is increased with running, cutting, or jumping. Resisted eversion may also increase pain. Radiographically, the apophyseal space may be enlarged and the apophysis irregular.	Management is conservative with relative rest and avoidance of any symptom-producing activities for a period of a few weeks to 2 months. Rehabilitation may include stretching of the evertors and plantarflexors and strengthening of the invertors and dorsiflexors. In rare cases, a period of soft-cast immobilization may be needed.

The preparticipation evaluation is not intended as a substitute for a full physical. A portion of the examination is intended as a health screen to discover any serious disorders. The primary focus is musculoskeletal. However, for many school-aged

children, the sports physical may be the only direct health evaluation access these children will have.<sup>44</sup>

A protocol for administration of the examination follows:

- Meet with the contact individual at an institution or sporting organization to determine specific needs. The variables to be discussed include:
  1. Which group of individuals is being examined (specific sport or general exam)?
  2. Where will the examination be performed?
  3. Which type of examination format will better suit the institution based on the numbers of individuals being examined, the facilities for the examination, and the intent of the examination?
- Send letters explaining to parents the intent of the examination, who is performing the examination, and where parents can call to ask questions. This letter would include an informed consent section to be signed by the parent.
- Perform the examination.
- Provide parents and students an evaluation summary with a copy sent to the coach and placed in the student's file. The information would include:
  1. Vitals and anthropometric measurements (blood pressure, temperature, pulse/respiration rate, height, weight, eyesight and hearing screening)
  2. Flexibility, strength, and endurance results with a sex- and age-matched comparison column
  3. A summary and recommendation section explaining areas that are below normal and how they may be improved

Dependent on the type of examination, the components of the preparticipation evaluation may vary. The constant component would be completing a general health questionnaire. The focus of the questionnaire is to screen for known problems such as disease, organ dysfunction (or absence), prior injuries, allergies, current medications, and familial tendencies. Focus is placed on two common tendencies; one is rare (but catastrophic), the other is common (but often undetected). The primary focus for detection of serious disorders is sudden death often due to undetected cardiac abnormalities such as hypertrophic cardiomyopathy. The history may be helpful, including a family history of cardiac disease causing death in a young, close relative and a personal history of syncope or heat intolerance. A screen for Marfan's syndrome is typically performed with a family history and physical examination. The second condition is exercise-induced bronchospasm. This condition may occur in as many as 15% of adolescents. Clues are exertional dyspnea or a complaint of wheezing during or after exercise.

The typical components of the examination include the following:

- Evaluation of vitals
- Evaluation of anthropometric measurements such as height, weight, body type, body fat composition, and general range of motion
- Medical evaluation including:
  1. vision evaluation
  2. auscultation of heart and lungs
  3. palpation of abdomen
  4. determination of Tanner staging (direct or indirect) to estimate physiologic maturity (optional)

The Tanner age classification system is as follows:

- Male Tanner staging<sup>45</sup>
  1. Stage 1: preadolescent with small testes, scrotum, and penis (same as proportions in childhood); no pubic hair
  2. Stage 2: scrotum and testes enlarge with some reddening of the scrotal area; sparse growth of pubic hair
  3. Stage 3: growth of penis in length and some breadth in addition to continued growth of testes/scrotum; pubic hair is darker, coarser, and curlier
  4. Stage 4: penis has enlarged with development of the glans; adult pubic hair but has not covered full area as in adult
  5. Stage 5: genitals and pubic hair are adult in size and shape
- Female Tanner staging of pubic hair development<sup>46</sup>
  1. Stage 1: preadolescent; no pubic hair
  2. Stage 2: sparse growth of long, downy hair, straight or curled mainly around labia
  3. Stage 3: hair is darker, denser, and coarser, spreading to junction of pubes
  4. Stage 4: hair is adult in type but not spread as far, not extending to medial thigh
  5. Stage 5: hair is adult in type and fully spread to medial thighs

More specific examination would include testing (**Table 53-9**) for:

- Strength: using sit-ups or push-ups, the squat, or one maximum-lift bench press (dependent on facilities and type of examination)
- Power: using the vertical jump or medicine ball toss
- Anaerobic endurance: using jumping jacks, 20-yard dash, shuttle run, or hexagon drill
- Aerobic endurance: using either step test or timed mile run

<b>Table 53-9</b> Summary of Preparticipation Examination

- Flexibility: sit -and -reach test and goniometric measurement

These may be general examinations or examinations focused on target areas based on the specific sport or sports in which the individual will participate. Statistically, there are common biomechanical requirements for specific sports and common injury patterns for that sport.<sup>47</sup> The intent of the preparticipation examination is to focus on these requirements and give suggestions to prevent injury.

The age of the athlete will also influence the focus of concern.<sup>48</sup> Children between ages 6 and 10 years are more involved in spontaneous play, becoming increasingly involved in organized sports. The focus of the examination in this group is on scoliosis, congenital anomalies, visual problems, and mesenchymal disorders such as Marfan's syndrome. In the young athlete, generally between the ages of 11 and 15 years, the focus shifts to more complex areas such as psychosocial influences. Particular attention is given to questioning regarding sexual activity, drug and alcohol use, and a determination of physical maturity with regard to risk of injury in contact sports. The most appropriate time for a preparticipation physical is six weeks prior to the season. This usually gives adequate time to further investigate any areas of concern or follow a prescribed program of stretching or strengthening.

The seven most important physical examination factors are:

1. *Are there any major medical restrictions or contraindications to a specific sport activity?* (major eyesight, hearing, cardiorespiratory, renal, or hematologic concerns)
2. *Any past injuries that tend to be recurrent?* (shoulder and patellar dislocations/subluxations, etc.)
3. *What are the major areas of imbalance musculoskeletally?*
4. *What is the level of maturation?* (The Tanner criteria determine skeletal maturity indirectly through the maturity of secondary sexual characteristics such as

pubic hair growth or breast development. Stages are 1 through 5; musculoskeletal injuries occur more often during the peak height velocity phase of growth, which corresponds to Tanner 3 or 4. Also, mismatched Tanner-staged individuals are more likely to create a scenario where injury will occur to the lower Tanner individual such as matching a Tanner 1 with a Tanner 4, particularly in a contact sport.)

5. *What is the individual's motivation regarding participation?*
6. *Is there a family history of sudden death in relatives under the age of 50 years? (hypertrophic obstructive cardiomyopathy)*
7. *Are there any allergies to insect bites?*

**Table 53-10** contains specific questions by organ or system.

Nine areas of special concern follow:<sup>49</sup>

1. **Viral infections.** Most viral infections are worsened by physical activity. They may adversely affect performance in the following situations:
  - Pharyngeal inflammation may decrease upper airway capacity.
  - Inner ear infections may affect balance and equilibrium.
  - Viral disease can occasionally lead to myocarditis. Infectious mononucleosis may result in splenomegaly, which may predispose the spleen to blunt trauma.
  - Herpetic skin lesions can be transmitted between players.
2. **Hematologic disorders.** Hematologic disorders are not screened for in all individuals; however, in those complaining of fatigue:
  - Be careful to test for suspected anemia or abnormalities of the red blood cells (RBCs).
  - Sickle cell crisis can be precipitated by dehydration, lactic acidosis, or hypoxia.
  - False physiologic anemia is associated with increased volume expansion.
3. **Asthma.** Up to 17% of youngsters have exercise-induced bronchospasm.<sup>50</sup>
  - Dry, cold weather is usually worse.
  - Prolonged intense activity is worse.
4. **Renal disorders.** If the patient has a unilateral kidney, he or she is predisposed to serious renal problems with dehydration.
5. **Cardiovascular disease.** Key cardiovascular concerns on the physical examination include the following:
  - Heart rate over 120 beats per minute or any inappropriate tachycardia
  - Arrhythmias
  - Midsystolic clicks
  - Murmurs that are grade 3 or 4. (Most innocent murmurs should diminish with Valsalva. The murmur associated with hypertrophic cardiomyopathy increases with sitting and standing and with exercise. Individuals who have structural heart disease or a significant conduction defect [e.g., abnormal auscultation, chest radiograph, electrocardiogram, or echocardiogram] or those who are symptomatic [i.e., have syncope, near syncope, chest pain, pallor, or other related symptoms] require consultation with a cardiologist for recommendations/restrictions with regard to sports participation.<sup>51</sup>)
  - Hypertension (HTN). Resting blood pressures (includes range of systolic/range of diastolic):<sup>52</sup>
    - age 6 to 9 years: 122–129/70–85 mm Hg is considered significant HTN; >129/>85 mm Hg is considered severe
    - age 10 to 12 years: 126–133/82–89 mm Hg is considered significant HTN; >133/>89 mm Hg is considered severe

- age 13 to 15 years: 136–143/86–91 mm Hg is considered significant HTN;  
>143/>91 mm Hg is considered severe
- age 16 to 18 years: 142–149/92–97 mm Hg is considered significant HTN;  
>149/>97 mm Hg is considered severe
- over 18 years is considered an adult (see [Chapter 24](#))

If there is no target organ damage or heart disease, significant hypertension should not limit sports activities; however, the individual should be monitored frequently and given advice regarding exercise and diet. Those with severe hypertension should be restricted from competitive sports and highly isometric activities and referred for evaluation by a specialist. All young people with HTN should be given advice regarding avoidance of exogenous androgens, growth hormone, drugs (in particular cocaine), asthma medications, alcohol, and tobacco.

**Table 53-10** Screening Questions for Specific Organs or Systems

Questions	Concern/Disorder
<b>Pulmonary</b>	
Do you experience long periods of coughing?	Asthma (including cough-variant asthma and exercise induced)
Do you experience coughing after exercise or sports?	
Do you experience shortness of breath or wheezing during or after exercise?	
<b>Cardiovascular</b>	
Have you ever passed out with exercise or sports or felt like you would?	Arrhythmias and structural abnormalities
Do you ever get dizzy with exercise or sports?	Vertigo versus cardiopulmonary
Have you ever experienced chest pain with exercise or sports?	Angina
Do you fatigue earlier than you feel is normal when exercising or playing?	General cardiopulmonary
Do you have hypertension?	Hypertension
Do any of your immediate family members have heart problems or hypertension?	
Has anyone in your immediate family (including uncles) died suddenly of a heart problem before the age of 50 years?	Hypertrophic cardiomyopathy
<b>Neurologic</b>	
Have you ever been knocked out or lost consciousness?	Concussion, risk of second-impact syndrome
Have you ever had a head injury?	
Have you ever had a seizure?	Epilepsy

Have you ever had what is called a “burner” or a “stinger”?	Narrow spinal canal or instability
Have you ever not been able to move a limb after an accident?	
Do you ever have headaches when you exercise?	Aneurysm, tumor, AVM versus dehydration or primary headache
<b>Musculoskeletal</b>	
Have you ever broken a bone or bones?	Past fracture history
Have you ever dislocated or “put a joint out”?	Instability of shoulder, knee, ankle, etc.
Have you ever sprained or torn a ligament?	
Have you ever strained a muscle or tendon that took a long time to recover?	Predisposed area
Do any of your joints swell?	Spondylolisthesis, Scheuermann’s, scoliosis, etc.
Have you ever been told you have a condition of your spine?	
<b>Urogenital</b>	
Do you ever experience burning when you urinate?	Urinary tract infection
Have you ever noticed any discharge or skin lesions around your genitals?	Sexually transmitted disease
Have you ever noticed any blood in your urine?	Kidney, bladder, or urethra
Have you ever been diagnosed with any kidney, bladder, or other genitourinary conditions?	Congenital or acquired kidney problems
Have you ever been told that you had blood, protein, or sugar in your urine?	Kidney disorders or diabetes

- Discrepancy between femoral and brachial pulse (coarctation of the aorta)
- Other conditions that have cardiovascular risk potential and should be looked for on the history and physical include:
  - hypertrophic cardiomyopathy (HC)
  - mitral valve prolapse syndrome
  - Marfan’s syndrome
  - congenital heart disease
- Other concerns include:<sup>51</sup>
  - Some forms of congenital heart disease are contraindications for sports participation including some conduction deficits.
  - Certain medication or drug abuse may cause dysrhythmias such as antidepressants, asthma inhalants, and cocaine.
  - Patients with anorexia nervosa may develop a prolonged QTc interval or have significant bradycardia.
  - If there is an obvious immediate family history of cardiovascular disease it might be prudent to test the child for cholesterol/high-density lipoprotein (HDL).

- Most children with high blood pressure are “hyperadrenergic” and in fact benefit from exercise. Still it would be best to avoid purely anaerobic activities such as weight lifting. Also prolonged isometric exercise should be avoided.
- 6. *Epilepsy.*** Physical and mental activities seem to be deterrents to seizure activity. Many school systems make little distinction between epileptic and nonepileptic children in their athletic programs. Concerns regarding risk for seizure should include:<sup>53</sup>
  - fatigue
  - sleep deprivation
  - hypothermia, hyperthermia, and hypoxia due to high altitude
  - dehydration
  - skipped meals and hypoglycemia
  - excessive alcohol intake and ingestion of “street drugs”
  - hyperventilation with activity is not a concern; it is different from voluntary or forced hyperventilation, which may precipitate petit mal spells

Epilepsy is not a contraindication to sports participation although caution should be used with climbing, horseback riding, diving, and swimming in general. Buddy participation is recommended. With gymnastics the biggest concern is a fall, due to a seizure, from a height that may lead to serious injury. Those with uncontrolled seizures should avoid water, heights, and speed.

- 7. *Diabetes.*** Regularly exercising diabetics are better controlled than sedentary diabetics. Special focus should include:
  - Anticipate a reduction in insulin requirements. Food may be necessary before, during, and after exercise to avoid hypoglycemia.
  - Exercise should be avoided before bedtime to avoid hypoglycemia during sleep.
  - Changes in insulin and diet need to be established by trial and error, realizing that a reduction is often necessary on days of strenuous exercise.
  - Active children are better controlled with two doses of insulin a day (before breakfast and dinner).
  - There is an increased release of insulin from the injection site that can be decreased by:
    - twice-a-day, meal-related dose
    - injection in the abdomen instead of the arms or legs
  - A portable snack is necessary.
  - In long-duration diabetes with severe microangiopathic complications, exercise should be limited because:
    - Decreased splanchnic blood flow during strenuous exercise may lead to renal cortical ischemia.
    - The exercised-induced increase in blood pressure may stress the vasculature in the eye leading to hemorrhage.
    - Increased transglomerular passage of albumin (exercise induced) may lead to nephropathy.
  - Children must be taught to give prompt attention to abrasions and lacerations and burning or freezing of the feet; they should trim their toenails properly and not wear tight shoes or socks.
  - Dehydration can complicate diabetes.
- 8. *Chronic fatigue.*** Fatigue is common with illness, lack of sleep, and poor diet. Chronic fatigue lasting weeks or longer should be investigated. Some of the

possibilities include:

- infection
- anemia
- burnout
- depression
- overtraining
- ergolytic drugs
- endocrine dysfunction
- respiratory and cardiovascular dysfunction

**9. Other concerns.**

- Document unequal or unreactive pupils prior to sports participation to serve as a comparison should head trauma occur.
- Look for necrotic or perforated nasal septum, which indicates drug (i.e., cocaine) abuse.

The decision to disqualify or modify an individual's participation in a particular sport is based on the American Academy of Pediatrics guidelines.<sup>54</sup> The format of this decision matrix is to classify sports into:

- contact/collision (e.g., boxing, hockey, lacrosse, martial arts, soccer, wrestling, football)
- limited contact/impact (e.g., baseball, basketball, bicycling, diving, high jump, pole vault, gymnastics, volleyball, skiing)
- noncontact; divided into:
  - 1.** strenuous (e.g., aerobic dancing, crew, fencing, running, swimming, tennis, track, discus, javelin, shot put, weight lifting)
  - 2.** moderately strenuous (e.g., badminton, curling, table tennis)
  - 3.** nonstrenuous (e.g., archery, golf, riflery)

A full list of conditions or disorders is then matched with these categories with a recommendation regarding participation. Absence of a paired organ would, for example, exclude an athlete from a contact sport if the organ was a kidney, whereas it would require an eye guard if it was an eye (or functional loss of 20/400). An acute illness with a fever greater than 38.3°C (101°F), a pulse greater than 100, or severe or uncontrolled hypertension may prevent participation in all sporting activities until the illness resolves or is treated. If a parent (or coach) has a concern about the recommendation, he or she should seek a second opinion with the student's personal physician.

There are no standard legal guidelines in most states. However, based on a screening for serious problems and those problems that may increase the chance of injury for a specific sports profile, recommendations should be made. Generally, there are four levels of recommendations:

- 1. unrestricted and unconditional.** This level of approval includes all sports regardless of level of exertion or degree of contact/collision.
- 2. approval with restrictions, or pass with conditions or reservations.** This level of approval allows recommendations with regard to referral for medical evaluation of suspected conditions, restrictions with regard to the level of activity or type of activity (i.e., contact/collision), recommendations for strengthening/stretching, or requirements for protective gear not usually required in a sport.

3. *fail with reservations or conditions.* This designation allows restriction from participation in some sports; however, it may allow participation in others (e.g., collision vs no collision). It would also allow medical consultation to determine whether the failure can be reversed by meeting certain criteria (e.g., diabetic patient is under control, asthmatic is properly medicated).
4. *fail.* No participation in any sport under any conditions.

Obviously, some of the concerns and restrictions may be transient when the underlying concern is self-resolving or treatable. Exclusion from sports based on the preparticipation physical is extremely rare. Studies have shown a rate between 0.3% and 1.3%.<sup>55</sup>

## A Region-Based Approach to Complaints and Concerns of Patient/Parent

The young patient has the potential of presenting with complaints that reflect an underlying disorder seen at any age or disorders that are age-specific. The following section discusses the differential approach to the young patient based on regional concerns. These concerns generally will fall into two categories: (1) pain, and (2) deformity or asymmetry.

Each section approaches the patient based on region and type of complaint or concern and differentiates based on type of onset—traumatic versus nontraumatic, overuse, and insidious. Although most of the conditions are covered in more detail in other areas of this text, a brief overview is presented here with reference to the appropriate chapter. For those conditions that are not covered in other areas of this text, a more detailed description is given. Accompanying tables summarize the salient differential features of disorders that are region-related (see [Table 53-8](#)).

The approach to musculoskeletal complaints in the young patient must include a focus on specific developmental issues (see [Table 53-11](#)).

**Table 53-11** Selected Disorders and Anomalies of the Spine

Regional Disorder or Anomaly	Diagnostic Features and Considerations
<b>Arnold-Chiari</b>	These malformations are characterized by elongation of the brainstem and/or protrusion of the cerebellar tonsils below the foramen magnum. Type I cases usually present later in life with mild hydrocephalus and possible syringomyelia. Headache and cervical spine pain may be the only symptoms. An atypical scoliosis pattern may develop with a left-sided thoracic, right-sided lumbar curve. Type II cases are more severe and appear during infancy with breathing and feeding problems most common. Hydrocephalus is more evident. Other concerns are dorsal kinking of the medulla and spinal problems such as spina bifida and meningocele. Posterior fossa and upper cervical decompression along with shunting if a syrinx is present are the standard approach.
<b>Syringomyelia</b>	A congenital or developmental dilation of the central canal of the spinal cord. When acquired it may be secondary to trauma or an intramedullary tumor. Often associated with Arnold-Chiari malformation and an atypical double

	major scoliosis (left thoracic/right lumbar). Symptoms and signs include loss of pain and temperature sense in a shawl-like distribution over the upper trunk and arms. This may lead to painless injury visible superficially at the skin. Atrophy and areflexia may be present. Magnetic resonance imaging will demonstrate the level and extent of the syrinx and whether there is associated Arnold-Chiari malformation. Treatment is to shunt fluid into the peritoneum and decompress the area such as with laminectomy of the cervical spine.
<b>Klippel-Feil syndrome</b>	A spectrum of disorders characterized by various congenital osseous abnormalities of the cervical spine. Primarily the upper cervical spine is affected with blocked vertebrae, occipitalization of C1 and platybasia, and odontoid abnormalities. Classically, the patient has a short neck, low posterior hairline, and limitations of lateral bending and rotation of the cervical spine. However, these occur in only about half of patients. Congenital scoliosis, Sprengel's deformity, hearing problems, and congenital heart disease occur in half of patients. It is also possible that renal agenesis or other renal abnormalities may be present. Patients may be asymptomatic or complain of neck pain. Radiographs should include the cervical, thoracic, and lumbar spines and audiologic testing is recommended. If there is instability of the upper cervical spine or platybasia, neurologic evaluation is necessary and caution with sports and obviously cervical adjusting is recommended. It is recommended that yearly neurologic examination and flexion/extension views of the cervical spine be performed in high-risk patients. In others, these exams should occur every 3 years.
<b>Juvenile rheumatoid arthritis (RA)</b>	Onset of RA in childhood occurs at two times, between the ages of 2 and 5 years and again at ages 9 to 12 years. There is a 2:1 ratio of male to female. Unlike the adult form, systemic signs are common including high fever, rash, uveitis, and possible pericarditis. When an acute attack occurs it is referred to as Still's disease. Unfortunately, rheumatoid factor is usually negative, and the acute onset of symptoms seems flu-like except for the fever pattern of spiking once or twice daily to 39.4°C (103°F) or 40°C (104°F) combined with a migratory maculopapular rash that is generally nonpruritic. The diagnosis is more assured with at least 6 weeks of joint swelling in a characteristic joint such as the knee, ankle, or wrist, although other causes such as Lyme disease must be considered. Concerns include the involvement of type II or pauciarticular RA where involvement of the SI joint or lumbar/thoracic vertebrae is typical. This may represent a precursor to ankylosing spondylitis. The polyarticular type involves joints symmetrically with the hip, knee, ankle, elbow, and small joints most commonly affected. The temporomandibular joint is also affected. There is always a concern of atlantoaxial instability. Flexion/extension views of the cervical spine are required prior to adjusting.
<b>Odontoid anomalies Agenesis/hypoplasia Os odontoideum Os terminale</b>	These anomalies are more frequent with disorders such as Klippel-Feil, Down's, and Morquio's. The odontoid process may be absent (agenesis) or hypoplastic. Instability may be present, requiring flexion/extension views and orthopaedic/neurologic consult if found. Os odontoideum is possibly due to traumatic interruption of growth and may represent an ununited fracture or nonunion of the dens at the neurocentral synchondrosis. Although the transverse ligament is usually intact, it is important to check for spinal cord signs and to radiographically evaluate for instability. Os terminale is failure of the tip of the dens to completely ossify. Ossification generally should occur by age 12 years. There seems to be little clinical relevance to this finding.
<b>Congenital torticollis (wryneck)</b>	May be apparent at birth or within a few weeks. Usually due to fibrous contracture and/or hematoma of the sternocleidomastoid (SCM). A mass may be palpable. May be associated with congenital hip dysplasia or spinal developmental disorders. It must be differentiated from other causes usually evident radiographically. This condition usually self-resolves. Mild stretching may aid in resolution.

## Spine

- Congenital anomalies may represent, in some cases, a source of a patient's complaint or a caution flag for modification of adjusting procedures.

- Rheumatoid, hyperelasticity conditions (e.g., Marfan's syndrome, Ehlers-Danlos syndrome) or abnormal chromosome conditions (e.g., Down's syndrome, Turner's syndrome) may cause laxity, in particular in the cervical spine.
- Developmental disorders of vertebrae may be the cause of blocked motion (e.g., blocked vertebrae, Klippel-Feil syndrome) or curvature of the spine (e.g., hemivertebrae, unilateral bar vertebrae, butterfly vertebrae).
- Developmental disorders may cause spinal cord or nerve compression (e.g., spinal cord/brainstem—Arnold-Chiara syndrome, syringomyelia [not technically compression], spondylolisthesis).

## Extremities

- Muscle/tendon tightness occurs during growth spurts due to disproportionately more bone growth, which may predispose the young athlete to overuse injury.
- With trauma, the “weak” points are tendon and ligament attachment to bone (e.g., apophyseal injury) and epiphyseal injury. Given the same mechanism of injury in a child compared with an adult, the child will likely injure the ligament/tendon attachment and growth plate, whereas the adult will likely sustain a soft tissue injury such as a mid-substance ligament tear.
- Secondary centers of ossification (e.g., bipartite patellae) and accessory bones (e.g., os talotibiale) may be misdiagnosed radiographically as the cause of an extremity complaint if the doctor is unaware of these normal variants and age-related issues; trauma or repetitive stresses to these anomalies may cause irritation and pain.
- Fractures heal more quickly in young patients than in adults.
- Developmental changes in the angulation of the lower extremity are age-related and may not represent pathology, especially when bilateral; most resolve over time.
- Asymmetric angulation of the hip, knee, or foot/ankle often represents a disturbance in growth (e.g., Blount's disease), lack of differentiation (e.g., tarsal coalition), or hereditary predisposition.
- Certain tumors are more likely in the young versus the older patient (see [Tables 53-5](#) and [53-6](#)).

## Neck

In addition to the information presented here, the reader is referred to [Chapter 2](#).

## Pain

Neck pain is a relatively uncommon complaint as an isolated regional presentation. Acute onset of pain with trauma warrants radiographic evaluation first. Nontraumatic acute pain should be cross-checked against systemic and neurologic signs. Neck pain with extreme limitation in motion and associated fever should be evaluated with Kernig's and Brudzinski's tests to determine if meningeal irritation causes a flexion reaction in the extremities. If present, it is often due to septic meningitis. Referral for medical management is required. Neck pain associated with cranial nerve dysfunction or signs of upper motor neuron lesion should result in referral to a neurologist. Lateral

flexion injuries often result in a “burner” or “stinger” seen commonly in sports. Radiographic evaluation of these patients is recommended to both determine the approximate size of the spinal canal and determine if any instability is present. If instability or a very small canal is present, it is prudent to consider restrictions in sports (e.g., football) where head and neck trauma is common.

## Deformity

- *Torticollis*. Parental concern over a fixed head tilt in their infant or child is not uncommon. In infancy, the most common cause of torticollis (wryneck) is a contracture of the sternocleidomastoid (SCM) muscle, presumably due to a breech delivery or other birth trauma resulting in a hematoma or fibrous mass in the SCM. Plagiocephaly, which is common with this type of torticollis, is visually seen as a flattening of the malar prominence and occiput opposite the side of head tilt. Ninety percent of these cases resolve spontaneously. There is debate as to whether gentle stretching accelerates this resolution.<sup>56</sup> If unresolved, it is recommended that if surgery to release the SCM is considered, it should be delayed for at least one to two years. Also, it is important to refer for an ultrasound or radiograph of the pelvis (after the child is 10 weeks old) to determine whether there is an associated hip dysplasia. In the differential list of possibilities, it is important to rule out other possible causes including infection and spinal cord tumor prior to diagnosing the benign form. In older children, torticollis may be acute following no specific event, minimal trauma, or a respiratory infection. The muscle spasm may be secondary to lymphadenitis or subluxation. Spontaneous resolution is generally in a day or two. Adjusting the cervical spine may decrease any associated pain and may resolve the problem earlier although there are no studies comparing natural history and treatment results. Chronic torticollis in an older child is often due to contracture in both heads of the SCM muscle. If due to muscle spasm, gentle stretching and adjusting the cervical spine may be of benefit. Failure to respond likely indicates the rare, fixed type requiring surgical release.
- *Short Neck*. It is unusual to have a parental complaint of the appearance of a short neck in their child without accompanying concerns. When a short neck is the only concern, evaluation for Klippel-Feil syndrome should be performed. In addition to a radiographic confirmation indicated by blocked vertebrae, occipitalization of C1, and associated odontoid anomalies, a referral to a pediatric specialist with recommendation for evaluation of renal structure with diagnostic ultrasound should be part of the overall management strategy.

## Thoracic Region

The reader should also see [Chapters 4](#) and [5](#).

## Pain

Midback pain is a common complaint with children and adolescents. Most pain described as diffuse and aching is generally a postural problem. A stooped forward posture and wearing of heavy backpacks are common causes. When associated with a

stooped posture, a search for Scheuermann's disease should be included. An acute pain that is rather localized is found with infection, tumor (usually osteoid osteoma), or trauma.

**Scoliosis** Scoliosis is discussed in detail in [Chapter 5](#). Painful scoliosis is rare in children and would dictate a radiographic search for processes such as osteoid osteoma or infection. The general approach to scoliosis is to determine if the scoliosis is present using Adam's test and lateral bending to determine if the curve corrects (functional) or does not (structural). Those patients with curves that do not improve on forward bending should be measured for rotational deformity using a scoliometer. Congenital causes include neurologic deficit disorders and congenital disorders that affect the growth of vertebrae including hemivertebrae, unilateral bar vertebrae, and butterfly vertebrae. These underdevelopments or failure of segmentation (becoming separate) may occur with a portion of or the entire segment. Radiographic discrimination is usually evident on standard radiographs; however, CT differentiation may be required. Dependent on the level, number, and degree of compensation, the prognosis varies (see [Chapter 5](#) for recommendations regarding management and referral). Radiographic evaluation of all scolioses involves a determination of the degree of severity measured by the Cobb angle (although this is a one-dimensional view of a three-dimensional problem). Generally, the initial radiographs include a full-spine evaluation.

**"Stooped Posture"** A hunched or stooped posture is often evident in the adolescent. Generally this represents a postural syndrome with varying degrees of psychologic causes including self-confidence seen most often in shy or tall individuals, or with females during breast development. The primary differential goal is to determine whether the hyperkyphosis is structural or functional. The difference clinically is to observe whether correction occurs on forward bending in the standing position or with hyperextension in the prone position. Failure to correct with hyperextension or an accentuation of the kyphosis on forward bending is indicative of a structural cause and necessitates a radiographic evaluation. The most common cause of structural kyphosis is Scheuermann's disease. The incidence is estimated at between 1% and 8%.<sup>57</sup> Although approximately 50% of adolescents will have pain initially, by the time of skeletal maturity this number has decreased to 25%. A modified Cobb angle is taken off the lateral thoracic radiograph to determine severity. Generally, most cases less than 60° do not progress, and extension exercises of the trunk combined with hamstring stretching seem to be the standard (yet unsubstantiated) approach.<sup>58</sup> For a kyphosis greater than 60°, a Milwaukee brace has been recommended with apparently good initial correction (10° to 20°); however, many studies are flawed and the success rates may be overestimated due to lack of followup to determine which curves regress when the brace is removed.<sup>57</sup> For severe curves (>80°), surgical correction has been successfully performed. It is important to note, though, that this is an expensive procedure that carries some formidable risks.

**Straight Back** Occasionally, there is a concern by the parent of a flattened appearance to the midback. This may present as a secondary effect to a severe spondylolisthesis. More often this is due to a condition referred to as "straight back syndrome" (sometimes referred to as cobbler's chest). With the thoracic kyphosis diminished, the anterior-to-posterior diameter of the chest is also decreased. Pectus excavatum is also seen with this disorder. With a narrowed chest dimension, mediastinal structures are compressed. On a posteroanterior (PA) chest view, the heart appears "pancake" shaped with a shift to the left and prominent upper left border. There may also be downward angulation of the anterior ribs. On a lateral

thoracic view, the straightly stacked thoracic vertebrae are visible with no apparent structural abnormality. Patients with this condition often have a functional murmur often due to mitral valve prolapse (MVP) syndrome. Sixty-seven percent of individuals have echocardiographic (definitive test) evidence of MVP syndrome (see [Chapter 39](#)). Straight back syndrome may be inherited as an autosomal-dominant condition.<sup>59</sup>

## Low Back/Pelvis

The reader should also see [Chapter 6](#).

## Pain

It appears that although as many as 36% of adolescents will have had low back pain by age 15 years, only about 2% will seek treatment.<sup>60</sup> A 25-year prospective study followed 14-year-old adolescents to age 39 years and found that those with low back pain at age 14 years were significantly more likely to have low back pain as an adult.<sup>61</sup> Although 36% of individuals had findings of radiographic abnormalities, these changes were not related to an increased risk of low back pain as an adult. In fact, one study<sup>62</sup> indicated that about 26% of asymptomatic individuals at age 18 years had signs of degenerated discs and 16% had signs of disc protrusion. Radiographic findings and evidence of disc protrusion are higher in symptomatic individuals, yet do not seem to be a reliable diagnostic indicator of cause given the high incidence in the asymptomatic population.<sup>63</sup>

Although the most frequent causes of persistent low back pain are either postural, sprain/strain, or spondylolisthesis, less frequent, but certainly more serious, causes can include tumor and infection. In children it is more common to develop an infective discitis than in adults. This infection is often self-resolving. In fact, the diagnosis is often made late in the course due to nonspecific clinical indicators. With infants, children, and adolescents, a fever may be present, yet the child may simply complain of a stiff back and try to remain relatively still. With infants or children, they may be reluctant to bear weight and walk due to the jarring effect on the spine. Adolescents are more likely to report a poorly localized pain. Radiographically, findings may be delayed. These findings may include narrowing of the disc space to the point of fusion. End-plate irregularities are common. If discovered at an earlier stage, antibiotic treatment (usually for staphylococcal infection) is recommended in an attempt to prevent these residual destructive changes. Spondylolysis occurs in approximately 6% of the population.<sup>64</sup> It may be due to repetitive microtrauma such as hyperextension. Spondylolysis is more common in female gymnasts, college football linemen, weight lift ers, and rowers. Spondylolisthesis in adolescents is generally the dysplastic or isthmic type. Oblique lumbar radiographs will demonstrate a pars defect. Standing lumbosacral, lateral radiographs will indicate the degree of slippage. Generally, slippage is categorized based on grades of slippage 1 through 4 of 25%, 50%, 75%, or 100%, respectively. Single-photon emission tomography (SPECT) is often used to distinguish athletic patients who require an antilordotic brace and rest from those patients who do not have an “active” lesion.<sup>65</sup> Spondylolisthesis (also see [Chapter 9](#)) is not a common sequela to spondylolysis. There are several factors that may increase risk of slippage including the growth spurt, being female, and trauma. Recommendations for management are as follows:<sup>66</sup>

- For slippage up to 25% in asymptomatic children, observe radiographically every six months up to age 15 years and then annually up to age 18 years. This schedule is sufficient to catch any significant slippage. Slippage after adolescence is rare.
- For slippage between 26% and 50% in asymptomatic individuals, the above approach is reasonable with the addition of caution and perhaps the recommendation to avoid contact sports and hyperextension sports (such as gymnastics) if possible.
- For symptomatic cases less than 50% slippage, follow up with radiographs as indicated above, perform spinal and pelvic adjusting, recommend strengthening exercises for the abdominals and stretching of the paraspinals and hamstrings, and consider bracing. Lumbopelvic manipulation is considered safe in the up-to-25%-slip group. Modification of adjusting procedures may be required including anterior drop maneuvers for those with slips greater than 25%.
- For slippage greater than 50% in a growing child or in patients who have persistent pain with lesser slippage, surgery should be considered. In situ posterolateral fusion is the recommended surgery for those cases of intractable pain and slips under 50%. Past 50%, anterior and posterior fusion with cast immobilization and instrumentation are sometimes required.

## Hyperlordosis

### A hyperlordotic posture may:

- Be visually confused with prominent buttocks.
- Occur as a result of pathology in the lumbosacral area such as spondylolisthesis.
- Be due to a hip flexion contracture.
- Be compensatory to a hyperkyphosis in the thoracic region.

The diagnostic approach is to determine if the hyperlordosis decreases with forward bending. If persistent with forward bending, a fixed deformity seems likely. If a hip flexion contracture is the cause, the hyperlordosis will decrease when the child is sitting. Also, determine if a flexion contracture exists by performing the Thomas test (see [Chapter 11](#)). Radiographic evaluation will determine if there is a structural cause. In most cases this would be represented by some degree of spondylolisthesis. Myofascial stretching of hip flexors, strengthening of the abdominals, stretching of the paraspinal muscles, and possibly adjusting of the anterior superior (AS) iliums will be effective only if the hyperkyphosis is functional. Fixed deformities usually indicate a cause that requires surgical correction.

### Shoulder/Acromioclavicular Joint

The reader should also see [Chapter 7](#).

## Pain

Nontraumatic pain at the shoulder is an unusual complaint by children. Adolescents may complain of pain secondary to overuse as the level and intensity of sports involvement increase. Due to the relative looseness of the shoulder capsule, it is not

uncommon to have overstrain of the rotator cuff muscles acting as secondary stabilizers. Caution should be recommended with overstretching in sports such as swimming. Also, some children can spontaneously dislocate their shoulders posteriorly and may feel this “party trick” is benign. It is important to discourage this activity due to chronic and permanent stretching of the shoulder capsule. Persistent or acute-onset pain in the shoulder due to throwing activities warrants a radiographic evaluation to determine involvement of the proximal epiphysis of the humerus or, in acute scenarios, the possibility of pathologic fracture through a tumor or bone defect (i.e., unicameral bone cyst). Also, persistence of various secondary growth centers may cause pain due to sprain of the fibrous connections, avulsions of these centers, or secondary impingement of other structures. Persistent pain at the shoulder unrelated to activity and present at night warrants a radiographic evaluation for possible tumor.

Traumatic pain at the shoulder may be the result of falls or blows. The differential list is similar to that in adults, yet fracture is more common in the growing child, in particular, mid and distal clavicular fractures in place of acromioclavicular (AC) separation.

## Deformity and Masses

Deformity at the shoulder may be localized or generalized. Generalized deformity having to do with carriage and shape or size is often either congenital or associated with nerve damage. Examples of congenital deformity may include Sprengel’s deformity (congenital elevation of the scapula), varying degrees of underdevelopment of the limb, or absence of muscle (i.e., Poland’s syndrome—unilateral absence of the pectoralis muscle). Upper brachial plexus damage may result in Erb’s palsy with adduction, internal rotation, and pronation of the arm (waiter’s tip) deformity. Lower brachial plexus damage may result in Klumpke’s palsy with hand paralysis and hyperextension of the metacarpophalangeal joints and wrist flexion (no sensory loss). Localized masses may be due to osteochondromas (see [Table 53-8](#)) or at the clavicle due to pseudarthrosis.

<b>Elbow/Forearm</b>
----------------------

The reader should also see [Chapter 8](#).

## Pain

Nontraumatic pain at the elbow is also an unusual presentation. Nontraumatic osteochondroses such as Panner’s disease of the capitellum may spontaneously occur in later childhood and must be considered (see [Table 53-10](#)). Overuse in sports is the most common scenario, especially with baseball and gymnastics. Constant medial stress or lateral compression at the elbow may result in varying degrees of soft tissue and bony consequences. Generically called Little League elbow, this spectrum of changes may affect either epiphyseal or apophyseal centers about the elbow (see [Table 53-10](#)). Evaluation for traumatic causes of pain unassociated with obvious deformity is based on mechanism and location of pain. A medically subluxated radial head causes lateral elbow pain following a traction stress such as being lift ed by the

arms or dragged by the arm. Falls onto an outstretched hand may result in a variety of fractures or dislocations that may not be visually apparent (see [Table 9-1](#)).

**Deformity and Masses** Deformity may be congenital with the same possibilities as outlined in the shoulder section. In addition, an increased carrying angle, hyperextension angle, or flexion contracture may be the sequelae to a fracture or dislocation (i.e., supracondylar fractures may result in all of the above). Hyperextension may also be the result of a connective tissue disorder; however, this hypermobility will be evident at the wrists and knees also. Caution must be used in jumping to the conclusion of a connective tissue problem due to the normal hypermobility of many young people's joints. It is clear that there is a statistically significant increase in the number of distal forearm fractures in both children and adolescents.<sup>67</sup>

There is still some debate regarding the primary reasons for this: one being a changing pattern of physical activity and the other being decreased bone density due to a decrease in calcium intake. The theory is that there is a transient increase in cortical porosity due to increased bone turnover, possibly resulting from an increase in calcium demand during longitudinal bone growth spurts.

Deformity secondary to trauma is almost always an indicator of fracture and/or dislocation. It is important to consider supracondylar fractures when a deformity following hyperextension occurs. Supracondylar fractures are more often the cause of residual deformity at the elbow and forearm due to neurovascular involvement such as Volkmann's contracture of the forearm.

## Wrist/Hand

The reader should also see [Chapters 9](#) and [10](#).

## Pain

Nontraumatic pain in the hand or wrist is unusual. A forgotten fall on an outstretched hand may eventually reveal the source of the problem. Traumatic causes include occult fracture without deformity (i.e., torus fracture) and dislocation. It is always prudent to check the proximal radius and ulna for associated fracture/dislocation. Soft tissue concerns from overuse are uncommon with the exception of gymnasts. Various types of capsular and osseous reactions may occur in the gymnast due to the repetitive compressive and distractive forces applied to the wrist. Epiphyseal damage should always be considered with a single traumatic event such as a fall on an outstretched hand or a history of repetitive trauma from weight-bearing forces such as handstands. Varying degrees of carpal dissociation must be considered with single-event traumas (see [Chapter 9](#)).

**Deformity and Masses** Congenital deformity may result from brachial plexus damage (as mentioned under the shoulder section), developmental defects such as syndactyly (abnormal connections between digits), polydactyly (extra digits), bent fingers (camptodactyly, clinodactyly, or delta phalanx), macrodactyly (i.e., overgrowth of digits), radial club hand (absence of radius or associated musculature), or Madelung's deformity (radial epiphyseal defect). Various chromosomal and metabolic disorders may result in a variety of changes in the shape of the hand or its creases. Traumatic considerations include the deformity or mass associated with fracture, healing from a fracture, or results of an unattended dislocation or fracture of a finger. Rotation deformities of the fingers (evident with flexion of fingers to the palm) are

often the residual of a failure to address a metacarpal fracture. A bony mass subsequent to wrist trauma may indicate lunate dislocation and associated scapulolunate dissociation. Small painful nodules at the dorsum of the wrist often represent ganglion cysts that are the result of repetitive microtrauma. Deformity may rarely be associated with tumors such as enchondromas.

## General Lower Extremity Overview

### Torsion

Developmental twisting of the tibia or femur is referred to as *torsion*. *Version* indicates forward or backward projection of a bony landmark from the coronal plane. Specifically, *tibial version* is the angular difference between the axis of the knee and transmalleolar axis. *Femoral version* is the angular difference between the transcervical and transcondylar axes. *Anteversion* is associated with internal femoral torsion, and *retroversion* is associated with external femoral torsion. The consequence of version is often compensatory, involving a toeing in or out or bowing in or out of the knee. It is important to note that version often represents developmental change that is normal (**Figure 53-2**). For example, femoral anteversion is normal in the adult progressing from about 30° at birth to about 10° as an adult. Lateral tibial torsion progresses from about 5° at birth to an average of about 15° as an adult. There are also familial tendencies to increases in torsion, and it is suggested that evaluating the parents is an important diagnostic and prognostic tool. When there is concern, the following approach will help in identifying serious causes of abnormal torsion:

- Screen for possible congenital or early acquired disorders such as cerebral palsy, hip dysplasia, achondroplasia, etc.
- Check the foot for abnormalities that commonly self-resolve such as metatarsus adductus (inward curved forefoot), pes planus, etc.
- Check hip range of motion and follow with Craig's test for a check of anteversion/retroversion of the femur.
- Check internal/external (medial/lateral) tibial torsion by first noting the position of the feet in a seated position (outward rotation of the dependent ankle may suggest lateral tibial torsion; a turned-in ankle may represent internal tibial torsion) and measuring the angle at the malleoli (usually the lateral malleolus is 15° [range of 13° to 18° in adults, less in children] behind the medial malleolus using the coronal plane as the reference point; greater than 30° may indicate external tibial torsion; less than 15° may represent internal tibial torsion).
- Observe the walking child and estimate the angle between a straight line of progression and the angle of the feet to that angle (foot progression angle). Greater than 15° in-toeing indicates a more severe problem and should be referred for orthopaedic consult, especially if unilateral.

Many orthopaedic appliances can be prescribed to correct version. It is important to note that most bilateral and some unilateral problems correct over time with no intervention. There are numerous studies showing no long-term difference in outcome with most patients.<sup>68,69</sup>

### Leg Length Inequality

Leg length inequality may be clinically silent, evident as a limp, or suggested by scoliosis. The key in evaluation is to consider significant causes that might require medical intervention versus functional causes that either self-resolve or may be managed conservatively through treatment or orthotics. Evaluation should always include an observation of gait. Orthopaedic tests to determine a possible anatomic short or long leg include:

**Figure 53-2** Physiologic evolution of lower limb alignment at various ages in infancy and childhood.

- Ali's test is performed with the patient supine and the legs and hips flexed. A long tibia is evident by a higher patella. A longer femur is evident laterally by a tibial tuberosity forward of the opposite leg. It is important to consider that the abnormal leg may be the long leg or the short leg. With hemihypertrophy it is important to consider an association with Wilms' tumor warranting an abdominal ultrasound evaluation. Also a lengthening occurs in the active phase of osteomyelitis of the femur. The majority of growth in the lower extremity occurs at the distal end of the femur.
- Tape measure assessment of true and anatomic leg length is performed using the medial malleoli and ASIS as the fixed points and the umbilicus as the functional comparison mark. A discrepancy evident with ASIS to malleoli comparison is indicative of an anatomic deficiency that warrants a radiographic evaluation.
- Orthodiagrams (orthoroentgenograms) are radiographs that include three exposures using a full spine film. Divided into thirds, the top third includes the femoral heads, the middle third the knees, and the bottom third the ankle joint. Differences can then be determined and a site of inequality determined. For infants who can neither stand nor be immobile, a teleroentgenogram is used as a screen for radiographic apparent causes such as hip dysplasia. Large discrepancies should be referred for orthopaedic consult.

General orthopaedic rules of management are:<sup>70</sup>

- Calculation of projected height is made using one of several methods including the arithmetic, growth remaining, or straight-line graph method.
- Discrepancy at maturation may also be used in estimating corrective procedures.
- If the projected difference is large or would adversely affect total height, various procedures are considered including epiphysiodesis, bone shortening, or limb lengthening. The choice is based on whether the abnormal leg is short or long

and the bone age of the individual coupled with growth spurt occurrence or projection.

### **Hip/Groin**

The reader should also see [Chapter 11](#).

## **Limp**

The limping child may potentially have a problem anywhere from the pelvis to the foot. The type of limp and the history should first indicate whether it is due to pain or compensatory for a biomechanical deficiency. Painful limping is then pursued based on which is the painful joint. Pain at the hip may represent a myriad of problems that are to some degree age-specific. Considerations include stress fracture (history of repetitive weight-bearing activity), Legg-Calvé-Perthes disease, slipped capital epiphysis, transient synovitis, and infection, among others. Radiographic discrimination is often possible and must include lateral views. One recent study<sup>71</sup> indicated that the primary diagnosis in the emergency department was “irritable hip”/transient synovitis. Only 2% represented Legg-Calvé-Perthes disease. In another study,<sup>72</sup> predictors for the possibility of septic (versus aseptic [transient] synovitis) were identified:

- fever/chills
- inability to bear weight
- an elevated erythrocyte sedimentation rate (ESR)
- leukocytosis ( $>12,000$  cells/mm<sup>3</sup>)

Patients with three or four predictors were good candidates for aspiration; those with two predictors had an intermediate risk and may be candidates; those with no predictors were considered low-risk and not in need of aspiration. Biomechanical compensation may be due to an angulation abnormality of the femoral head/neck, femoral torsion problem, or muscle weakness pattern.

## **Deformity**

Femoral anteversion (medial torsion) is a common cause of in-toeing in children older than 3 years. This inward twisting of the femur usually resolves between the ages of 10 and 12 years. Children with excessive anteversion may exhibit an “eggbeater” pattern when running with legs flailing outward during the swing phase. During resolution, signs and symptoms of patellofemoral tracking problems may be found due to a possible increase in the quadriceps (Q) angle increasing medial stress to the knee and lateral tracking of the patella. Femoral anteversion or retroversion is evaluated using Craig’s test (see [Chapter 11](#)).

## **Knee**

The reader should also see [Chapter 12](#).

# Pain

In children, pain at the knee may represent a referral phenomenon from the hip. Always evaluate possible hip pathology as a source. Nontraumatic pain at the knee should always raise the suspicion of infection or tumor especially if accompanied by systemic or “red flag” indicators such as fever, swelling, or night pain. Other causes of nontraumatic pain, but associated more often with snapping or clunking at the knee, are a plica (see [Table 53-10](#) and [Chapter 12](#)) and discoid lateral meniscus, respectively.

Overuse pain is first approached by location. It is not uncommon to have pain and swelling at the tibial tuberosity (Osgood-Schlatter disease) or lower patella (Sinding-Larsen) indicating an apophysitis (especially with a history of running or jumping). Pain at the proximal or middle tibia warrants an investigation into possible stress fracture (especially with runners). With children, pain at the medial joint line more often indicates a medial collateral ligament sprain rather than a meniscal lesion.

Traumatic causes of knee pain are similar to the adult with the following age-specific, radiographic-evident exceptions:

- patella: bipartite patella irritation
- medial knee: epiphyseal injury (especially with any valgus or rotational mechanism of injury)
- anterior knee: tibial spine fractures and tibial plateau avulsions (anterior cruciate ligament [ACL] injury in children)

Rarely, pathologic fracture may occur through a large fibrocortical defect or undetected tumor secondary to trauma.

## Deformity and Masses

- *Tibial Bowing*: Lateral bowing is a normal variant in infants and often resolves spontaneously. Anterior bowing may be associated with fibular hemimelia (absence) and requires radiographic confirmation. Posteromedial bowing is often associated with calcaneal deformity and often resolves with a residual of midlimb shortening. Anterolateral bowing is serious and requires orthopaedic referral. It may progress to fracture with a complication of pseudarthrosis of the tibia with nonunion. If attempts at union fail, amputation is unfortunately necessary.<sup>73</sup> Parental concern over a knock-kneed or bow-legged appearance in their child is common. General rules of thumb include:
  1. There are familial tendencies toward a more knock-kneed or bow-legged appearance. Always check the parents.
  2. There are developmental changes that emphasize different angulations with different ages. For example, when learning to walk through the second year, a bow-legged appearance is normal (especially if bilateral). During the third and fourth years, a knock-kneed appearance is often a normal developmental variation with a wide range of severity (see [Figure 53-2](#)).
  3. Bilateral appearance suggests a physiologic cause that resolves the vast majority of time, whereas unilateral deformity raises the suspicion of a pathologic cause. A full lower extremity evaluation should occur including an

evaluation of femoral torsion, tibial torsion, foot deformity, and leg length differences. Radiographic evaluation should include weight-bearing views.

4. Local deformity is often physiologic, whereas, when generalized throughout the lower limb, it suggests a more serious cause and warrants an investigation of metabolic problems. The evaluation, in addition to a full physical examination, should include a laboratory evaluation of calcium, phosphorus, creatine, alkaline phosphatase, and hematocrit.
- *Genu Varus* (bow-legged): The fetal position in utero often involves flexion of the lower extremity with internal rotation of the knee and foot. Contractures of the medial capsule of the knee (especially the posterior oblique fibers) may persist, causing a restriction that is compensated by external rotation of the femur when walking. If persistent past 6 months of walking, stretching at each diaper change may help. This involves gradually stretching the tibia into external rotation with the knee flexed to 90°. Rarely, a varus deformity is due to either Blount's disease (see [Table 53-10](#)) or epiphyseal damage secondary to trauma. This would, of course, be unilateral in most cases.
- *Genu Valgus* (knock-kneed): It is a physiologic condition in most cases, seen primarily in children age 3 to 8 years, especially when seen bilaterally. Unilateral valgus appearance warrants a weight-bearing radiographic search for rare causes including posttraumatic genu valgum secondary to overgrowth following proximal tibial metaphyseal fracture. Also, malunion or soft tissue interposition may be the cause.
- *Genu Recurvatum*: Hyperextension at the knees is often a normal variant, especially in females. However, connective tissue disorders such as Marfan's or Ehlers-Danlos syndrome (see [Table 53-10](#)) may cause hyperelasticity manifested as hyperextension at the knees. A check of elbows and wrists may suggest a further search is necessary. Hyperextension predisposes the individual to patellar malalignment and subluxation/dislocation.

Bulging or masses at the joint line may represent meniscal cysts (seen more commonly in adults). These cysts usually represent an outward sign of meniscal damage. Anterior swelling at the tibial tuberosity is usually Osgood-Schlatter disease. Localized masses at the medial proximal tibia or at the patella usually represent localized bursitis. A posterior-medial mass is usually a popliteal (Baker's) cyst. This represents a lesion of the synovial sheath in children and is not as commonly associated with intra-articular disorders as in the adult (e.g., rheumatoid arthritis or infection). In children, these popliteal cysts are smooth, fixed, and transilluminate. They usually resolve over a year or two and, unless large or painful, do not require excision. A posterior-medial mass above the joint line may represent a fascial herniation of the semimembranosus muscle. This is apparent with contraction. Osteochondromas may be large enough to be seen at the knee (see [Table 53-8](#)). Differentiation is made radiographically. Ganglion cysts around the knee are also possible.

## Lower Leg

The reader should also see [Chapter 13](#).

## Growing Pains

Although the exact cause of “growing pains” is unknown, it is recognized as a diagnostic entity. Growing pains

- are characterized by intermittent, bilateral pain, usually in the lower legs
- occur at night and are severe enough to awaken the child
- usually are asymptomatic during the day with no swelling, tenderness, or stiffness reported
- are associated with complaints of headache and stomach ache

The incidence is approximately 15% in children between the ages of 6 and 19 years, with a bimodal distribution peaking first at ages 3 through 9 years and again at adolescence.<sup>74</sup> Although it might be assumed that these pains would be associated with growth spurts or gains in the child’s weight, there are no clear direct indicators of a relationship between height, weight, or rate of growth. Although the list of differential diagnostic causes is quite long and often contains serious conditions, the process of elimination is begun with a careful history. Bilateral pain unrelated to activity level and unassociated with systemic indicators such as fever or fatigue is likely benign and often represents “growing pains.” Unilateral pain that is associated with systemic signs or associated with activity warrants a careful palpatory examination followed by a radiographic search for infection, tumor, or other potential causes. A screening lab test including a complete blood cell (CBC) and ESR will usually screen out serious causes. If radiographic and laboratory screens are negative, growing pains are not likely due to a serious cause.

## Deformity

- *Internal tibial torsion*: An inward twisting of the tibia results in compensatory changes in walking. Although visually the patella faces forward, the foot is turned inward. It is apparent clinically by noting the lateral malleolus is in line or anterior to the medial malleolus. Spontaneous resolution is common. Prior to resolution, malalignment at the knee may result in patellofemoral tracking signs/symptoms.
- *External tibial torsion*: Visually the patella faces forward; however, the foot is turned outward. When the angle between the malleoli is measured, it is greater than 25°. External (lateral) tibial torsion may be progressive due to the natural developmental increase in lateral rotation. Combined with femoral anteversion, there may be an associated knee pain due to patellofemoral tracking abnormalities.

<b>Ankle/Foot</b>
-------------------

The reader should also see [Chapter 14](#).

## Pain

Although pain in the foot or ankle may be the result of sprain, strain, or other forms of trauma, there are some age-related considerations to add to the list of possibilities. These include the following:

- Osteochondritis. Pain secondary to avascular necrosis may occur in the navicular (Kohler's disease) or metatarsal head (Freiberg's disease). Both conditions are rarely treated surgically. Radiographic demonstration of increased radiopacity or increased uptake on bone scan may be found. Symptomatic treatment with orthotic support and protection of the involved bone is usually the only treatment needed.
- Syndesmosis sprains or fractures. Persistence of accessory ossicles (secondary centers of ossification that remain ununited) may cause pain in children or adolescents. Sprain or total disruption of the fibrous or cartilaginous connection between the two fragments may occur. It is important, though, not to assign a diagnosis simply based on the finding of an accessory ossicle. Pain localized to the site combined with an appropriate mechanism of injury is needed to raise the suspicion of syndesmosis sprain or rupture. Rest, immobilization, and support will assist in healing. One of the most common accessory bones in the foot is an accessory navicular found in about 2% of the population as a nonunion into adulthood. Late childhood or adolescence is a common time for this to become symptomatic. Immobilization with a soft cast for a limited period of time usually allows healing. Another common location is inferior to the lateral malleolus, which must not be confused with an avulsion fracture secondary to an ankle sprain.

## Deformity

- *Flatfoot*: Although a common parental concern, flatfeet are often either part of normal development or, if persistent, an inherited tendency. This type of flatfoot is referred to as physiologic and accounts for 99% of cases.<sup>75</sup> From a developmental perspective, flatfoot is normal prior to the development of a bony support (i.e., sustentaculum tali) and with inherent pediatric ligament laxity. Even if persistent, flatfoot does not necessarily lead to symptoms, and in fact may be somewhat protective for stress fractures. A stiff flatfoot is found in only 1% of cases. Generally, when the foot is non-weight-bearing, an arch will appear in the flexible (physiologic flatfoot) whereas no arch will appear with the stiff (pathologic) form. A check of Achilles flexibility and a radiographic evaluation will help distinguish the pathologic form causes (the difference between soft tissue contracture and bony developmental problems). Specifically, when no arch appears (without weight-bearing), a search for causes includes a distinction based on the following possibilities:
  1. Flexible flatfoot (FF) with tight Achilles tendon—contracture of the heel cord may be associated with a hypermobile FF causing obligatory heel valgus
  2. Calcaneovalgus deformity—caused by a calcaneus that is in dorsiflexion due to intrauterine crowding (*Note*: associated with hip dysplasia); resolves spontaneously
  3. Vertical talus—congenital deformity where the talus is in a vertical orientation (seen on a lateral radiograph); causes not only FF but also convexity of the sole
  4. Tarsal coalition—connections between tarsal bones decreasing inversion and eversion; often familial; symptoms often appear during adolescence; either radiographs or CT scans are needed dependent on whether the connection is bony or fibrous

5. Neurogenic FF—common with spastic cerebral palsy, poliomyelitis, or myelodysplasia
- *High Arch (Cavus Foot)*: Like FF, a high-arched foot is most often a physiologic variation of normal. When not, it is most often associated with neurologic disease that results in muscular tightening including Charcot-Marie-Tooth, spinal dysraphism, or muscular dystrophy. A search using radiographs, electromyography (EMG), and nerve conduction studies or creatine phosphokinase (CPK) evaluation will help differentiate among these possibilities.

**Figure 53-3** Components of talipes equinovarus.

- *Toe Walking (Equinus Gait)*: Some children may have a tendency to toe walk constantly. Although this may represent “hysterical” manifestations, often it represents a muscular/soft tissue contracture or neurologic disorder. Children with cerebral palsy, muscular dystrophy, and uncorrected clubfeet may have this deformity. Gastrocnemius contracture is probably the most common cause. It is differentiated by a plantar-flexed foot that improves with the knee flexed (i.e., dorsiflexion of the foot increases significantly with knee flexion). Another rarer possibility is an accessory soleus. Both conditions usually require surgical lengthening and are not likely to respond to traditional stretching or physical therapy.
- *Toe-in (Pigeon-toed)*: Often this is a compensatory position when first learning to walk. Medial (internal) torsion of the tibia is the most common cause in children under age 3 years. It resolves in most cases over time. In children over age 3, femoral anteversion (medial femoral torsion) is the most common cause. Spontaneous resolution is seen usually by age 10 years.<sup>76</sup> Metatarsus adductus is a deformity due to intrauterine positioning resulting in an inward turning of the forefoot with a normal hindfoot. It can be unilateral or bilateral and spontaneously resolves in almost all cases over a year or two.
- *Toe-out*: Three causes of toe-out walking should be considered: (1) talipes equinovarus (clubfoot; **Figure 53-3**), (2) calcaneovalgus foot, and (3) pes planus (flatfeet).

Clubfoot is either congenital or teratologic (associated with spina bifida and other spinal deformities requiring surgical correction), or it can be postural (due to intrauterine position), which resolves after birth. Calcaneovalgus is due to intrauterine positioning of extreme dorsiflexion of the ankle to the tibia, which resolves after birth. For pes planus, see the discussion above or [Chapter 14](#).

## Some Childhood Diseases\*

### **Measles (Rubeola)**

#### **Classic Presentation**

The patient presents with a history of a high fever 39.4°C to 40.5°C (103°F to 105°F), runny nose, sore throat, and cough several days before the appearance of a bright red rash. The rash began on the face and behind the ears and then spread to the trunk and extremities.

#### **Cause**

Infection is by paramyxovirus acquired through inhalation of droplets. Measles is most communicable before the rash appears and is essentially noncommunicable when the rash disappears. The incubation period is 10 to 14 days. Worldwide, 1 million children per year die of measles.

#### **Evaluation**

Prior to the onset of the rash, the patient may have a pathognomonic finding of tiny white spots on the mucous membranes in the mouth; they are called Koplik's spots. The spots are still present when the rash appears. Laboratory testing is usually not necessary. A serum hemagglutination inhibition antibody level that is found to be four times normal is diagnostic for measles. Standard laboratory tests demonstrate leukopenia and possible proteinuria.

#### **Management**

Treat measles symptomatically.

### ***German Measles (Rubella)***

#### **Classic Presentation**

The patient may report having had a mild fever or malaise up to a week prior to the appearance of a light rash that appeared on the face first and then spread to the trunk and extremities. The rash faded (or is fading) quickly over one day per site.

#### **Cause**

Rubella is caused by inhalation of droplets of togavirus. The incubation period is between two and three weeks. Communicability occurs one week before the rash and continues for up to two weeks.

#### **Evaluation**

There is a characteristic cervical and postauricular lymphadenopathy in most patients. The rash does not appear in all cases and, without its appearance, the diagnosis is difficult to make unless there is a history of exposure. Laboratory testing with rubella virus hemagglutination inhibition and fluorescent antibody tests is usually not necessary except in the case of pregnancy. A pregnant female infected with rubella during the first trimester carries the risk of conveying congenital rubella 80% of the time.<sup>36</sup>

#### **Management**

Treat rubella symptomatically.

### ***Varicella (Chickenpox)***

## **Classic Presentation**

The patient presents with a history of mild malaise, anorexia, mild headache, and fever followed in 24 hours by the appearance of a pruritic, vesicular rash that began first on the trunk (and oropharynx), spread to the face, and spread less to the extremities. New vesicles are appearing as the older ones are crusting (over one to five days).

## **Cause**

Chickenpox is a highly contagious infection with human herpes virus 3 (the same organism for herpes zoster [shingles]). Infection is through either inhalation of infective particles or direct contact with lesions. The incubation period is 10 to 20 days.

### **Evaluation**

The rash is usually diagnostic. Laboratory evaluation could include a Tzanck test of vesicle scrapings for confirmation, although it is rarely necessary.

## **Management**

The patient should be isolated because of the contagious nature of the vesicles. Topical calamine lotion or over-the-counter antihistamines may help with the itching. It is important to keep the skin clean and to avoid scratching in order to prevent scarring. Children should not be given aspirin because of the possibility of acquiring Reye's syndrome.

The use of a herpes zoster (shingles) vaccine has been recently evaluated. The decrease in incidence appears to be about 50%.<sup>37,38</sup> This is particularly important for seniors who may develop a painful and disabling condition given that herpes zoster is far more common in older age groups.<sup>39,40</sup>

### ***Mumps***

## **Classic Presentation**

The patient presents with painful, swollen parotid glands. Mild malaise or fever may be present.

## **Cause**

Paramyxovirus is the cause of mumps. Inhalation of infective droplets is the mechanism. The salivary glands become inflamed. Complications such as orchitis, pancreatitis, and meningitis are more likely to occur when the patient is older. The incubation period is two to three weeks.

## **Evaluation**

The presentation of parotid gland swelling is usually quite clear, often beginning with one gland first and in one to three days the other. A headache and stiff neck suggest meningeal involvement. Abdominal pain with nausea and vomiting suggests pancreatitis. Testicular pain suggests orchitis. Lymphocytosis and an elevated serum amylase (with or without pancreatitis) are often found. The organism may be tested in saliva; if present, there is a sharp increase in complement-fixing antibodies.

## **Management**

Isolate the patient while the glands are swollen. If the patient has a fever, require bed rest because of the strong possibility of aseptic meningitis. Watch for complications.

## ***Fifth Disease (Erythema Infectiosum)***

### **Classic Presentation**

A child presents with a facial rash (“slapped cheek” appearance), but no fever. The rash is spreading to the trunk and limbs.

### **Cause**

There are generally five causes of rashes in children: rubella, measles, scarlet fever, Filatov-Dukes disease (a mild form of scarlet fever), and erythema infectiosum (Fifth disease). Fifth disease is caused by human parvovirus B19. It is spread via the respiratory route. The incubation period is 4 to 14 days. The rash is maculopapular.

### **Evaluation**

No evaluation is necessary unless accompanied by a high fever. Refer to pediatrician if a high fever is present.

### **Management**

No treatment is necessary. The typical course is a fading and intensifying of the rash from hour to hour. Fading often takes a few weeks. There are no limitations to activity for the child; however, exercise, sunlight, heat, or fever may exacerbate the rash.

## CHAPTER 54

# The Geriatric Patient

### Context

Studies suggest that the senior or geriatric patient (over age 65 years) represents approximately 12% to 17% of most chiropractic practices.<sup>1-3</sup> This percentage will likely increase given the projection that in the United States between the years 1989 and 2030 the population over age 65 years will double (12.5% to 22% of the total population).<sup>4</sup> Although currently accounting for only about 12.5% of the population, geriatric patients account for 21% of patient visits and purchase almost one-third of prescription medications.<sup>5</sup> The over-85 age group represents approximately 3 million individuals in the United States and is the fastest growing segment of the population. Currently, the average age of death is about 75 years. This may increase to 80 years by the year 2020. A 2007 survey by Wolinsky et al.<sup>6</sup> indicates that utilization by older adults in the United States for chiropractic care is only 4.6% on an annual average. Over a four-year period the percentage who had one or more visits to a chiropractor was 10.3%. Demographically, Caucasians, patients reporting pain, those who could afford care, and those who were close in vicinity to the chiropractor and who had transportation, were more likely to see a chiropractor. What this represents to the physician is a unique patient population with specific needs that must be addressed. Logically the majority of problems in the senior patient are represented by signs and symptoms that reflect the accumulation of lifelong environmental impact combined with decreased function of most organ systems. Ironically, signs and symptoms may be minimal or often minimized by the patient and may misdirect the doctor to the wrong organ system. Also, atypical presentations of common disorders are more likely in the senior.

The ultimate goal with the senior patient is to prevent or delay functional decline and restore and/or maintain function to allow as much independent living as possible. It is clear that the ability for the senior to remain independent has a significant effect on his or her perceived

quality of life.<sup>7</sup> Generally, independent living is more satisfying and less expensive than institutionalized living.

There are some myths with regard to senior citizen function and capacity. Following are some statistical corrections of these assumptions:<sup>8</sup>

- Only 5% of individuals over the age of 65 years live in nursing homes.
- Eighty-five percent of individuals between the ages of 65 and 69 years experience no difficulty in self-care activities or walking (66% of individuals between ages 80 and 84 years).<sup>9</sup>
- One-third of individuals over the age of 80 years have no difficulty walking a quarter of a mile, lifting 10 lb, or climbing 10 steps without resting.

The senior patient is often viewed with some degree of ambivalence. Often signs and symptoms are attributed to the normal aging process. It is logical that normal aging does result in some decreases in function; however, the distinction between this process and other disease processes is not always readily evident. Being cognizant of the effects of normal aging may facilitate a more focused examination allowing modification of the examiner's interpretation of "normal." Unfortunately, working off of the assumption that all decreases in function are age-related may delay intervention or allow a misdiagnosis that seriously restricts a patient's lifestyle; in turn, this may compound his or her problems.

One solution to this overgeneralization is not to look at all seniors as the same. Shepard<sup>10</sup> suggests dividing the elderly population into the following functional categories:

- Young-old: Patients who have maintained a level of fitness that allows participation in recreational and daily activity requirements.

- Middle-old: Patients who are independent with daily activities; however, they need assistance with more demanding tasks.
- Old-old: Disabled patients who require nursing care.

These three categories often correspond to the age categories of 65 to 75 years, 75 to 85 years, and older than 85 years, respectively. Generally, classifying a person as being a senior is based largely on social and political events that take place when a person reaches the age of 65 years.<sup>11</sup>

Second, it is important to understand those changes expected with aging and those that are the result of disuse or misuse (modifiable aspects). With this anticipation, the patient may also be educated as to what is normal and what is pathologic and perhaps become a more

responsible partner in his or her healthcare. An educated patient and doctor may decrease the number of unnecessary visits and therefore increase the doctor's concern when a senior does have a complaint.

In the primary care setting, the 10 most common chronic conditions in the elderly, in decreasing order of occurrence, are as follows:<sup>12</sup>

- 1.** Osteoarthritis
- 2.** Hypertension
- 3.** Hearing impairment
- 4.** Heart disease
- 5.** Orthopaedic deformity or impairment
- 6.** Chronic sinusitis
- 7.** Visual impairment
- 8.** Diabetes
- 9.** Varicose veins
- 10.** Abdominal hernia

It is striking that four out of the five top conditions are treatable and in some cases preventable. The disability represented by many of these conditions may be minimized with appropriate strategies that allow for acceptable function. Heart disease, cancer, and stroke account for 75% of deaths in the senior population.<sup>8</sup> Campbell et al.,<sup>13</sup> performing a systematic review, evaluated the effects of various dosages of aspirin to determine the most desirable dose that would have the fewest gastrointestinal (GI) complications. Long-term use of dosages greater than 75 to 81 mg/D were found not to be any more effective, but did increase the risk of GI bleeding. It is important, however, to note some oddities with regard to mortality. One is that the suicide rate in the elderly is five times the national average.<sup>7</sup> Second, the death rate from complications associated with a hip fracture is approximately 15%. Particular attention must be paid to the most common conditions seen in the elderly (see **Table 54-1**).

There are obviously numerous possible causes of morbidity and mortality in the senior. Most are addressed under the chapter associated with the related symptom or complaint. The focus of this chapter will be appropriate evaluation and screening of the senior patient, the most common diseases/disorders in this population, and the underlying physiologic and social causes of morbidity.

The doctor must always consider the following in evaluating the senior patient:

- Seniors often present atypically for a specific disease/disorder, usually due to symptoms in the most vulnerable organs rather than the organ of involvement (e.g., goiter, tremor, or exophthalmos are

less common signs of hyperthyroidism as compared with atrial fibrillation, signs of heart failure, confusion, or weakness, because the “weakest link” in the older patient is more often the brain and cardiovascular system).

- An abrupt onset of symptoms or signs will usually represent a disease rather than “normal aging.”
- Seniors are more likely to develop drug side effects and at lower doses.
- Seniors often suffer the effects of multipharmaceutical prescription.
- Seniors often develop symptoms at an earlier stage of disease due to a decreased physiologic reserve.
- Seniors have less reserve to deal with infections such as pneumonia or simple viral infections.
- Seniors are particularly vulnerable to the effects of inactivity, creating a downward spiral of disability and risk of injury mainly through falls and the continued inactivity during recovery from fractures.
- A substantial percentage of seniors are prone to depression and alcoholism.
- Seniors, in particular those being cared for, are often victims of verbal or physical abuse and/or neglect.
- Seniors who are “successful” at aging are more active physically, are involved socially, and adapt to their disabilities.

**Table 54-1** Most Common Conditions Seen in the Elderly

<b>Musculoskeletal</b>	<b>Cardiovascular/Renal</b>
<ul style="list-style-type: none"> <li>• Arthritis (osteoarthritis, rheumatoid arthritis, DISH [diffuse, idiopathic, skeletal hyperostosis], crystalline arthritides such as gout and pseudogout) • Osteoporosis (in particular in the postmenopausal female) and associated fractures</li> <li>• Paget’s disease</li> <li>• Fat pad syndrome (common cause of heel pain)</li> </ul>	<ul style="list-style-type: none"> <li>• Congestive heart failure</li> <li>• Coronary artery disease and associated angina or myocardial infarction</li> <li>• Hypertension</li> <li>• Stroke</li> <li>• Abdominal aneurysm</li> <li>• Temporal arteritis</li> <li>• Chronic renal failure</li> <li>• Incontinence (stress incontinence and detrusor instability)</li> </ul>

## General Strategy

## Evaluation

For all geriatric patients, perform a full baseline evaluation to include:

- a focused history
- an examination
- evaluation of mental function
- evaluation of socioeconomic health
- nutritional status
- risks to health including a screening for risk of falling, a thorough drug history, history of last examination for screening of senior-related disorders (e.g., colorectal cancer, breast cancer, prostate cancer, diabetes, hearing, glaucoma, cataracts) • a nonfasting total blood cholesterol, urinalysis (dipstick for hematuria, bacteriuria, and proteinuria), mammography (up to age 75 years), and thyroid function tests (in older females) in asymptomatic seniors<sup>14</sup>
- an electrocardiogram, fecal occult blood, sigmoidoscopy or colonoscopy, fasting plasma glucose or glucose tolerance test, Pap

smear (females), and tuberculin skin testing in high-risk seniors The general strategy for the symptomatic patient includes:

- Consider the most common conditions seen in the elderly.
- Consider atypical presentations of common conditions.
- Consider that the symptoms may be the result of a drug or interactions of drugs.
- Screen for cancer if complaints include weight loss, night pain, unresponsiveness to previous care, or history of cancer.
- Perform a more comprehensive evaluation than in a younger patient, taking into account that symptoms or signs are more often the consequence of deterioration or dysfunction of the brain, cardiovascular, lower urinary tract, or musculoskeletal systems.

## **Management**

### **For all geriatric patients:**

- Establish a regular routine of an annual physical examination and focused examinations based on risk factors and national guideline recommendations. Give advice with regard to the general benefits of exercise and nutrition including the potential of prolonging functional capacities.
- Provide information with regard to reducing risk of disease.
- Provide information with regard to reducing the risk of falling.
- Provide the patient contacts for a support network of individuals or agencies including mobility, social contact, and care, including referral sources to other healthcare services.

For patients with diagnosed or suspected conditions:

- Refer patients who are suspected of having drug-related symptoms or signs to their prescribing physician.
- Refer patients with suspected cancer or serious visceral condition for further evaluation by a specialist.
- Comanage patients with hypertension, obesity, and non-insulin-dependent diabetes to aid in the support network for patient compliance with diet and exercise prescriptions.
- Manage musculoskeletal complaints with an emphasis on stability, pain reduction, and maintenance of as much joint mobility as possible.

- Modify adjusting procedures based on the patient's underlying health status and bone and joint integrity (see **Table 54-2**).

## Relevant Anatomy and Physiology

### Theories of Aging

There are many theories of aging; however, they can be organized into two main groups: (1) genetically determined, and (2) accumulated damage to key cellular processes. It seems clear that there are certain cultures in which age is independent of environment and must therefore have a strong genetic component. This has also been demonstrated with simple organisms; however, the degree to which this affects humans is unknown.

Change in technique approach or modification to most of the above presentations includes:

- Specific recommendations include:
  - 1.** Flat hand contact for anterior thoracic maneuvers begun in supine position (versus seated to supine) or light-force techniques for osteoporotic patients
  - 2.** Avoidance of excessive rotational techniques for neck and low back
  - 3.** Avoidance of extreme spinal flexion positions with osteoporotic patients
  - 4.** Allow the headpiece (i.e., elevated to position the head/neck in flexion) to provide support for patient's head/neck to allow for more relaxation
  - 5.** With extremity adjusting, always provide some degree of distraction prior to thrusting and avoid thrusting into a full flexion or extension position
- Light-force technique options may be considered such as:
  - 1.** Logan basic
  - 2.** Distraction techniques (e.g., Cox traction)
  - 3.** Pelvic blocking (e.g., Sacro-occipital technique [SOT])
  - 4.** Instrumented adjusting (e.g., Activator)
- Soft-tissue approaches

There are generally two theories put forth regarding accumulated damage with aging. The first of these focuses on the damage caused by oxidative metabolism with the production of superoxide and hydroxyl free radicals (also hydrogen peroxide). The transcription of genes encoded for protective enzymes (e.g., superoxide dismutase, catalase) decreases

with age. This has led to the recommendation by some nutritionists to supplement these enzymes.

**Table 54-2** Yellow Flag Indicators of Caution with Possible Modification of Manipulative/Adjustive Procedures

<b>Caution Disorder of Indicator</b>	<b>History or Exam Indicator(s)</b>	<b>Concern</b>
<b>Osteoporosis</b>	<ul style="list-style-type: none"> <li>• Suspicion due to age or posture</li> <li>• Radiographic confirmation</li> </ul>	<ul style="list-style-type: none"> <li>• Fracture</li> </ul>

<b>Use of corticosteroids or</b>	<ul style="list-style-type: none"> <li>• Patient presentation</li> </ul>	<ul style="list-style-type: none"> <li>• Fracture</li> </ul>

<b>Cushing's disease</b>	<ul style="list-style-type: none"> <li>• Past diagnosis</li> <li>• Current history of medications</li> <li>• Radiographic indicators</li> </ul>	
<b>Use of anticoagulant medication</b>	<ul style="list-style-type: none"> <li>• Patient report</li> </ul>	<ul style="list-style-type: none"> <li>• Bleeding (e.g., subarachnoid bleeding)</li> </ul>
<b>Psychiatric disorder</b>	<ul style="list-style-type: none"> <li>• Indicators from history or questionnaire</li> <li>• Past diagnosis</li> </ul>	<ul style="list-style-type: none"> <li>• Abreactive response to manipulation</li> </ul>
<b>Previous adverse reaction to a specific therapy or therapeutic trial</b>	<ul style="list-style-type: none"> <li>• Past history from patient description</li> </ul>	<ul style="list-style-type: none"> <li>• Repeating adverse reaction</li> </ul>
<b>Acute pain presentation</b>	<ul style="list-style-type: none"> <li>• Patient presentation</li> </ul>	<ul style="list-style-type: none"> <li>• Increase in symptoms</li> </ul>

The glycation theory postulates that glucose reactions with certain proteins and nucleic acids generate glycoadducts called advanced glycosylation end-products (AGEs). Through either cross-linkage or other modifications, molecules are altered, reducing certain key physiologic functions. Prevention of AGE formation has been demonstrated to retard the aging process in animals.

It is unclear whether the above indicators of increased damage or insufficient repair are the cause or the result of aging. Many of the theories regarding the mechanisms of aging have not been supported by the literature.<sup>15</sup> These theories include:

- somatic mutation theory—aging results from cumulative spontaneous mutations

- error catastrophe theory—aging is due to errors in protein synthesis
- intrinsic mutagenesis theory—aging results from DNA “rearrangements”

### **Age-Related Physiologic Changes**

At the molecular level, aging does result in the following:

- protein deamidation, oxidation, cross-linking, and glycation increase
- DNA cross-linking
- single-strand breakage
- decrease in DNA methylation
- decrease in DNA telomeric sequences (length of telomeres)

On the macro level, there are age-related organ and system changes that must be considered when evaluating a patient’s complaint or apparent dysfunction. **Table 54-3** illustrates some of these changes and the possible clinical consequence.

Evaluation

General Examination Approach

# Comprehensive Geriatric Assessment

The approach to geriatric assessment is to gain a comprehensive appreciation of the total patient in order to establish a baseline for comparison and to avoid or prevent potential risks for disease, misdiagnosis, and functional decline.<sup>16</sup> The intention is to provide the best care and advice to an older patient in the hope of extending the quality and sometimes quantity of life. A comprehensive database is also useful in communication with the patient’s other healthcare providers.

Table 54-3 Consequences of “Normal” Aging		
Structure	Changes	Clinical Consequences
Spine		
Intervertebral disk	Dry, fibrocartilaginous, islands of hyaline cartilage, little or no proteoglycans; after age 40 years	Disk herniation not likely in the elderly

	virtually no nucleus pulposus	
Uncinate processes	Become flat, and project bone laterally and posterolaterally	Prevent disk herniation
Dural root sleeves	Become fibrotic and rigid	More prone to stretch injury
Spinal canal	Hypertrophied ligamentum flavum and osteophytes compromise canal space	Cord compression more likely than in younger patients
Zygapophyseal joints	Menisci have tendency to proliferate as a fibrous pannus	Joints less mobile
<b>Cardiovascular</b>		
Blood vessels	Some degree of atherosclerosis and thickening, which create aortic stiffening	Increase in blood pressure
Heart	Ventricular thickening in response to increased peripheral resistance, leading to LVH Decrease in pacemaker cells Decreased response to sympathetic, specifically beta-adrenergic, stimulation	Decrease in stroke volume
Baroreceptors	Decreased sensitivity	Decreased response to pressure changes
<b>Respiratory</b>		
Chest wall	Stiffening	Increases work of breathing

Lungs	Decrease in elastic tissue, destruction of alveolar septa, loss of capillaries, and calcification of bronchi	Reduction in various measures of air flow with an increase in residual volume
<b>Gastrointestinal</b>		
Esophagus	Diminished peristalsis amplitude and decreased lower sphincter tone	Slower transit time to stomach Reflux and hiatal hernia
Stomach	Decrease in acid production and hyposecretion of intrinsic factor	Digestion less effective B <sub>12</sub> deficiency more common
Small intestine	Absorption functions decreased; in particular calcium	Decrease in vitamins B <sub>12</sub> , C, and D
Liver	Slower biotransformation of lipid-soluble drugs Decrease in albumin production	Relative increase in drug bioavailability Serum concentrations of albumin decreased (liver function tests are normal)
Pancreas	Usually unimpaired	
Colon	Transit time is usually normal	Constipation is not necessarily a result of aging unless associated with diabetes or other disorders
<b>Genitourinary</b>		
Kidney	Shrinkage with loss of almost half of the glomeruli	Decreased excretion function (significant with drugs)
Bladder	Bladder capacity, bladder and urethral elasticity are reduced (combined with decrease in CNS inhibition)	Nocturia and frank incontinence increase with age

<b>Endocrine</b>		
Female	Ovarian secretion of estrogens and progestins ends	Atrophic changes in uterus, vagina, and mammary glands
Male	Increased prostatic binding of dihydrotestosterone	Prostatic hypertrophy
Blood sugar	Decreased peripheral response to insulin (pancreatic function of insulin secretion is usually normal)	Fasting blood sugar increases 5 mg/dL per decade after age 50 years (do not confuse with diabetes)
Thyroid	Thyroid function should not decline with age; however, the thyroid may migrate down toward manubrium	Thyroid function tests are normal. Palpate lower in elderly for thyroid.
<b>Musculoskeletal</b>		
Bone	After age 40 years, bone mass decreases by 5%–10% per decade (faster in women until seventh decade)	Osteopenia more likely, leading to susceptibility to compression fractures of the spine and hip fractures
Muscle	Decrease in muscle mass (increase in fat)	Gradually declining strength; may be more susceptible to injury
<b>Nervous System</b>		
Brain	Shrinkage of cerebral sulci and enlargement of gyri with fibrosis of meninges; 20%–25% loss of cerebral and cerebellar neurons;	More susceptible to subdural hematoma with minor head trauma

	lipofuscin accumulates Decrease in stage 4 sleep Decrease in dopaminergic synthesis	
Peripheral nerves	Slower transmission; velocity decreases by 10%	Reaction time and adaptive responses to posture
Eyes/ears	Decreased accommodation and increased lens opacity Decrease in high-frequency perception	May need more light and possibly cataract surgery May have difficulty hearing in noisy rooms

Key: LVH, left ventricular hypertrophy; CNS, central nervous system.

## History Strategies

In addition to eliciting a history of chief complaint in those presenting with complaints, it is important to include a screening history of current drug history, dietary history, history of falling, history of incontinence, and questioning or questionnaires evaluating possible depression, anxiety, and mental functioning. It is also important to include a history of significant medical events such as surgeries, illnesses, accidents, and any diagnosed conditions. *Significant* may be defined as a condition or event that resulted in an appreciable loss of time at work, hospitalization, or being bedridden. Family history questions are less crucial given that many hereditary or family-related disorders would have appeared at an earlier age. Those factors that have significance to the elderly include a family history of cancer (in particular colon cancer and breast cancer), Alzheimer's, Huntington's chorea, osteoporosis, and hypertension. Questioning regarding mental function is addressed later.

---

## Examination Strategies

All seniors should have baseline vitals taken on the first visit, and more frequently than younger patients on subsequent visits. Establishing a baseline is particularly important for height and weight. For patients who have not had a physical within the previous year or for patients who do not have a medical physician, it is requisite to perform a comprehensive evaluation of the whole person with particular focus on senior-related

concerns. **Table 54-4** outlines the various portions of a comprehensive senior examination and the specific concern or focus of each.

<b>Physical Examination Focus</b>
-----------------------------------

## Vitals

It is particularly important to check vital signs frequently with older patients. The role of the initial measurements is to establish a baseline from which to make future comparisons. This is especially important when trying to determine if there has been significant weight loss (i.e., possible cancer, depression, or metabolic dysfunction) or significant height loss (i.e., osteoporotic vertebral compression fractures). The senior response to infection and inflammation may be blunted. It is important to establish the patient's baseline temperature on a well visit for future comparison. Generally, a rise above 1.33°C (2.4°F) is a significant rise and should be investigated.

**Table 54-4** Important Aspects of the Physical Examination of Older Patients

Area	Pathology Screen	Examination
Eyes	Acuity (far/near vision)	Snellen eye chart, normal print
	Macular degeneration	Grid matrix Peripheral fields by confrontation
	Cataracts	Lens opacification
	Glaucoma	Funduscopy (increased cupping)
Head	Temporal arteritis	Palpate temporal arteries for tenderness, nodularity, and pulsations, scalp tenderness and nodules
Ears	Hearing	Hand-held audioscope
		Free-field voice testing at 0.6 m (e.g., "What is your first name?" is a simple question even for the individual with cognitive impairments)
		Weber, Rinne tests
		Hearing Handicap Inventory for the Elderly
Mouth	Gingivitis	Inspect for erythematous, edematous gingiva, bleeding gums, loose teeth, exposure of the root surfaces of the teeth
	Dentures	
	Oral cancers	Check fit, food debris, bacterial plaque
		Inspect for persistent erythroplasia

Neck	Decreased mobility	Range of motion, observe dizziness
	Thyroid disease	Palpate thyroid for nodules or enlargement
	Jugular venous pulse	Check on right side of neck
	Carotid artery stenosis	Bruits
Thorax	Chronic obstructive pulmonary disease	Chest expansion
	Lung disease	Auscultation
Cardiovascular	Orthostatic hypotension	Measure blood pressure supine and upright (a drop of 20 mm Hg or more systolic and 10 mm Hg or more diastolic)
Breasts	Breast cancer	Annual clinical breast examination
Back	Vertebral compression fracture	Spinous percussion
	Osteoporosis	Kyphosis
Abdomen	Osteoporosis	Skin bunched into folds from collapse of multiple vertebra
	Urinary retention	Percussion of suprapubic area
	Aortic aneurysm	Lateral or anteroposterior pulsatile mass, bruit
	Constipation	Palpable mass
Prostate	Cancer	Palpable, hard nodule
	Benign prostatic hypertrophy	Enlarged, smooth soft prostate
Gynecologic	Stress incontinence	Pad test (have patient cover urethral area with a small pad and cough forcefully three times in the standing position to check for leakage of urine)
Extremities	Decreased mobility	Range of motion
	Arterial insufficiency	Peripheral pulses, temperature, ulcers
	Diabetic foot	Ulcers, fungal infections
	Falls	Check for proper footwear
Skin	Hydration status	Check skin turgor
	Senile purpura	Dorsum of hand and forearm
	Actinic keratosis	Sun-exposed areas of skin
	Physical abuse	Unexplained bruising
	Melanoma	Lesion larger than 6 mm across, deep black areas, irregular borders and shape
Neurologic	Balance	Push gently with eyes open, then closed
	Range of motion	Seated: Place hands behind head and back, touch toes (if normal, has adequate range of motion to allow normal grooming and dressing)
	Gait and mobility	Ask patient to sit and then rise from armless chair, ask patient to walk across room, turn 180°, and return to chair
	Gait	Normal older female: Waddling, narrow-based, decreased arm swing Normal older male: Wider-based, smaller-stepped, decreased arm swing
	Parkinsonism	Short steps, shuffling feet, stooped trunk, decreased arm swing, festination, tendency to fall backward
	Pernicious anemia	Sensory ataxic gait (wide based)
	Motor tone	Check for spasticity, lead pipe stiffness, paratonia
	Tremor	Check for Parkinson's disease, cerebellar dysfunction, hyperthyroidism, or essential tremor
	Vibratory sense	Normal decrease (especially in lower extremities)
	Primitive reflexes	Normal release (snout, glabella, palmomental)

Reproduced from L. J. Bowers, *Clinical Assessment of Geriatric Patients: Unique Challenges*, *Topics in Clinical Chiropractic*, Vol. 3, No. 2, pp. 16-17, © 1996, Aspen Publishers, Inc.

Blood pressure (BP) measurements are important for two reasons: (1) to determine if the patient has hypertension, and (2) to determine if the patient has orthostatic hypotension (common side effect of medications and secondary to diabetes). Blood pressure and pulse are measured with the patient seated and standing. Systolic pressure often increases with age. In the patient age 65 years or older a BP of 160/90 mm Hg constitutes the beginning level of mild hypertension. An isolated systolic

BP over 160 mm Hg without an associated proportionate increase in the diastolic pressure warrants a referral for medical management. A pseudohypertension may be present due to stiff arteries. Osler's maneuver attempts to distinguish this type from true hypertension.<sup>17</sup> While taking the pulse, the artery proximal to the pulse is occluded with a finger or BP cuff. If the distal pulse remains unchanged, there may be sufficient stiffness in the arteries to falsely raise the BP measurement.

Orthostatic hypotension is common in the senior and may account for complaints of lightheadedness or falling when rising from a lying or seated position. If the pulse increases less than 10 beats per minute or the blood pressure drops from a lying to a seated position, a baroreceptor reflex dysfunction may be the cause. Generally, if the systolic BP drops 15 mm Hg or the diastolic BP decreases 10 mm Hg after moving from a lying to seated or seated to standing position, the patient has orthostatic hypotension. The most fruitful line of questioning is about medication. Common causes are antihypertensive medications. Also, diabetes may blunt the reflex splanchnic vasoconstrictive response that should occur on rising.

Respiratory rate for the older patient is within the range of 12 to 20 breaths per minute. If the rate is above this normal range, investigate the possibility of a lower respiratory tract infection.

## Eyesight and Hearing

Approximately 8% of U.S. seniors are significantly visually impaired.<sup>18</sup> In addition to using either a Snellen eye chart or a handheld Jaeger chart, the Activities of Daily Vision Scale helps determine functional capacity of those with vision loss.<sup>14</sup> Visual impairment places the individual at risk of falls and others at risk due to motor vehicle accidents. Several disorders are more common in the senior including age-related macular degeneration, glaucoma, cataracts, vitreoretinal traction, and amaurosis fugax (see [Chapter 42](#)).

Significant hearing loss is claimed by only 30% of older individuals; however, when tested with audiometric evaluation, 60% of individuals over the age of 70 years have a deficit. Routine screening should be part of all initial geriatric assessments given the psychosocial impact and commonality of this problem in the elderly. A handheld audioscope is a useful screening tool for detecting significant hearing loss, particularly in the frequency range for speech. The most common age-related problem in seniors is presbycusis (see [Chapter 45](#)). It is believed that this dysfunction involves the loss of high-frequency hearing first due to degeneration of the hair cells in the organ of Corti.

# Functional Assessment

Although many disorders of the elderly are not reversible, many individuals can adapt and function enough to retain their independence. A functional assessment is as important, if not more important, than a diagnosis in determining a patient's ability to function independently. Assessments are based on questions or questionnaires that focus on self-assessment. The basic intention is to determine a patient's ability to care for himself or herself.

## Activities of Daily Living

The assessment of self-care functions is often divided into three categories: (1) basic activities of daily living (ADLs), (2) intermediate ADLs, and (3) advanced ADLs. The basic ADLs include:

- bathing
- dressing/grooming
- self-feeding
- toileting
- maintaining continence (bowel/bladder)
- mobility level
- transferring (within the home)

The activities assessed have a somewhat hierarchical order. For example, if bathing is possible many of the following functions are available: continence, dressing, feeding, completing one's toilet, and transfer.

Intermediate ADLs include:

- using the telephone
- preparing meals
- performing work around the house
- doing laundry
- shopping
- transportation
- self-medication
- managing money

Advanced ADLs include:

- strenuous physical activity (e.g., hiking, bicycling, running, walking briskly)
- heavy work around the house
- number of times one can walk 1 mile or more without rest

- number of times one can walk a quarter of a mile or more without rest

The ADL score is an important indicator of health outcome compared with basing the prediction of outcome on a diagnosis.<sup>19</sup>

## Ancillary Testing

As with all patients, it is imperative that the following questions be posed prior to ordering what often is expensive, and occasionally uncomfortable, testing:

- What is the likelihood that the test will introduce information that appears to be related, yet has no proven relationship to the patient's complaint or dysfunction?

- What is the cost of the test and the ability of the patient to cover that cost?
- What is the availability of the test?
- Does the confirmation of a disorder by use of the test alter the treatment plan or prognosis for the patient?

## Radiographic Evaluation

Many bone and joint-related disorders are manifested by characteristic radiographic changes. The value in radiographs is therefore quite high in the differential diagnosis of musculoskeletal pain. However, the correlation between these findings, clinical symptoms, and patient function is not as directly related as might be assumed. Studies have indicated that radiographic indications of spinal degeneration, in either the cervical or lumbar spine, do not correlate with an increased incidence of pain or dysfunction.<sup>20</sup> Bone scans may be a useful tool for the evaluation of primary cancer or metastasis. Refer to [Chapter 1](#) for a comparison of magnetic resonance imaging (MRI) to computed tomography (CT) in the evaluation of musculoskeletal disorders.

## Laboratory Values

Clear data on the geriatric reference ranges for many tests are lacking. Each laboratory makes an attempt at adjusting the reference range based on gender and age; however, the ranges vary from lab to lab. The following information may help guide the ordering and interpretation of laboratory findings on the older patient:

- Erythrocyte sedimentation rate

(ESR) increases with age at a rate of 0.22 mm/hour/year beginning at age 20 years. Also, this test is easily affected by handling variations leading to increased values. Generally, unless values are above 50 mm/hour it is unlikely that any significant disorder is present. Levels above 80 mm/hour do correlate with the finding of neoplasm, rheumatic disease, or infection.<sup>21</sup>

- The definition of anemia by the World Health Organization (WHO) is a hemoglobin concentration below 7.5 mmol/L (120 g/L) in women and below 8.3 mmol/L (130 g/L) in men. Values below this level correlate well in establishing a concern in the elderly with an increased mortality risk (e.g., infection, malignant neoplasms, and respiratory disease) two times that of individuals with normal hemoglobin concentrations. Therefore, a low hemoglobin concentration indicates significant disease in the older patient. Eighty percent of anemic women and 92% of anemic men have normocytic anemia.<sup>22</sup>
- The level of antinuclear antibodies (ANA) is somewhat age-dependent, with a rise of 16% of normal older individuals having a positive ANA evaluation.
- Rheumatoid factor (RF) increases with age to 15% to 25% of healthy individuals testing positive in the age group over 70 years.
- Serum albumin level may decrease with kidney disease, especially in patients with rheumatoid arthritis (RA) or systemic lupus erythematosus (SLE); however, malnutrition, which is common in the elderly, may also be a cause. A screening for malnutrition is to check for decreased serum albumin (4 g/dL or less) and/or a decreased cholesterol level (160 mg/dL or less).
- Caution must be used in interpreting a finding of a monoclonal protein in the serum or urine. As many as 10% to 23% of patients between the ages of 75 and 84 years tested positive for a monoclonal protein.<sup>23</sup> In one study,<sup>24</sup> 55% had a monoclonal gammopathy of unknown origin, 18% had multiple myeloma, and 12% had amyloidosis. The distinction between multiple myeloma and that of monoclonal gammopathy of undetermined significance (MGUS) is that those with MGUS have immunoglobulin G (IgG) monoclonal protein less than 3.5 g/dL or IgA less than 2 g/dL with Bence-Jones protein (<1 g/24 hour) and less than 10% plasma cells in the bone marrow. There are no bony lesions, anemia, hypercalcemia, or renal insufficiency with MGUS. Still, about 30% of MGUS patients develop a malignant process in the future. Stability of the monoclonal protein levels over time is more predictive of a benign outcome.

## Focused Concerns

### Mental Health

## Mental Health Status Evaluation

The most common mental health problems seen in older patients are dementia, depression, and delirium. Each condition may mimic the other. The consequences of mistaking one condition for the other is that management is often entirely different. For example, if a patient is incorrectly diagnosed as having dementia, or more specifically Alzheimer's disease (AD), when in fact the patient is severely depressed, effective treatment may be withheld and major decisions regarding institutionalized living versus independent living may be made with an unfortunate outcome for the patient.

Age-related memory loss is distinct from other causes. It has been demonstrated that with age-related memory decline, there is no decline in language, visuospatial skills, or abstract reasoning.<sup>25</sup> Also, the decline with age-related memory loss is specific to the acquisition and early retrieval of new information, and not memory retention. Anatomically, this correlates with the hippocampal formation. Dementia is defined as the development of multiple cognitive deficits, not memory deficits alone. The severity must be enough to impair occupational or social functioning and must be shown to decline compared with previous functioning. The two main causes of dementia are Alzheimer's disease and multi-infarct dementia (MID). Characteristically, the clinical presentation is distinct. MID is characterized by a more abrupt onset of focal neurologic signs that have a stepwise deterioration. Associated factors are hypertension and other signs of cardiovascular or atherosclerotic disease. Common motor problems that more often dominate MID are dysarthria, dysphasia, pseudobulbar paralysis, seizures, and gait disturbances, with pathologic reflexes sometimes evident.

The differential diagnosis for dementia should also include a multitude of other causes as illustrated by the mnemonic DEMENTIA:<sup>26</sup>

- **D**rugs
- **E**motional illness including depression
- **M**etabolic/endocrine disorders
- **E**yes/ear/environment
- **N**utritional/neurologic
- **T**umors/trauma

- Infection
- Alcoholism/anemia/atherosclerosis

The work-up (in addition to evaluation of mental function as discussed below) includes a neurologic and cardiovascular evaluation. Neurologic deficits are unusual with early and intermediate AD. Laboratory testing must include vitamin B<sub>12</sub> and thyroid function. Additional tests may include folate, blood urea nitrogen (BUN) and creatinine, hematocrit and hemoglobin, alanine transaminase, glucose, electrolytes, venereal disease research laboratories (VDRL), and calcium. An electrocardiogram and electroencephalogram should be ordered if seizures are present. In the search for structural central nervous system (CNS) causes, an MRI or CT may be necessary.

Delirium is more often an acute, reversible brain dysfunction associated with many disorders. The onset is usually abrupt and associated with illness, drugs, or acute metabolic imbalances. The symptoms often fluctuate frequently (even within minutes); they are often worse late in the day (sundowning). Clouding of consciousness, confusion, irritability, inappropriate behavior, delusions, and hallucinations are all characteristic of delirium. The distinguishing tests are the same as for dementia; however, the urgency for an early diagnosis is important due to the reversibility of delirium in many cases.

In the portal of entry of the primary care setting, various tools and questionnaires are available to screen individuals at risk. In the distinction among delirium, depression, and dementia, it is helpful to use screening tools prior to laboratory testing or neuropsychologic testing. A test designed to screen for the five most common mental/behavioral disorders is the PRIME-MD (Primary Care Evaluation of Mental Disorders).<sup>27</sup> These disorders include depression, anxiety, alcohol abuse, somatoform disorders, and eating disorders. The first versions were administered by the doctor and took approximately 8 to 10 minutes. The most recent version is the self-administered PRIME-MD Patient Health Questionnaire (PHQ).<sup>28</sup> This tool has been shown to be diagnostically valid and efficient.

The most commonly used test when patients appear to have a memory or other cognitive dysfunction is the Mini-Mental Status Exam (MMSE). This cognitive screening examination assesses orientation, language, attention, concentration, mental flexibility (i.e., working memory), short-term memory, and constructional praxis (see **Exhibit 54-1**). The MMSE does not test abstract thinking or judgment, and it is more sensitive to left-hemisphere dysfunction than right. A score range of 0 to 30 is possible. If a score of 24 is used as a cutoff point for normal, the MMSE has a sensitivity of 87% to 90% and a specificity of 80% to

82%.<sup>29</sup> Adjusted for education level, a score of 17 or less is abnormal in those with eight or fewer years of education. For all others, a score below 24 would direct a search for the types of questions missed. Alzheimer's patients often fail the memory portion. Another quick screening assessment for nonverbal ability is the Draw-a-Clock test. Alzheimer's patients do poorly on this task. The patient is asked to draw a clock with all the hour numbers on it. They are then asked to place hands on the clock to read 11:15.

### **Exhibit 54-1 The Annotated Mini-Mental State Examination (AMMSE)**

NAME OF SUBJECT \_\_\_\_\_ Age \_\_\_\_\_  
 NAME OF EXAMINER \_\_\_\_\_ Years of School Completed \_\_\_\_\_  
 Approach the patient with respect and encouragement. Date of Examination \_\_\_\_\_

Ask: Do you have any trouble with your memory? ☐ Yes ☐ No  
 May I ask you some questions about your memory? ☐ Yes ☐ No

#### **SCORE ITEM**

#### **5 ( ) TIME ORIENTATION**

Ask:

What is the year \_\_\_\_\_ (1), season \_\_\_\_\_ (1),  
 month of the year \_\_\_\_\_ (1), date \_\_\_\_\_ (1),  
 day of the week \_\_\_\_\_ (1)?

#### **5 ( ) PLACE ORIENTATION**

Ask:

Where are we now? What is the state \_\_\_\_\_ (1), city \_\_\_\_\_ (1),  
 part of the city \_\_\_\_\_ (1), building \_\_\_\_\_ (1),  
 floor of the building \_\_\_\_\_ (1)?

#### **3 ( ) REGISTRATION OF THREE WORDS**

Say: Listen carefully. I am going to say three words. You say them back after I stop. Ready? Here they are . . . PONY (wait 1 second), QUARTER (wait 1 second), ORANGE (wait 1 second). What were those words?

\_\_\_\_\_ (1)  
 \_\_\_\_\_ (1)  
 \_\_\_\_\_ (1)

Give 1 point for each correct answer, then repeat them until the patient learns all three.

5 ( ) SERIAL 7s AS A TEST OF ATTENTION AND CALCULATION

Ask: Subtract 7 from 100 and continue to subtract 7 from each subsequent remainder until I tell you to stop.

What is 100 take away 7? \_\_\_\_\_ (1)

Say:

Keep going. \_\_\_\_\_ (1), \_\_\_\_\_ (1),  
\_\_\_\_\_ (1), \_\_\_\_\_ (1).

3 ( ) RECALL OF THREE WORDS

Ask:

What were those three words I asked you to remember?

Give one point for each correct answer. \_\_\_\_\_ (1),  
\_\_\_\_\_ (1), \_\_\_\_\_ (1).

2 ( ) NAMING

Ask:

What is this? (show pencil) \_\_\_\_\_ (1). What is this? (show watch) \_\_\_\_\_ (1).

1 ( ) REPETITION

Say:

Now I am going to ask you to repeat what I say. Ready? No ifs, ands, or buts.

Now you say that. \_\_\_\_\_ (1)

3 ( ) COMPREHENSION

Say:

Listen carefully because I am going to ask you to do something:

Take this paper in your left hand (1), fold it in half (1), and put it on the floor (1).

1 ( ) READING

Say:

Please read the following and do what it says, but do not say it aloud. (1)

# Close your eyes

1 ( ) WRITING

Say:

Please write a sentence. If patient does not respond, say: Write about the weather. (1)

---

---

1 ( ) DRAWING

Say: Please copy this design

# Alzheimer's Disease

AD is the most common cause of dementia in the United States and accounts for approximately 65% to 75% of all cases.<sup>30</sup> There are more than 4 million Americans affected by AD. Women with AD live longer than men with AD and as a result, represent twice as many cases. The combined cost of direct management and lost productivity is currently at least \$100 billion annually.<sup>31</sup> AD is characterized pathologically by the accumulation of senile plaques in the cerebral cortex and subcortical gray matter. These plaques contain  $\beta$ -amyloid and neurofibrillary tangles made up of tau protein. The cause of AD is not entirely understood. However, the elevation of amyloid-peptide prior to the development of significant tau pathology suggests an initiating role in mediating pathologic progression, especially in the frontal cortex.<sup>32</sup> The enzyme responsible for the accumulation of amyloid appears to have been uncovered. It appears that  $\beta$ -secretase splitting of the Alzheimer amyloid

precursor protein is by the transmembrane aspartic protease (BACE) enzyme.<sup>33</sup> Future therapeutic strategies will be focused on inhibition of endogenous BACE messenger-RNA and other related approaches. There are some common features of neurodegenerative disorders. One feature is that overstimulation of the N-methyl-D-aspartate (NMDA) receptor by glutamate leads to neuronal damage in a phenomenon termed *excitotoxicity*. It is believed that such excitotoxicity leads to neuronal calcium overload. An approved drug, memantine, is an uncompetitive NMDA-receptor antagonist (antiglutamatergic) that may be effective in reducing clinical deterioration in moderate to severe AD.<sup>34</sup>

There are many risk factors, but, most define only subgroups at risk. For example, the early-onset form of AD is associated with an autosomal-dominant transmission with gene mutations on chromosomes 21, 14, and 1. However, this accounts for only 2% of all cases of AD. Associated with the more common, late-onset AD is the presence of the *APOE*  $\epsilon$  4 allele on chromosome 19.<sup>35</sup> The presence of a single allele increases the risk of AD twoto fourfold, whereas the presence of the double  $\epsilon$  4 allele increases the risk fourto eightfold. Those patients with the *APOE*  $\epsilon$  4 allele in combination with atherosclerosis, peripheral vascular disease, or diabetes mellitus are at substantially higher risk of cognitive decline.<sup>36</sup> However, it is not currently recommended to use genotyping as a predictive test in asymptomatic individuals because having the *APOE*  $\epsilon$  4 allele does not consistently predict AD, and not having it does not protect an individual from acquiring AD. Other factors being investigated are: • Hyperhomocysteinemia. Patients in the upper third of serum homocysteine have at least a twofold increase in risk of developing AD (independent of all other known risk factors).<sup>37</sup> Also, an inverse relationship exists between serum folate and vitamin B<sub>12</sub> levels and risk of AD. It is unknown whether decreased levels are functionally related to hyperhomocysteinemia.

- In a recent study, serum total cholesterol levels were not associated with an increased risk for AD.<sup>38</sup>
- A recent study indicates that depression is a possible risk factor for AD.<sup>39</sup> Depression, in addition to contributing to a higher risk of suicide attempt, also appears to be a risk factor for coronary heart disease.<sup>40</sup> Associated is the growing evidence that low Vitamin D levels are associated with the risk for AD.
- The effects of estrogen on prevention of dementia have been well documented, including neurotrophic effects, reductions in  $\beta$ -amyloid accumulation, augmentation of neurotransmitters, and some oxidative damage control.<sup>41, 42</sup> Estrogen receptors are found in areas of the brain related to memory and learning, including the hippocampus and amygdala. Yet recent studies have failed to

demonstrate a significant effect in large populations of postmenopausal females. In fact, a randomized controlled study indicated there was no beneficial effect for estrogen therapy in women with known Alzheimer's.<sup>43</sup> Combined therapy with estrogen and progestin appears to increase the risk to some extent. A Women's Health Initiative project evaluating estrogen/progestin therapy and stroke provided data that indicated an increased risk of ischemic (but not hemorrhagic) stroke in generally healthy postmenopausal women.<sup>44</sup> A memory study portion of the Women's Health Initiative concluded that estrogen/progestin combination therapy did not improve cognitive function in postmenopausal women 65 years or older, and in fact may cause a small increased risk of clinically meaningful cognitive decline.<sup>45</sup> A part of the same study indicated increased risk for probable dementia.<sup>46</sup>

- Smoking. Although smoking has been found to increase the risk for AD, quitting smoking may cause a slight reduction in risk for AD.<sup>47</sup>
- Hippocampal atrophy. Hippocampal atrophy based on premorbid MRI-based volume measurement may be predictive for conversion to AD in patients with mild cognitive impairment.<sup>48</sup>
- Cerebrospinal fluid (CSF). CSF levels of  $\beta$ -amyloid appear to be decreased in patients with AD as compared with normal individuals.<sup>49</sup>

Factors that may be protective for AD include higher education, nonsteroid anti-inflammatory drugs (NSAIDs), vitamins D and E, and high monounsaturated fatty acid intake.<sup>50,51</sup>

The diagnosis of AD is both one of exclusion and inclusion. Although a definitive diagnosis cannot be made without autopsy or biopsy of the brain, there are clinical distinguishing features described in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-V).<sup>52</sup>

- The development of multiple cognitive impairments that impact significantly on the occupational or social functioning of the patient. This decline is significant when compared with previous levels of functioning. The decline is not associated with any other known cause of dementia or delirium.
- Memory impairment and one or more of the following: aphasia, apraxia, agnosia, or disturbance in executive functioning (i.e., planning, organizing, sequencing).

Other distinguishing factors are:

- A slower onset than a vascular cause of dementia or delirium

- Late onset of motor dysfunction
- Classic behavioral problems including:
  1. sundowning (late-day agitation)
  2. wandering
  3. sleep disturbances

The differential diagnosis is discussed above under dementia.

Management of AD is complex, involving not just the patient but also the caregiver. Early diagnosis and a correct diagnosis are important for future planning regarding living environment, supervision and care, and estate planning. The caregiver now has access to centers and groups offering training, support, and counseling. The AD patient cannot be cured; however, the process may be slowed or the cognitive and behavioral problems may be managed medically. For the cognitive impairment associated with AD, the primary medications are cholinesterase inhibitors such as tacrine (Cognex) and donepezil (Aricept). These drugs inhibit degradation of acetylcholine at the synaptic cleft. Cholinesterase inhibitors appear to provide modest benefit on neuropsychiatric and functional outcomes for mild to moderate Alzheimer's disease.<sup>53</sup> Memantine, is an uncompetitive NMDA-receptor antagonist (antiglutamatergic) and has been shown to be effective in reducing clinical deterioration in moderate to severe AD.<sup>34</sup> **Table 54-5** is a list of common medications used in the management of AD. Disease-altering strategies include the use of *ginkgo biloba* extract, vitamin E, monounsaturated fatty acids, NSAIDs, and estrogen (see **Table 54-6**).<sup>54,55</sup> A recent randomized, double-blind, placebo-controlled study<sup>56</sup> did not demonstrate any effect of slowing AD in women who took estrogen replacement therapy (ERT) for one year. It appears that ERT may not slow the progression, but more research is needed to determine if it has a protective effect if started early enough. Novel approaches are being developed for the treatment of AD. One approach is based on the observation that mice minus one-third of the cells needed for cognitive function were able to regain cognitive function when their brains were infused with nerve growth factor (NGF).<sup>57</sup> Apparently, this research implies that function of the remaining cells can be enhanced enough to make up for the loss of other cells.

**Table 54-5** Alzheimer's Medications

Drug Class	Examples	General Mechanism	Interactions/Side Effects
Cholinesterase inhibitors	Donepezil HCL	A cholinesterase inhibitor used in the management of mild to moderate Alzheimer's disease. Works in the cerebral cortex blocking degradation of acetylcholine.	May cause headache, fatigue, insomnia, nausea, diarrhea, vomiting, cramps, anorexia, or muscle cramps.
	Aricept		
	Tacrine	A cholinesterase inhibitor used in the management of mild to moderate Alzheimer's disease. Works in the cerebral cortex blocking degradation of acetylcholine.	May cause headache, fatigue, insomnia, nausea, diarrhea, vomiting, cramps, anorexia, or muscle cramps
	Cognex		
	Rivastigmine tartrate	A cholinesterase inhibitor used in the management of mild to moderate Alzheimer's disease. Works in the cerebral cortex blocking degradation of acetylcholine.	May cause headache, fatigue, insomnia, nausea, diarrhea, vomiting, cramps, anorexia, or muscle cramps
	Exelon		
NMDA-receptor antagonist	Memantine	Memantine is an uncompetitive NMDA-receptor antagonist (antiglutamatergic) and has been shown to be effective in reducing clinical deterioration in moderate to severe Alzheimer's.	May cause emotional agitation, confusion, stomach upset, and nervousness.
	Axura		
	Namenda		
Butyrophenone derivative	Haloperidol	A butyrophenone derivative similar to phenothiazines but with more extrapyramidal effects and less hypotensive and sedative effects. Used for psychotic disorders, tics, Tourette's syndrome, management of agitated states with Alzheimer's, and severe behavioral problems with children.	May cause extrapyramidal effects such as Parkinsonian symptoms, tardive dyskinesias, neuroleptic malignant syndrome. Agranulocytosis, laryngospasm, hyponatremia, hyperglycemia, and EEG changes.
	Haldol		
	Peridol		

**Table 54-6** Nutritional Support for Dementia

Substance	How Might It Work?	Dosage	Special Instructions	Contraindications for Possible Side Effects
Ginkgo ( <i>ginkgo biloba</i> )	Has antioxidant properties and platelet-inhibiting activity; may be neuroprotective and may improve circulation.	120–240 mg twice daily	None	Gastrointestinal upset and transient headache may occur in first few days of use. Interactions with anticoagulants may occur. Pregnancy and lactation are not contraindications.
Ginseng (Panax ginseng)	An adaptogen that enhances the immune system and acts also as an energizer and mood elevator (especially in the elderly).	0.5 to 1 g in two divided doses (capsules commonly contain 250 mg of the root/capsule); can also be taken as a tea with 3 g (1 teaspoon) ginseng steeped in 1 cup boiling water for 5–10 minutes.	Take in the morning and evening on an empty stomach. Limit the use to 3 months at a time.	Massive overdosages may result in ginseng abuse syndrome with sleeplessness, hypertonia, and edema.
Vitamin E	Antioxidant used to prevent progression of Alzheimer's disease.	2,000 IU/day	None	None at recommended dosage.
Acetyl-L-carnitine	Contributes to the production of acetylcholine.	1 g taken three times daily	None	Rare reports of skin rash, increased appetite, and body odor.
Coenzyme Q10	Assists in mitochondrial function.	Minimum dose usually 90–150 mg/day	Take with iron and B <sub>6</sub> (according to study demonstrating effect).	Congestive heart failure patients should not abruptly discontinue use.

*Note:* The following have not been approved by the Food and Drug Administration for the treatment of this disorder.

A promising study was published in 2008 that indicates that a novel approach to Alzheimer’s may be effective. Reger et al.<sup>58</sup> found that intranasal insulin improved cognition and actually modulated betaamyloid in patients with early AD. This follows on the heels of an earlier publication that indicated that insulin increased levels of cerebrospinal fluid norepinephrine in normal patients, which correlated with better cognition.<sup>59</sup> Dimebon (dimebolin) is an antihistamine showing promise.

Two reports of note involve the Mediterranean diet (MeDi) and a decrease in risk for Alzheimer’s, as well as a decrease in mortality with Alzheimer’s.<sup>60, 61</sup> A MeDi is high in vegetables, fruits, legumes, and cereals, high in unsaturated fatty acids (primarily olive oil), low in saturated fatty acids, a moderately high intake of fish, meat, and poultry, a moderate amount of wine (usually with meals), and a low intake of dairy products. Interestingly, according to one recent study,<sup>62</sup> a low-carbohydrate diet may not be preventive as some suggest.

## Depression

Although when compared with younger patients, older patients are affected less often (7% to 10% of community dwellers) by obvious depression, atypical presentations are more common in the elderly.<sup>63</sup> Most specifically is the misdiagnosis of dementia (i.e., memory loss), when in fact depression is the cause (i.e., pseudodementia). Also, older patients may suffer from the depression associated with chronic disease, cancer, and prescribed medications. Some drugs that can cause depressive symptoms include antibiotics, anticonvulsants, antihypertensives, antineoplastic agents, antiparkinsonian agents, corticosteroids, digitalis, and hormones. Depression is covered more extensively in [Chapter 20](#); however, for the older patient two screening tools may be useful: the Beck Depression Inventory (BDI) and the Geriatric Depression Scale (GDS).<sup>64</sup> These questionnaires can identify almost 90% of patients with depression. The longer version of the GDS takes approximately 10 to 15 minutes to fill out, whereas the shorter 15-item version (GDS15) takes only a few minutes and is recommended by some groups as the screening tool of choice (see **Exhibit 54-2**).<sup>65</sup> The BDI is short and takes only 5 to 10 minutes to complete; it is considered reliable and valid for screening.

Exhibit 54-2 Geriatric Depression Scale	
	Yes/No Key

Are you basically satisfied with your life?	no
Have you dropped many of your activities and interests?	yes
Do you feel that your life is empty?	yes
Do you often get bored?	yes
Are you hopeful about the future?	no
Are you bothered by thoughts you can't get out of your head?	yes
Are you in good spirits most of the time?	no
Are you afraid that something bad is going to happen to you?	yes
Do you feel happy most of the time?	no
Do you often feel helpless?	yes
Do you often get restless and fidgety?	yes
Do you prefer to stay at home rather than go out and do new things?	yes
Do you frequently worry about the future?	yes
Do you feel you have more problems with memory than most people?	yes
Do you think it is wonderful to be alive now?	no
Do you often feel downhearted and blue?	yes
Is it hard for you to get started on new projects?	yes
Do you feel full of energy?	no
Do you feel that your situation is hopeless?	yes
Do you think that most people are better off than you are?	yes
Do you frequently get upset over little things?	yes
Do you frequently feel like crying?	yes
Do you have trouble concentrating?	yes
Do you enjoy getting up in the morning?	no
Do you prefer to avoid social gatherings?	yes
Is it easy for you to make a decision?	no
Is your mind as clear as it used to be?	no
Total score (number of answers matching key)	
Score 0-10 = No depression	
Score 11-14 = Mild depression	
Score >15 = Moderate to severe depression

## Drugs

The elderly account for about 30% of prescription drug purchases and 40% of nonprescription drug purchases. Over a five-year period, 90% of the elderly are taking at least one medication, with the average noninstitutionalized patient often taking three to four medications.<sup>66</sup> The risks from drug usage increase exponentially with each additional drug. Forty percent of the elderly must take one drug each day to perform ADLs.<sup>67</sup> In addition to the high percentage of the elderly taking medication, the issues of polypharmacy and age-related changes affecting dosage are of particular concern. The taking of several medications at a time is common for several reasons:

- Many medical physicians rely on medications to achieve treatment goals because it is less timeconsuming than nondrug management and gives greater immediate patient satisfaction.

- The patient seeks care from several medical physicians forgetting or purposefully omitting information regarding other prescribed (self or doctor) medications.
- The patient takes a friend's or family member's medication because he or she feels that his or her symptoms are the same.

It is also important to consider drug interaction with over-the-counter medications and herbal/supplemental products. Some common adverse reactions and associated medications are listed in **Table 54-7**. Be particularly vigilant in investigating drug interactions or cause when patients present with signs or symptoms of cognitive impairment, gastrointestinal bleeding, syncope and falls, arrhythmias, and extrapyramidal effects.

The physiologic factors related to drug absorption and concentration in the older patient are:

- **Absorption.** Decreases in splanchnic blood flow and hypochlorhydria may decrease absorption of some medications and also herbal/supplement products. Interference in absorption includes: **1.** the effects of cholesterol-binding medications (e.g., cholestyramine or colestipol) on drugs such as digoxin, warfarin, and thyroxine **2.** the binding of tetracycline by dairy products, antacids, and iron **3.** the effects on gastrointestinal motility by anticholinergics, antidepressants, and narcotics
- **Distribution.** Many drugs bind to albumin. As part of normal aging and particularly with renal or liver disease, the amount of albumin decreases. The effect is that for drugs that usually bind to albumin, there is a greater amount of free, active drug available. Total body water and lean body mass decrease while body fat increases in the elderly. Therefore, drugs that are hydrophilic have higher

concentrations. This is true of ethanol, digoxin, and cimetidine, among others. Lipophilic drugs will have a higher concentration in the elderly including steroids and benzodiazepines.

- **Hepatic and Renal Effects.** Due to decreases in hepatic blood flow, there may be an increased half-life of medications that are processed through the liver for elimination. These include imipramine, amitriptyline, long-acting benzodiazepines, and theophylline. Decreases in renal blood flow are about 1% per year after age 50 years accompanied by decreases in creatinine clearance. This may result in proportionately more drug availability over any given period of time due to slowed elimination.

**Table 54-7** Common Adverse Drug Reactions in Older Persons

<b>Adverse Reaction</b>	<b>Example</b>	<b>Common Causes</b>
Sedation	Drowsiness and sleepiness	Sedative-hypnotics, narcotic analgesics, antipsychotics
Confusion	Disorientation, delirium	Antidepressants, narcotic analgesics, anticholinergic drugs
Depression	Intense sadness and apathy	Barbiturates, antipsychotics, alcohol, antihypertensive agents
Orthostatic hypotension	Dizziness or syncope when assuming an upright position	Antihypertensives, antianginal agents
Fatigue and weakness	Strength loss and inability to perform normal activities	Muscle relaxants, diuretics
Dizziness	Loss of balance and falling	Sedatives, antipsychotics, narcotic analgesics, antihistamines
Anticholinergic effects	Confusion, nervousness, drowsiness, dry mouth, constipation, urinary retention	Antihistamines, antidepressants, certain antipsychotics
Extrapyramidal symptoms	Tardive dyskinesia, pseudoparkinsonism, dystonias	Antipsychotic medications

Reproduced from K. A. McCarthy, Management Considerations in the Geriatric Patient, *Topics in Clinical Chiropractic*, Vol. 3, No. 2, p. 69, © 1996, Aspen Publishers, Inc.

It is imperative for the chiropractor to obtain a full list of prescribed and nonprescribed medications, herbs, and supplements. Often the patient is more open about the total list knowing that chiropractors do not prescribe medication. Of particular concern for the chiropractor is that chronic or excessive use of analgesics is more likely to have serious

renal and gastric effects in the older patient as compared with a younger patient. Also sedatives or CNS depressants carry with them a higher degree of sedation and risk of extrapyramidal effects. The complexities of interaction are beyond the training of the chiropractor; however, if the patient presents with suspicious complaints and a drug interaction, overdose, or underdose is the possible cause, a written or verbal referral to the primary prescribing physician is in the patient's best interest.

## Falls

A longitudinal study by Baloh et al.<sup>68</sup> evaluated vestibular, visual, auditory, and somatosensory decline in normal older people. Although there were declines, they did not seem to contribute to changes in gait and balance. Highly correlated were white matter hypersensitivities on magnetic resonance imaging. Researchers in another study<sup>69</sup> found that certain reflexes were diminished such as the visual-vestibular-ocular reflex and the vestibulo-ocular reflex and likely accounted for some of the changes in gait seen in older individuals. In a review by Ganz et al.<sup>70</sup> the only indicators for risk of falling were a history of a fall within the past year and abnormalities found on assessment of gait and balance. Orthostatic hypotension, impaired cognition, visual impairment, medication variables, or decreased levels of activities of daily living were not predictive. Although falls are considered an almost natural result of growing older, the impact is far greater than often assumed. With the exclusion of nontraumatic causes of death, falls are the leading cause of death due to trauma, primarily from head injury and complications associated with hip fracture.<sup>71</sup> A fall may be the decision point for nursing care or extended-care residency. In addition to the obvious pain, the associated loss of mobility leads to dependence and often results in depression and other secondary consequences. The increased risks of injury from falling arise from poorer reaction time, osteoporosis, and, if the head is involved, more intracranial space, which allows more shear to the dura and blood vessels. As many as one-third of patients over the age of 65 years report one or more falls per year. This rate dramatically increases over the age of 85 years. Women fall more often than men, with estimates as high as twice the rate of men. The major causes of falling include (in order): accidents, gait disturbance, dizziness/vertigo, drop attacks (no loss of consciousness), confusion, postural hypotension, visual disturbance, and syncope.<sup>72</sup> The reasons for these causes include primarily age-related changes in posture and proprioception and the effects of medication(s).<sup>73</sup> In the elderly, postural changes exhibit an extrapyramidal pattern of more flexion, a gait that involves shorter stride

length and slower walking with increased muscle tone (stiffness). Increased sway is commonly the first sign of gait imbalance in the senior. Decreases in proprioception may be the result of normal aging; however, they are accelerated or augmented by dysfunction in the upper cervical spine and the result of diseases such as diabetes. Balance is coordinated through vestibular, visual, and proprioceptive interaction. Loss of one of these functions is more easily compensated for than loss or decrease of two. With poorer vision and/or proprioceptive loss or decrease, the patient is at substantial risk of loss of balance.

The first step in the differential is to attempt to determine whether an “accident” or a spontaneous fall occurred. Often these overlap and are hard to differentiate. The acronym SPLAT (**S**ymptoms associated with the fall, **P**rior falls, **L**ocation of the fall, **A**ctivity at the time of the fall, and **T**ime of day the fall occurs) may help.<sup>74</sup> For example, if the fall occurred after rising quickly from a seated or lying position and was associated with presyncope or syncope, orthostatic hypotension would be suspected. The most common causes considered would be medications (e.g., antihypertensives) or the autonomic reflex blunting effect of diabetes. If the patient stated that the fall occurred at night in a dimly lit area, proprioceptive dysfunction would be considered. If the patient stated that the fall occurred upon standing without ambulating, a cardiac or CNS cause would be suggested. A screening test that may be used is the Get Up and Go Test (GUGT). The patient is directed to stand up from a seated position, walk 3 meters (10 feet), turn, walk back, and sit down. The doctor observes and times the task to determine problems with rising, maintaining balance, and maintaining coordination. It is imperative to check for proprioceptive loss in the distal extremities, measure visual acuity, test for cerebellar dysfunction (in particular, Romberg’s test), and measure blood pressure lying and standing (to detect orthostatic hypotension). Laboratory investigation should include a general screen to determine problems with anemia and glucose metabolism. Further investigation may include evaluation of vitamin B<sub>12</sub> deficiency, thyroid disorders, or other specific concerns. In the patient with a suspected arrhythmia, a resting electrocardiogram (ECG) may be used as a screen; however, Holter monitoring is probably necessary in most cases due to the low sensitivity of a resting ECG.

Management approaches include:

- Referral to prescribing physician if medication is the suspected cause
- Referral for change in eyewear prescription, if necessary
- Lower extremity strengthening exercises

- Recommendation for t'ai chi classes; t'ai chi has been shown to improve balance in seniors<sup>75</sup>
- A home-site investigation of potential risks and suggestions on modifying or otherwise altering living environment to decrease risks (see **Table 54-8**) • Assisted devices such as walkers or canes may be necessary for some patients

## Urinary Incontinence

Incontinence is an involuntary loss of urine that is not an inevitable result of aging. Statistics vary based on living environment, time frame, and definition; however, estimates are that urinary incontinence affects approximately 30% to 50% of older adults.<sup>76</sup> The prevalence specifically in community-dwelling individuals older than age 65 years is approximately 15% to 30%. Women are twice as likely to be affected. Only about one-third of incontinent adults seek management. Those who do are patients with severe incontinence and those with better access to healthcare. Interestingly, the management strategies of men differ from those of women.<sup>77</sup> Men are more likely to limit fluids and traveling, and in fact are more likely to see a physician about incontinence. Women more frequently wear pads or perform exercises for their incontinence. In part, these differences reflect some differences in the types of incontinence seen based on gender. Men are more likely to have detrusor instability (i.e., involuntary contractions of the bladder) that increases with age. Also, enlargement of the prostate lengthens the urethra and moves the bladder neck more superiorly. Stress incontinence (due to urethral hypermobility in women) is uncommon in men, although radical prostatectomy may increase stress on the external urethral sphincter. Childbirth, aging, and hormonal influences may result in descent of the bladder neck or affect innervation to the bladder in women. Generally, the most frequent causes of urinary incontinence (UI) in women are stress incontinence and urge incontinence, whereas in men overflow incontinence and urge incontinence are more common. The cause of overflow incontinence in men is due to anatomic blockage of the bladder outlet, usually due to benign prostate hypertrophy, prostate cancer, or urethral stricture. For both men and women, incontinence associated with low back and/or leg pain warrants an investigation of cauda equina syndrome.

**Table 54-8** Home Safety Evaluation and Recommendations

Area	Recommendations
------	-----------------

General home environment	Floors/Rugs—Secure carpet edge, especially on stairs; remove throw rugs; keep areas clear of clutter, especially cords and wires; do not wax floors Other—Make sure there is adequate lighting especially at night; make sure that chairs are not too low and that the phone is accessible from floor
Bathroom	Install handrails for toilet and shower; use rubber bath mat; raise toilet seat if necessary
Outdoors	Make sure sidewalk and driveway are free of cracks; install handrails at areas with stairs; ensure adequate lighting; keep shrubbery trimmed

Focused questioning topics for UI include:

- frequency and amount of voiding
- situational aspects related to onset of UI (mechanical stimulation of voiding from coughing, laughing, sneezing, or jumping is likely stress incontinence, whereas UI without mechanical stimulation is more often due to detrusor instability) • any associated signs/symptoms of urinary tract infection
- bowel movements, in particular constipation (a distended distal colon with stool may affect bladder function through a pressure effect) • diagnosed conditions that may be the cause of voiding difficulty (e.g., congestive heart failure, diabetes, prostate or pelvic surgery for various conditions) or the medications used for the condition may exacerbate voiding problems • drug history (some medications may cause retention and lead to overflow incontinence [e.g.,  $\alpha$ -agonists and stimulants such as ephedrine found in nasal decongestants] while others may act as diuretics [e.g., prescription and herbal diuretics, alcohol, and caffeine]) • previous diagnosis and/or management of UI
- patient's desired goals of management

The evaluation may be limited for the chiropractor given that a rectal examination for both sexes and a pelvic examination for women are necessary for a complete evaluation. If these examinations are not part of the practitioner's skills, a referral for these evaluations is requisite. In addition to a urogenital examination, the following should be included in the work-up of UI:<sup>78</sup>

- Palpation for suprapubic tenderness, lower abdominal masses, and bladder distention
- Neurologic testing of the perianal area and lower extremity may be warranted when complaints of pain or numbness are reported • The cough test (a screening test for stress incontinence) to determine if there is loss of urine with coughing • Maintenance of a frequency-voiding record by the patient

- Urinalysis to determine if glucosuria, blood, or infection may indicate an underlying pathologic cause
- Referral for more extensive testing includes an estimation of post-void residual, uroflowmetry, and pressure flow studies Based on the type of UI, treatment options vary. Refer to [Chapter 34](#) for a more extensive discussion of the options. Generally, if stress incontinence is the cause, Kegel exercises are beneficial. If detrusor instability is the cause, bladder training, habit training, pelvic muscle exercises, and biofeedback are important nonsurgical, drugless approaches. Drug therapy involves antimuscarinic medications including oxybutynin and tolterodine.

---

## Male-Specific Concerns

A number of male-specific problems can occur in the senior patient. These include benign prostatic hypertrophy, prostate cancer, erectile dysfunction, and low testosterone. Prostate problems are discussed in the Selected Causes section of [Chapter 34](#), Urinary Incontinence/Dysfunctional Voiding.

## Erectile Dysfunction

The inability to acquire or sustain an erection for sexual intercourse is most often due to a secondary disorder, the most common cause being diabetes. Other medical conditions or the medications used to treat these conditions are also possible causes. Risk factors, in fact, include several of these disorders including diabetes, cardiovascular disease, metabolic syndrome, and smoking. Those patients with prior prostate surgery for prostatectomy are also at risk. Age is also a risk with the prevalence being quite high, with reports as high as 52% for males 40 to 70 years old; most of these cases are from ages 50 to 70 years.

Erection occurs with parasympathetic control of the central release of nitric oxide, which increases production of cAMP. This leads to a relaxation of the cavernous smooth muscle allowing an increase in penis blood flow. There are sinusoids in the cavernous muscle that fill with blood and compress the veins decreasing outflow. There are basically three general mechanisms that can interfere with this sequence. One is psychological including acute stress or chronic depression, vascular blockage, and the final possible contributor is neurological. The diagnostic work-up should then include a screen for pulses, reflexes, signs/symptoms (and lab) for diabetes, and psychological questioning.

Treatment of underlying disease such as diabetes is the first approach. For those with continuing problems, medications that act to increase

blood flow to the penis are a form enzyme blocker for phosphodiesterase type 5 (PDE-5). Familiar drugs are Viagra, Cialis, and Levitra. Common side effects are flushing, headache, orthostatic hypotension, and for those taking Levitra, low back pain. It is important to avoid grapefruit and limit alcohol intake when taking any of these drugs. Failing this approach, some patients are directed to intraurethral and intracavernosal injectables such as Alprostadil (prostaglandin E1). **Table 54-9** is a list of these drugs and their potential side effects.

## Low T Syndrome

Low testosterone is defined as levels  $<300$  ng/dL. Symptoms in addition to low sexual drive include decreases in muscle mass and strength, and fatigue. Clearly, these low levels may also be related in part to aging, and certainly are related to other disorders that may be risk factors such as obesity, diabetes, and COPD. Causes may include undescended testicles, mumps infection (orchitis), Cushing's syndrome, hemochromatosis, TB, HIV/AIDS, and testicular trauma. Luteinizing hormone released from the pituitary stimulates the release of testosterone from the testes. Treatment is with testosterone gels such as AndroGel or Testim. Those taking these medications are cautioned not to transfer the gel to females or children, which may result in increased testosterone and its effects. Other approaches include a patch (Androderm or Testoderm), and injection with Delatestryl or Depo-Testosterone.

## Nutrition

With the elderly, loss of weight is often more of a concern than weight gain. Chronic diseases can be tied to increases in weight, in particular diabetes, however. The focus here will be on the more immediate issue of weight loss. Weight loss is a multifactorial problem based primarily on feeding and appetite issues related to an underlying disease or disorder or secondarily due to psychosocial influences including accessibility to food sources, financial resources, nutritional knowledge, and social aspects of eating (i.e., not wanting to prepare a meal for self only). A line of questioning that centers around a typical daily meal schedule and content is the best approach to investigating a senior's nutritional status. If concerns surface, focus on common causes:

- Lack of appetite.

Investigate medication use and underlying diseases and disorders. If necessary, follow up with appropriate laboratory investigation. The most

common causes of lack of appetite in the elderly are depression and medication use.

- Difficulty with eating. Investigate dental problems including ill-fitting dentures and difficulties with swallowing or digesting food.

**Table 54-9** Erectile Dysfunction Medications

Drug Class	Examples	General Mechanism	Interactions/Side Effects
Tadalafil	Cialis	Used in the treatment of erectile dysfunction, it is a selective cyclic guanosine monophosphate (cGMP) inhibitor (specific phosphodiesterase type 5 [PDE5])	Headache, dizziness, abdominal pain, rash, chest pain, myalgias, spontaneous or long-lasting erections; caution if patient is taking alpha-blockers or nitrates
Vardenafil	Levitra	A phosphodiesterase-5 inhibitor. Used for erectile dysfunction. Causes a vasodilation effect in the corpus cavernosus of the penis through effect with nitric oxide.	May cause facial edema, postural hypotension, palpitations, headache (and other "cerebral signs/symptoms"), MI, angina, dermatitis, photosensitivity, and gout. For some, may experience a slight bluish tinge to vision.
Sildenafil citrate	Viagra	Used for erectile dysfunction. Causes a vasodilation effect in the corpus cavernosus of the penis through effect with nitric oxide.	May cause facial edema, postural hypotension, palpitations, headache (and other "cerebral signs/symptoms"), MI, angina, dermatitis, photosensitivity, and gout.
Vardenafil HCL	Levitra	Used in the management of erectile dysfunction in men. It acts as an enzyme blocker for phosphodiesterase type 5 (PDE-5), which results in increased blood flow to the penis.	Headache, indigestion, flushing, stuffy nose, and dizziness.

- Difficulty with preparing food. Evaluate for disorders that affect the use of the hands or the ability to ambulate around the kitchen.
- Difficulty obtaining food. Investigate transportation availability, affordability of groceries, and whether patient knows of resources such as home-delivery services including Mealson-Wheels and other resources.
- Nutritional knowledge. Investigate the senior's general knowledge of appropriate nutritional balance in diet, ability to read labels, and attitude toward maintaining a healthy diet and lifestyle.

More sophisticated approaches include the Nutrition Screening Initiative (NSI), a tiered approach to nutritional screening in the elderly.<sup>79</sup> The first-line screen is basically a checklist filled out by the patient, and two screening tests. These two screening tests are based on information obtained by the social service or other healthcare professional. Physical examination screens should include a check for weight loss, an estimation of percentage body fat, and a check for oral problems with a focus on dentition. Laboratory screening can include an evaluation for decreases in serum albumin (4 g/dL or less) or cholesterol (160 mg/dL or less).

Attention to underlying disorders and appropriate management is the primary focus. This may require referral or comanagement. Assisting with issues regarding food accessibility should include a list of phone numbers

of resource centers or individuals who can provide continuity in a schedule of regular meals and quality of those meals. Education of the senior patient of proper food intake through choice and preparation may be part of the services provided by the chiropractor or referred to focused sources such as a dietitian or other expert source.

**Physical/Verbal Abuse or Neglect**

Elder abuse or neglect is often undetected and may represent the most underreported type of domestic violence.<sup>80</sup> The National Center on Elder Abuse estimates that in 1996 there were over 1 million individuals over the age of 65 years who were mistreated.<sup>81</sup> Although there are laws in all states to protect the elderly from mistreatment, the specific criteria and penalties vary enormously. However, most states do require that all healthcare professionals report incidents of actual and suspected abuse. Types of mistreatment are numerous and include physical abuse, sexual abuse, emotional abuse, caregiver neglect, and material. When seniors have depression, dementia, falls, fractures, decubitus ulcers, or loss of weight, mistreatment must be considered. Screening with questions regarding who takes care of the individual or attempting to determine if the patient is afraid of his or her spouse or caretaker may initiate the dialogue. Frank questions about whether someone has struck or hurt the patient in any way must be approached delicately. About one-third of elderly patients who are mistreated deny abuse when questioned specifically. More alarming, physicians report as few as 2% of all cases.<sup>82</sup>

Table 54-10 Indicators of Possible Elder Abuse	
General Indicator	Specific Indicator
Elderly patient environment	Social isolation, primarily dependent on others, shared living environment, incontinence, dementia, or behavioral problems
Caregiver elements	Stress, substance abuse, mental or physical illness, dependence on elder for housing or finance, history of violence, unwillingness to leave elder alone with doctor, implausible explanation of physical injury
Physical findings in elderly patient	Depression, anxiety, dehydration, undernourished, weight loss, medical issues that go unresolved, bruises in unusual areas, patterned bruises, abrasions or burns, decubitus ulcers, clothing that is unclean or inappropriate for weather

The signs of mistreatment may be more clear when physical abuse has taken place. Emotional abuse or neglect is more difficult to detect. **Table 54-10** provides a list of risk factors and physical findings that suggest abuse.<sup>83</sup> **Table 54-11** suggests various avenues of management. Generally, the approach is to provide social support to reduce isolation, decrease caregiver stress, manage any medical issues, and evaluate the living environment to determine the need for a higher level of care.

**Table 54-11** Strategies for Managing Elder Abuse/Neglect

<b>Management Aspect</b>	<b>Specific Suggestions</b>
Prevent social isolation	Provide resource contacts for home health services, adult day-care or connection to senior center, meal-delivery services, and churches
Support for caregiver	Establish possible relief support for caregiver, connect to support groups to help deal with psychologic stresses, simplify activities by using central resource for medication and medical services
Determine home needs	Determine safety; provide resources for obtaining any special medical equipment; assess patient for activities of daily living performance; and determine need for caregiver or a higher level of care at a group home, assisted living, or skilled nursing facility

## Specific Management Issues

### Modification of Adjusting Procedures

There are a number of concerns to be considered when adjusting or manipulating the senior patient. The susceptibility of the elderly to injury varies; however, the primary issues are:

- Generally decreased flexibility and elasticity of soft tissue may predispose the elderly patient to a sprain-strain effect from treatment. Also, the senior patient, in an effort to assist with the doctor's positioning, often has difficulty relaxing in the end-range position for adjusting. This makes the adjustment more difficult and increases the possibility of overstretch.

- Generally seniors are more osteoporotic, which increases the risk of vertebral compression fractures and rib fractures with specific

positions and high-force approaches.

- Generally, the senior patient has more degenerative joint disease, which may include osteophyte formation into the neural foramina or spinal canal increasing the risk of nerve irritation.
- Generally, in the senior, early degenerative changes and/or lack of appropriate muscle tone and reaction result in functional instability.

Table 54-3 summarizes the specific focus for the senior patient including physical examination/history indicators, concerns, and modification options.

## Exercise Prescription

The ability to function, maintaining mobility and independence, is among the most important goals for the senior patient. It affects quality and, indirectly, quantity of life. The benefits of exercise are far-reaching and exponential. Individuals who exercise regularly have a better chance at preventing, slowing, or accommodating to the effects of many chronic diseases including congestive heart disease, coronary artery disease, diabetes, osteoarthritis, and intermittent vascular claudication, among others.<sup>84</sup> A regular exercise program combined with an appropriate diet is important for avoiding obesity and its consequences. Exercising has been shown to improve balance and decrease the chance of falling in the elderly. With exercise, joint reaction time is decreased and muscle mass is increased, which provides some protection from falls. A sedentary life due to lack of motivation or the consequence of chronic or progressive disease will often cause a downward spiral in function. Some of the most important concepts for older patients to understand are:

- Prolonged rest decreases and prolongs recovery.

- Moderate exercise does not increase the chance or progression of arthritis.
- Seniors can benefit from exercise in strength, flexibility, balance, and endurance.
- Osteoarthritis pain often responds to toning exercises even though existing degenerative changes (seen on radiograph) remain.

The primary concerns with exercise and the older patient include:

- Isometric exercises should not be performed at a maximum or held for longer than a few seconds due to the vascular effect of increased blood pressure.
- Sudden changes in posture may result in presyncope or syncope due to a blunted reflex vascular response causing a postural

hypotension (e.g., drug effect from antihypertensives or from diabetes).

- A safe aerobic exercise goal must be established for the older patient based on the patient's response to cardiopulmonary and endurance testing to determine cardiovascular response and avoid a cardiac event.
- Spinal flexion exercises place more stress on the vertebral body and have been shown to increase the risk of compression fracture.

## Preparticipation Evaluation

The preparticipation evaluation attempts to determine any known limitations, contraindications, or motivational issues with regard to an exercise program and to establish a baseline recommendation. Historical information on known chronic diseases including hypertension, chronic obstructive disease, coronary and cardiac disease, and orthopaedic limitations are important for determining exercise testing restrictions and future recommendations. Also needed is a list of medications, type of activities the individual is interested in, and availability of a facility or equipment (if appropriate).

Prior to exercise testing it is important to note the following absolute and relative contraindications:

- Absolute contraindications to office exercise testing

1. recent ECG changes or acute myocardial infarction
  2. unstable angina, third-degree heart block, or acute congestive heart failure
- Relative contraindications to office exercise testing
    1. uncontrolled hypertension
    2. cardiomyopathies, valvular heart disease, and complex ventricular ectopic arrhythmias
    3. uncontrolled metabolic diseases such as diabetes; thyroid or adrenal disorders

## General Cardiovascular Fitness

The office evaluation can be performed in approximately 20 minutes. The American College of Sports Medicine (ACSM) recommends cardiac treadmill stress-testing prior to engaging in vigorous exercise (i.e., > 60% of maximal oxygen uptake) for men over age 40 years, women over age 50 years, and all individuals who have cardiac risk factors with or without symptoms.<sup>85</sup> Because treadmill tests are generally unavailable in-office

for the chiropractor, referral for off-site testing or an in-office alternative testing approach is acceptable. Most physicians use the Kasch pulse recovery test to assess the patient's functional and aerobic capabilities.<sup>86</sup>

## General Musculoskeletal Evaluation

Although more formalized evaluation with equipment and testing protocols may be available, a general in-office approach may include:

- **Strength**—A general measure of upper body strength can be estimated using a dynamometer for grip strength and push-ups or modified pushups for proximal muscle (i.e., shoulder/elbow) strength; lower body strength may be estimated by watching a patient perform the sit-and-rise test. The patient leans back against a wall or door and slides down the surface bending the knees (no more than 90°) and then rises. The ability of the patient to perform and repeat this test is a good general screen for lower body strength.

- **Balance**—Balance can be assessed using Romberg's test or observing the patient rise from a seated position, walk 10 steps, turn, return, and sit.
- **Flexibility**—Low back and hamstring flexibility are often measured using the sit-and-reach test. Range-of-motion testing for other joints may aid in evaluating flexibility.

## Other Areas

- **Body mass index (BMI)**—BMI is a value used to determine, in particular, a threshold for obesity. It is determined by dividing body weight in kilograms by height in meters squared. A BMI over 25 indicates obesity. Skin-fold measurement may be used to estimate body-fat content.
- **Bone density**—In particular for the senior woman, bone-density estimation using x-ray absorptiometry may be useful in determining risk and/or degree of osteoporosis.
- **Lipid profile**—It is important to determine a baseline measure of lipids to measure the effect of exercise on these values.

Exercise prescription must take into account the limitations and needs established above. A summary of general recommendations is given in **Table 54-12**. In determining the frequency, duration, and intensity of exercises, a target heart range of 120–145 beats per minute or muscle fatigue in 8 to 12 repetitions is often used. More specifically, an exercise

target heart rate (ETHR) is determined by measuring the resting heart rate (RHR); determining the maximum heart rate (MHR) through exercise tolerance testing or through an estimate by subtracting the patient's age from 220; and estimating the exercise target heart rate using the following formula:  $ETHR = P \times (MHR - RHR) + RHR$

where P equals the percentage of MHR desired; for seniors P is between 60% and 80%.

Many seniors can surpass these cautionary limitations. Generally, two indicators are used for aerobic activities: **1. Metabolic equivalents (METs):** 3.5 mL of O<sub>2</sub> per kg of body weight per minute. Estimated METs for common activities include:

- bowling or playing music: 2–4 METs
- pleasure cycling, social dancing, walking while golfing carrying a bag, stair climbing, swimming, tennis, skiing downhill: 3–9 METs
- running, cross-country skiing, aerobic dancing: 6–12 METs

**2. Borg Scale of Perceived Exertion:**<sup>87</sup> A scale from 0 to 20 based primarily on the individual's ability to talk while exercising and with his or her perceived muscle fatigue with exercise.

- 7 = very, very light exertion
- 9 = very light
- 11 = light
- 13 = moderate
- 15 = heavy
- 17 = very heavy
- 19 = very, very heavy

**3. Light** is considered about 30% to 49% maximum oxygen uptake, while **heavy** is about 85% maximum oxygen uptake.

**Table 54-12** General Exercise Recommendations for the Older Patient

Element	Recommendations
Cardiovascular/Pulmonary Capacity	Perform a minimum of 30 minutes of physical activity, preferably aerobic, most days of the week.
Strength	<ul style="list-style-type: none"> <li>• Perform 1–3 sets of 8–12 repetitions 2–3 times per week with emphasis on both upper and lower body exercises.</li> <li>• If osteoporotic, begin with aquatic or bicycling, progress to walking, and gradually introduce weight training while weight bearing.</li> <li>• Include balance training and emphasis on strong lower body strength to prevent falls.</li> </ul>
Flexibility	<ul style="list-style-type: none"> <li>• Perform 6–10 general body stretches before and after activity; use prolonged stretch while continuing to breathe; do not hold breath creating a prolonged isometric contraction.</li> </ul>

	<ul style="list-style-type: none"> <li>• Emphasize the combination of lower body strength and flexibility to maintain mobility.</li> </ul>
Weight	<ul style="list-style-type: none"> <li>• For men: 12% to 20% fat; lean body mass between 125 and 150 lbs.</li> <li>• For women: 20% to 30% fat; lean body mass between 90 and 110 lbs.</li> <li>• Emphasize the combination of diet and exercise in maintaining proper weight.</li> <li>• Diet should include plenty of fruits/vegetables, and patient should be educated in reading labels in order to make proper choices.</li> </ul>

## Osteoarthritis

A recent literature review of athletes and osteoarthritis (OA) reveals some interesting findings:<sup>88</sup>

- Runners older than 60 years running three hours per week for 12 years showed no greater prevalence of OA when matched to nonrunning controls (they did demonstrate a 40% greater bone density of vertebral bodies).
- Radiographic evidence of OA in a group of middleaged runners was associated with genu varum, a history of a prior major joint injury, and more years of long distance running.
- Those with knee ligament or meniscal injury demonstrated a higher risk of developing degenerative changes earlier.
- Other factors that may be considered in some athletes are joint incongruity or joint dysplasia, muscle weakness, neurologic deficits, and increased weight.
- The ability to repair articular damage decreases with age; therefore, the healing response is less efficient as one ages.

What is clear clinically and substantiated in some literature reports is that moderate activity is beneficial to joints. It is also clear that, radiographic findings notwithstanding, patients improve symptomatically with toning exercises for the involved joint or joints. For weight-bearing joints, it is often helpful to begin with non-weight-bearing simulations of weight-bearing activities. For example, pool (aquatic) training is a valuable initial exercise prescription for those with lower extremity OA. Muscles must function against the resistance of water; however, the load applied is decreased due to the buoyancy of the water. Also there is no direct impact loading of body weight as would occur with walking, jogging, or running. Bicycle riding is also a great alternative, allowing passive and active range of motion with minimal loading of the joint. This accomplishes both goals of decreasing impact loads to the knee and

toning of muscles around the knee joint. With walking, a lateral heel wedge is often beneficial for relieving the pain of an osteoarthritic knee. As the medial meniscus degenerates, patients with OA develop a varus deformity or a closing down on the inside of the knee. A lateral heel wedge biomechanically shifts weight, opening up the medial joint area.

Nutritional management includes both glucosamine and chondroitin sulfate. Glucosamine seems to stimulate regeneration of articular cartilage and prevent its breakdown. Chondroitin draws fluid into cartilage, which helps to draw in nutrients. Recommended doses vary based on the size of the individual, but, in general are 1,500 mg of glucosamine sulfate and 1,200 mg of chondroitin sulfate. These daily doses should be divided into two to four doses and taken with food.

## CHAPTER 55

# The Female Patient

### Context

The female patient presents a unique challenge to the chiropractor. Many of the distinctions between male and female presentations are based on hormonal differences manifested often as gynecologic dysfunction or pathology. The inclusion of gynecologic differentials often requires that physical examination skills include breast and pelvic evaluation. For many chiropractors, examination skills and expertise are limited in these areas and would therefore affect the course and scope of evaluation. For example, in the evaluation of abdominal or pelvic pain, a pelvic examination is requisite in evaluating gynecologic causes. If the chiropractor is not experienced in pelvic examination, referral to the patient's obstetrician/gynecologist is necessary to complete a comprehensive search for cause. However, for many complaints, a clinical impression may still be gained through appropriate questioning resulting in either a limited trial of treatment or a referral for further testing or management.

Until recently, women were considered a subcohort of men; therefore, separate research studies for women were not performed. Also, women were excluded due to concerns regarding the effects of pregnancy or hormonal changes on the results of treatment studies. Most research efforts were directed at men with the assumption that the results could be extrapolated to women. Several major historical changes have updated the focus and strategic approach to research:

- In 1983, the U.S. Public Health Task Force on Women's Health Issues was established.
- In 1990, the National Institutes of Health (NIH) established the Office of Research on Women's Health.
- In 1991, the Women's Health Initiative (WHI) (a large prevention-based study) was developed.

One of the largest prospective studies, the Nurses' Health Study, evaluated women for 20 years (and continues to follow patients).<sup>1</sup> Interesting findings include the following:

- A strong relation between weight gain, heart disease, and mortality
- A lack of relation between calcium and osteoporotic fractures
- A positive relation between postmenopausal hormone use and the risk of breast cancer

Through ongoing research, several important differences have surfaced regarding women's health compared with men's health:<sup>2</sup>

- Women live longer than men.
- Women (primarily through what is believed to be an estrogen-protective effect) develop cardiac disease 10 years later than men, on average.
- Women may present atypically for heart disease; in particular, cardiac ischemia (i.e., dizziness, headache, or backache instead of chest discomfort).
- Women have a higher incidence of certain types of sports injuries; in particular, at the knee (e.g., anterior cruciate ligament).
- Women may have different nutritional needs than men.
- In addition to gender-specific disorders, women have a higher incidence of certain disorders including migraine headache, depression, specific immune-mediated diseases (e.g., rheumatoid arthritis, systemic lupus erythematosus, multiple sclerosis, Graves' disease, and thyroiditis), cholelithiasis, eating disorders, urinary incontinence, obesity, progressive scoliosis, osteoporosis, and osteoporotic-related fractures, among others.

Among women ages 24 to 34 years in the United States, the leading causes of death are accidents, homicide, and suicide. From ages 45 to 54 years, the leading causes of death are ischemic heart disease (IHD) and lung cancer. In women ages 65 to 74 years, the leading causes of death in order are IHD, lung cancer, cerebrovascular disease, and breast cancer.<sup>3</sup> IHD is, by far, the leading cause of death overall with a mortality rate five to six times higher than that of lung or breast cancer.

The top ten cancers in women (listed in order) are:

- 1.** Breast
- 2.** Lung
- 3.** Colorectal
- 4.** Uterine/Cervical
- 5.** Urinary tract
- 6.** Lymphoma
- 7.** Melanoma
- 8.** Thyroid
- 9.** Ovarian
- 10.** Leukemia

A Creighton School of Medicine study stated that vitamin D could cut the risk of any cancer by 60%.<sup>4</sup> A regimen of 15 minutes of sun exposure two to three times a week or 1,000 IUs of vitamin D with 1,400 to 1,500 mg of calcium per day was shown to be effective in reducing cancer risk. Vitamin D3 versus D2 is the recommended version.

The focus of this chapter is on issues specific to women. Many disorders are just as likely to be seen in either gender, and these conditions are covered in other areas of this text. Also, some female-related conditions are discussed under the related symptom-based chapter (e.g., the chapter on abdominal pain includes pelvic inflammatory disease, ectopic pregnancy, and dysmenorrhea). For those issues that are related to menstruation or not covered in detail in other areas of this text, a more detailed approach and description are given.

## General Strategy

### Evaluation

For female patients there are generalized guidelines for evaluation based on age and potential risks. While recommendations vary, a general summary follows:

- Screen for a family history of cancer, heart disease or hypertension, osteoporosis, depression, rheumatic diseases, headache, obesity, and diabetes.
- Perform or refer for the following screening examinations based on age-related concerns:
  1. blood pressure: every 2 years (if normal)<sup>5</sup>
  2. clinical breast examination: every 3 years for ages 20 to 39 years, then annually thereafter<sup>6</sup>
  3. mammography: every 1 to 2 years for women ages 40 to 49 years, annually for women ages 50 to 69 years (controversy exists regarding the benefits of screening annually after age 69 years)<sup>7, 8</sup>
  4. pelvic examination: every year
  5. Papanicolaou (Pap) smear testing: beginning at age 18 years or when a woman becomes sexually active, every year until three satisfactory results, then future testing is based on doctor's discretion (usually every 3 years thereafter); Pap smears can be discontinued in women after age 65 years<sup>9</sup>
  6. eye examination: once between puberty and age 40 years, then every 2 to 4 years through age 64 years, then annually after age 65 years; high-risk groups for screening of glaucoma include African

American women over age 40 years and Caucasian women over age 50 years<sup>10</sup>

- 7.** fasting plasma glucose: every 3 years if at high risk such as obesity or family history
  - 8.** cholesterol (total and high-density lipoprotein [HDL]): every 5 years (if normal)<sup>11</sup>
  - 9.** fecal occult blood: every year after age 50 years<sup>12</sup>
  - 10.** colorectal cancer testing (sigmoidoscopy, colonoscopy, barium enema, digital rectal exam): every 5 to 10 years based on familial risk
  - 11.** skin self-exam: monthly and every 3 years by a physician and annually for over age 40 years<sup>13</sup>
  - 12.** thyroid stimulating hormone: every 3 to 5 years in patients over age 65 years<sup>14</sup>
  - 13.** bone mineral density testing: use for screening purposes in high-risk females
- Evaluate the patient's nutritional status with a focus on common deficiencies such as:
    - 1.** inadequate calcium or vitamin D in all women
    - 2.** iron deficiency, B<sub>12</sub> and folate deficiency, and gestational diabetes in the pregnant patient
    - 3.** iron deficiency, calcium/vitamin D/phosphorous deficiency in athletic females
    - 4.** calcium/vitamin D/phosphorous and iron deficiency in the elderly female
  - Evaluate patient's weight and make recommendations regarding appropriate diet and exercise for weight loss when appropriate.

The general strategy for the symptomatic patient includes:

- Consider the most common conditions that are seen in females.
- Consider the atypical (compared with males) presentation for cardiac disease (e.g., dizziness, headache, backache).
- Be vigilant for detection of signs and symptoms related to possible abuse.

For the athletic patient, the general strategy is as follows:

- Screen for regional weakness; in particular, the upper extremity.
- Screen for indicators of generalized joint instability, paying particular attention to the knee and shoulder.
- Screen for patellar tracking abnormalities.
- Watch for indicators of the female athlete triad: disordered eating, amenorrhea, and osteoporosis.

- Make recommendations with regard to specific nutritional demands for the female athlete (i.e., iron and calcium).
- Watch for signs of stress fractures, especially of the tibia and proximal femur.

For the pregnant patient, the strategy includes the following:

- Reinforce the need for regular prenatal check-ups with the patient's chosen specialist.
- Support prenatal recommendations regarding supplementation of folate and possibly iron, avoidance of alcohol and smoking, control of diabetes, adequate weight gain during pregnancy, and safe exercise.
- Monitor patient's blood pressure.
- Be alert to hyperthyroidism, postpartum blues and depression, and endometritis (uterine infection following birth [more common after caesarean section] or abortion) in the postpartum patient.

For the postmenopausal patient, the strategy is as follows:

- Pay particular attention for signs of osteoporosis.
- Watch and screen for indicators of diminishing cognitive function.
- Watch and screen for signs of breast cancer.
- Watch and screen for signs of colon cancer.
- Pay attention to psychosocial needs of women living alone.

## **Management**

For all female patients, management consists of the following:

- Stress the importance of monthly breast and skin self-exams.
- Ensure that the patient has an established routine of periodic health check-ups and counseling/education to address age-related concerns for females.
- Give advice with regard to the general benefits of exercise, nutrition, and smoking cessation in relation to prevention of obesity, heart disease, and diabetes.
- Provide information with regard to reducing the risk of osteoporosis.
- Modify adjusting procedures based on differences in anatomy and with pregnancy.

For patients with diagnosed or suspected conditions, management consists of the following:

- Refer patients with suspected gynecologic pathology.
- Manage musculoskeletal complaints with an emphasis on stability, pain reduction, and maintenance of as much joint mobility as possible.

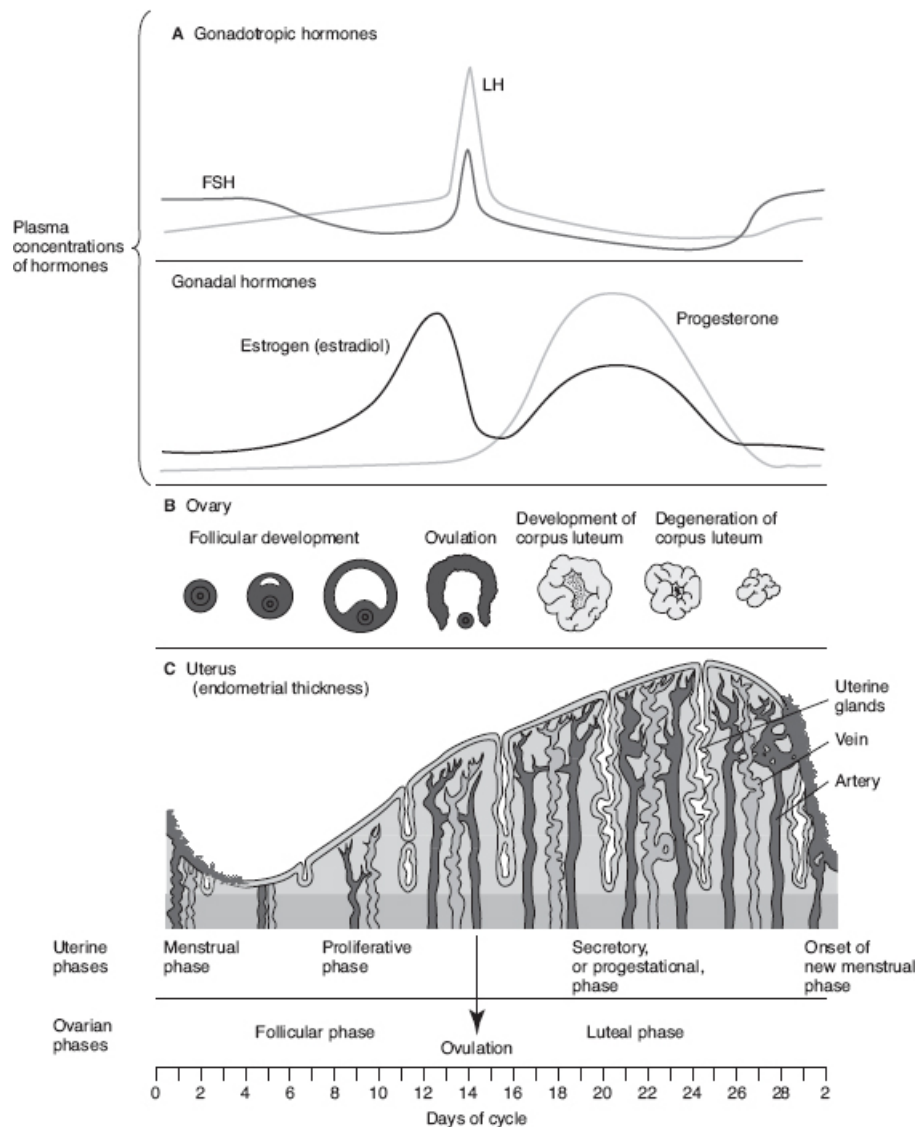

# Female Hormonal and Reproductive Physiology

The balance of reproductive hormones with endocrine and target organ interaction is a complex but essential coordination necessary for sexual development, puberty, and menarche. Ovulation and menstruation do not occur or are abnormal if the required level and balance of hormones and endocrine function are not correctly timed. Estrogen and progesterone have stimulating effects on reproductive target organs such as the breasts, uterus, and vagina. Through negative and positive feedback loops with the central nervous system (CNS)-hypothalamic-pituitary axes, estrogen and progesterone join with the gonadotropins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH), in providing the correct balance for ovulation, pregnancy, or menstruation.

LH and FSH, although elevated at birth, are at low levels until puberty. Adrenal androgens dehydroepiandrosterone (DHEA) and DHEA sulfate (DHEAS) seem to initiate the development of pubic and axillary hair growth due to gradual increases seen during the few years preceding puberty.

The menstrual cycle is divided into different phases based on whether the uterine changes are the prime focus or whether endocrine changes are the primary focus. With uterine changes as the focus, there are three phases (see **Figure 55-1**):

1. Menstrual phase: shedding of endometrium with vaginal bleeding; first week of cycle

**Figure 55-1** Physiologic events of the normal menstrual cycle. During days 1 to 14, the egg follicle in the ovary grows to maturity. The abrupt rise in luteinizing hormone (LH) as ovarian estrogen production increases during the first 2 weeks of the cycle triggers ovulation. The corpus luteum then develops and functions until it disintegrates at cycle's end if the egg is not fertilized. These events are reflected indirectly by visible and palpable changes in cervical mucus.

2. Proliferative phase: estrogen release from ovaries stimulates proliferation of endometrium; second week of cycle
3. Secretory phase: progesterone release from ovarian follicle stimulates endometrial secretion in preparation for implantation of the embryo; final two weeks of cycle

When the focus is on endocrine changes, the phases are described as follows:

1. Follicular (preovulatory) phase: first day of menses to the day before the LH surge

2. Ovulatory phase: release of the ovum from the Graafian follicle (i.e., ovulation) due to LH surge occurring approximately 16 to 32 hours after the surge
3. Luteal (postovulatory) phase: cells of the follicle reorganize to form the corpus luteum, which secretes increasing amounts of progesterone peaking at about six to eight days after the LH surge

The sequential hormonal events of the cycle proceed as follows:

- Low levels of estrogen and progesterone released from the ovaries cause the secretion of releasing factors from the hypothalamus. These releasing factors cause the anterior pituitary to release FSH and LH. The FSH increase stimulates primordial follicles, with one follicle becoming dominant.
- This dominant follicle matures and secretes estrogen causing proliferation of the endometrial lining of the uterus and the breast's glandular and ductal tissue. With increasing estrogen levels, FSH decreases while LH increases dramatically. The LH increase is referred to as the LH surge.
- This LH surge is necessary for the follicle to release an egg (i.e., ovulation). Ovulation then occurs at around the 14th day of a 28-day menstrual cycle. The corpus luteum inside the ruptured follicle develops and secretes progesterone. Due to the thermogenic effect of progesterone, basal body temperature rises about 0.5°C (0.9°F) and remains elevated until menstruation begins. Progesterone prevents further development of the endometrium and stimulates differentiation into a secretory epithelium in preparation for implantation of the embryo. Progesterone also has an inhibitory effect on LH secretion.
- If conception does not occur by day 23, low levels of LH cause the degeneration of the corpus luteum. Levels of progesterone and estrogen then drop.
- If fertilization does occur, the fertilized ovum travels from the fallopian tube to the uterus for implantation. The trophoblastic cells of the outer layer of the embryo (precursors of the placenta) secrete human chorionic gonadotropin (hCG). Serum level of hCG is the primary laboratory indicator of pregnancy.

During adolescence, ovulation does not occur initially. Gonadotropin levels must reach a level high enough to stimulate development of ovarian follicles, which in turn produce estrogen, which in turn leads to the necessary LH surge leading to ovulation. This LH surge may not occur until as late as five years postmenarche. Approximately 75% of abnormal bleeding in the adolescent is due to immaturity of this system.<sup>15</sup>

Dysfunctional bleeding occurs in the perimenopausal (before menopause) woman because of the decreased sensitivity of the ovary to FSH and LH. The resulting decrease in estrogen prevents the LH surge necessary for ovulation. However, similar to the adolescent, there is still enough estrogen being produced to stimulate endometrial growth. Without the balance of progesterone (that would normally be produced by the corpus luteum), the endometrium becomes extremely vascular and friable, leading to intermittent sloughing. This type of bleeding is often referred to as estrogen withdrawal bleeding. Estrogen breakthrough bleeding may be due to (1) constant low levels of estrogen, causing portions of the endometrium to degenerate (often seen with low-dose oral contraceptive use) and (2) high levels of estrogen, which allow the endometrium to become hyperplastic and outgrow its blood supply, leading to degeneration and often profuse bleeding. Another type of hormonal imbalance bleeding is progesterone withdrawal and breakthrough bleeding. This is usually the result of exogenous administration of progesterone.

## **Focused Issues**

### **Menstrual-Related Concerns**

#### **Amenorrhea**

Amenorrhea is generally classified into primary, if menarche has not occurred by age 16 years, and secondary, when menses have ceased for at least three months. Amenorrhea is normal before menarche, during pregnancy and early lactation, and after menopause. Pathologic causes of primary amenorrhea include both anatomic abnormalities such as cervical stenosis or imperforate hymen, or vaginal or uterine aplasia. These conditions are rare and will generally be evident prior to the age of menarche. Hormonal imbalances or dysfunction of the hypothalamic-pituitary-gonadal-uterine axis and endocrine dysfunction are the most common causes of amenorrhea. There are many influences on hypothalamic function including modifiable factors such as weight loss (including anorexia nervosa), emotional stress, and excessive exercise. Rarer causes include tumors, Prader-Willi syndrome, or Kallmann syndrome. Metabolic abnormalities include adrenal and thyroid dysfunction, medications (e.g., antipsychotics and antidepressants), androgenic tumors, obesity, and polycystic ovary syndrome.

Investigation for amenorrhea should occur with the following presentations:

- No signs of puberty by age 13 years, or menarche has not occurred by age 16 years, or five or more years have passed since puberty without menarche
- Women who have had menses, however, are amenorrheic for three or more months or who have fewer than nine menses per year

For the girl who has not achieved menarche, it is important to have anatomic abnormalities ruled out. Second, an evaluation of normal secondary sexual characteristics development using a Tanner scale (see [Chapter 53](#)) is useful. Abnormalities in this development suggest hormonal imbalances due either to congenital problems or possible tumor.

The most common source of amenorrhea other than pregnancy is lifestyle excess and its effect on hypothalamic dysfunction. Questioning with regard to diet, dieting, weight loss, excessive stress, and excessive exercise often reveals a potential underlying cause.

The congenital or developmental abnormalities that may cause amenorrhea are complex and should be referred to a specialist; however, indicators that may necessitate the referral include:

- signs of androgen imbalance indicated by virilization (masculinization), hirsutism, a deep voice, balding, increased muscle mass, clitoromegaly, or galactorrhea
- abnormal development of the breasts or genitalia or abnormalities in the growth of pubic hair or its distribution
- internal obstruction to menstrual outflow would be difficult to ascertain; however, it may be represented by a bulging vagina or pelvic mass (accumulation of menstrual blood or distention of uterus)

Laboratory investigation for amenorrhea is complex; however, it is based on a sequential approach:

- A basal measure of thyroid stimulating hormone (TSH), FSH, and prolactin may be helpful; when prolactin is increased, it needs to be remeasured due to increases found with stress, sleep, or food stimuli. When prolactin is increased with normal thyroid, a prolactin-secreting tumor is possible. When prolactin is normal with an increased TSH, hypothyroidism is the cause (although increased prolactin may occur). Increased FSH suggests ovarian failure.
- If the above tests are normal, and there are signs of hirsutism or other androgen effects, total serum testosterone and DHEAS tests should be ordered. Testosterone greater than 200 ng/dL indicates an androgen-producing tumor. If the levels are twice as high, an adrenal neoplasm is likely.
- Other testing may include a check for Cushing's syndrome (check for cortisol excess) or a measure of LH to help distinguish between

polycystic ovary disease versus hypothalamic or pituitary dysfunction. With polycystic ovary disease there are increases in LH, whereas LH and FSH are generally normal or decreased with hypothalamic or pituitary disease. If pituitary disease is suspected, a radiograph of the sella turcica is warranted. If positive for possible tumor, magnetic resonance imaging (MRI) or computed tomography (CT) scan to determine the extent is then necessary.

Management of amenorrhea is obviously based on the suspected underlying mechanism. **Table 55-1** lists some medications used to manipulate the hormonal status of females including use for birth control and dysfunctional bleeding. For those found to have polycystic ovary disease, there is no known treatment, although hormonal manipulation may be possible if pregnancy is desired. For those with possible structural abnormalities or hormonal imbalance (including neoplasm induced), referral for appropriate therapy is required. Those who have no known structural or hormonal imbalance may benefit from modification of exercise, stress, and diet. This would be most common in the high-level female athlete.

**Table 55-1** Medications Affecting Hormonal Status of Women

Drug Class	Examples	General Mechanism	Interactions/Side Effects
<b>Estrogen (conjugated) and esterified</b>	C.E.S. Premarin Cenestin Progens Estratab Menest Menrium Neo-Estrone Kestrone	A short-acting estrogen used in the treatment of atrophic vaginitis, postmenopausal symptoms, postmenopausal osteoporosis, and abnormal bleeding, and palliative treatment of both breast and prostate carcinoma.	May cause libido changes, depression, nausea, mastodynia, hypertension, and thromboembolic disorders.
<b>Estrogen-progestin combinations</b>	<i>Monophasic</i> Alesse Demulen Desogen Levlite Levora Loestrin Necon Nordene Ogestrel Others <i>Biphasic</i> Jenest Kariva Mircette Others <i>Triphasic</i> Ortho-Cept Triphasil Trivora Others	In addition to oral medications listed to the left, there are transdermal (Ortho Evra), intravaginal (Nuva Ring), and postcoital contraceptives (Plan B, Preven). Monophasic has the estrogen and progestin amounts remain the same. Biphasic has the estrogen remain the same with progestin initially less in first half of cycle, and increased in second. Triphasic has the progestin vary and the estrogen remains the same or varies. Prevents ovulation and creates a hostile environment for sperm.	May cause early or midcycle breakthrough bleeding, nausea, gallstones, thrombotic disorders such as thrombophlebitis, decreased glucose tolerance pyridoxine deficiency, vaginal candidiasis, weight gain, paresthesias, hypertension, and chloasma.
<b>Progesterone</b>	Crinone gel Gesterol Progestaject Progestasert Prometrium	Transforms endometrium from proliferative to secretory state and has pituitary gonadotropin secretion suppression as another effect. Not used as much due to newer medications. Can be used for secondary amenorrhea, dysfunctional uterine bleeding, and premenstrual syndrome.	May cause breakthrough bleeding, many GI symptoms, migraine headache, weight change, dizziness, and possible thromboembolic disorders.
<b>Danazol</b>	Cyclamen Danocrine	A synthetic androgen derivative from testosterone used in the management of endometriosis and fibrocystic breast disease. Causes a reduction in FSH and LH leading to anovulation and amenorrhea.	May cause hypersensitivity reaction, weight gain, hair loss, deepening of voice, breast reduction, hot flashes, hirsutism, irregular menstrual periods/amenorrhea, dizziness, tremor, and rarely hepatic damage. May increase LDL cholesterol.
<b>Tamoxifen</b>	Nolvadex Nolvadex-D Tamofen	Competes with estradiol and estrogen receptors causing a strong anti-estrogen effect. Used in the palliative treatment of advanced breast cancer in postmenopausal women and adjunctively with surgery for women with breast cancer and positive lymph nodes.	May cause hot flashes, thrombosis, leucopenia, thrombocytopenia, with nausea and vomiting occurring in about 25% of patients.

## Premenstrual Syndrome

Premenstrual syndrome (premenstrual tension) is a hormone-mediated, varied response to fluctuating levels of progesterone and estrogen. The timing of the onset of symptoms is characteristically 7 to 10 days prior to menses (luteal phase) and improves within hours to days following the onset of menses (although dysmenorrhea may then appear). Symptoms

vary in severity and frequency from woman to woman but generally represent the consequences of emotional lability (e.g., mood swings, anxiety, depression) and hormonal effects on neuroendocrine function including headaches, food cravings, fluid retention, breast tenderness or fullness, and back pain. When premenstrual syndrome (PMS) is chronic and severe, a psychologic disorder may be the primary source; it is referred to as premenstrual dysphoric disorder (PDD).

The theories proposed to explain why PMS symptoms occur and why they vary from woman to woman include the following:

- Some women may metabolize progesterone differently with the result of less allopregnanolone (enhances gamma-aminobutyric-acid [GABA]) resulting in a pregnenolone increase that decreases GABA effects.
- Serotonin levels decrease.
- There is estrogen excess or progesterone deficiency (through stimulation of the renin-angiotensin system, increased levels of aldosterone lead to fluid retention).
- Thyroid dysfunction exists. (Hypothyroid state may lead to increased levels of prolactin, which has been associated with increased PMS in some studies.)
- There are nutritional imbalances in B<sub>6</sub> and magnesium, altered blood sugar levels, and prostaglandin imbalance (see **Table 55-2**).
- Psychological factors exist.

Recommendations for conservative management include:

- Exercise. Although no specific exercise appears to have benefit, exercise may help decrease the frequency or intensity of PMS symptoms.<sup>16</sup>
- Smoking cessation
- Diet. Recommendations for diet modifications include:
  1. Eat small, regular meals.
  2. Follow a low-fat or vegetarian diet; limit red meats, dairy products, foods with a high sugar content, and fried foods.
  3. Increase carbohydrate consumption with a temporary reduction in protein.
  4. Limit or eliminate caffeine and alcohol.
  5. Increase dietary fiber and water (increase to six to eight glasses/day for natural diuresis).
- Spinal manipulation. Most studies have tested the treatment effect for dysmenorrhea; however, some studies<sup>17, 18</sup> have indicated manipulation has a positive effect on PMS.

Medical therapeutic approaches include:

- Serotonin reuptake inhibitors (e.g., fluoxetine and nefazodone)
- Hormones (e.g., oral contraceptives, Danazol [testosterone derivative], and Lupron [a gonadotropin-releasing hormone agonist])
- Benzodiazepines (e.g., alprazolam [Xanax] taken during the luteal phase)

## Dysmenorrhea

Dysmenorrhea is classified as either primary or secondary. Primary dysmenorrhea is common and is considered a functional problem without an underlying pathologic cause. Secondary dysmenorrhea is due to a pathologic etiology that, in most cases, represents endometriosis. Other causes include a tight cervix, endometrial polyps, or pelvic inflammatory disease.

Primary dysmenorrhea usually begins in adolescence and diminishes with age and/or after pregnancy. There is a wide range of severity among women, yet a given woman generally has a baseline of discomfort that is consistent with each period. The patient is at least one to two years postmenarchal with increasing pain associated with menses. The pain is felt in the lower abdomen and pelvis, sometimes radiating to the back or inner thighs. The pain may begin before or with menses, peaking after 24 hours. Discomfort continues, on average, approximately two days after the onset. Some possible structural factors include a narrow cervical os or malposition of the uterus. Functional relationships have been found with lack of exercise and with anxiety.

Pain is mediated via prostaglandins. The cause is a combination of vasoconstriction and myometrial contraction leading to uterine ischemia. Increased discomfort may be caused by fluid retention (estrogen causes salt retention). No examination usually is necessary unless the pain is “new” or suddenly increased. Then a pelvic examination is warranted. With primary dysmenorrhea there are no obvious pathologic findings, but the examination may be more uncomfortable during menses.

**Table 55-2** Nutritional Support for Premenstrual Syndrome

Substance	How Does it Work?	Dosage	Special Instructions	Contraindications and Possible Side Effects
<b>Primrose oil</b>	Source of omega-6 fatty acids (in particular, gamma linolenic acid [GLA]), which act as precursors to synthesis of prostaglandin E <sub>1</sub> (anti-inflammatory prostaglandin).	1,000 to 2,000 mg/day (researchers have used as high as 3,000 to 6,000 mg/day, which provides 270–540 mg of GLA).	None.	None at recommended dosage.
<b>Flaxseed and borage oil</b>	Source of omega-3 fatty acids, which are precursors to synthesis of anti-inflammatory prostaglandins.	1–2 tablespoons flaxseed daily.	Keep refrigerated; keep away from light; do not heat.	None at recommended dosage.
<b>Vitamin B<sub>6</sub></b>	Cofactor in the production of dopamine.	50 to 500 mg/day.	None.	Dosages above 600 mg/day have been associated with peripheral neuropathy.
<b>Vitamin E</b>	Possible reduction in breast pain.	100 to 400 IU/day.	None.	None at recommended dosage.
<b>Magnesium</b>	Cofactor in the production of dopamine.	400 to 1,000 mg/day.	None.	High dosage may cause diarrhea.
<b>Valerian</b> ( <i>Valeriana officinalis</i> )	Unknown; however, used for anxiety and as a sleep aid.	2 to 3 g taken 1–3 times/day.	Valerian smells bad even when encapsulated. The active ingredients are unstable, therefore, should use only fresh valerian.	Should not be taken during pregnancy or with drugs used to treat anxiety or as sleep enhancers.
<b>St. John's wort</b> ( <i>Hypericum perforatum</i> )	Works synergistically with 5-HTP; also anti-inflammatory and analgesic properties.	(0.3% hypericin content) 300 mg. 3 times/day (as high as 600 mg 3 times/day for some patients).	If taken with 5-HTP, reduce 5-HTP dose to 100 mg/day.	Possible mild stomach irritation; may cause photosensitivity of skin in fair-skinned individuals; rarely allergy, tiredness, weight gain, headache, or restlessness.

*Note:* The above substances have not been approved by the Food and Drug Administration for the treatment of this disorder.

Key: HTP, hydroxytryptophan.

Management of primary dysmenorrhea draws from a variety of therapeutic interventions. Some examples of conservative approaches include:

- Exercise. Studies indicate that exercise may decrease the frequency or intensity of pain with dysmenorrhea.<sup>19</sup>
- Nutritional and herbal supplementation. Magnesium, calcium, omega-3 polyunsaturated fatty acids, and vitamin B<sub>12</sub> are recommended (see **Table 55-3**).
- Spinal manipulation. Studies<sup>20, 21</sup> indicate a possible benefit with the use of spinal manipulative therapy. A recent study<sup>22</sup> failed to determine the superiority of a low-force mimicking maneuver versus a high-velocity, short-lever, low-amplitude, high-force manipulation approach.

- Stimulation of sacral and low-back reflex points. Stimulation via acupressure, electrical stimulation,<sup>23</sup> or acupuncture may provide relief.<sup>24</sup>

**Table 55-3** Nutritional Support for Dysmenorrhea

Substance	How Might It Work?	Dosage	Special Instructions	Contraindications and Possible Side Effects
Niacin	Relieves menstrual cramping.	200 mg/day throughout menstrual cycle and 100 mg/day every 2–3 hours while having menstrual cramping (may be combined with 300 mg of vitamin C and 60 mg of rutin/day to increase effectiveness).	Generally not effective unless taken 7–10 days prior to menstrual flow.	A flushing effect, headache, and stomachache may occur with high doses of niacin. Also high doses should not be taken if the patient has gout, diabetes, liver damage, or eye damage.
Calcium	Maintains normal muscle tone.	1,000 mg/day throughout the month; during cramping, 250–500 mg every 4 hours for a total of 2,000 mg/day.	Some sources of calcium such as bonemeal, oyster shell, dolomite, and amino acid chelates may contain lead.	Calcium supplementation should not be used in individuals with sarcoidosis, hyperparathyroidism, chronic kidney disease, or milk-alkali syndrome.
Magnesium and vitamin B <sub>6</sub>	Possible decrease in menstrual cramping.	400 mg/day throughout the cycle; 100 mg/2 hours as needed during menses.	None.	High doses of magnesium may cause diarrhea.
Omega-3s (EPA & DHA)	Source of omega-3 fatty acids increases anti-inflammatory prostaglandins.	1,000 mg of EPA and 700 mg of DHA daily for at least 2 months.	None.	Long-term use of fish oils at more than 3–4 g/day may cause problems due to elevated blood sugar, cholesterol, or glucose levels. Side effects may then include nose bleeds or gastrointestinal upset.
Cramp bark ( <i>Viburnum opulus</i> ) Black Haw ( <i>V. prunifolium</i> )	A spasmolytic effect on the uterus.	Extract is a tea combination with Black Haw Bark, camomile flowers, and peppermint leaves.	None.	None.
Black cohosh	Has a weak estrogen-like effect to help reduce hot flashes. May decrease levels of luteinizing hormone.	Highly concentrated extract at 40 mg 2 times/day in a 40%–60% alcoholic extract.	Because long-term studies have not been conducted, it is recommended to limit to 6 months of usage.	Not to be used in pregnant or lactating women. Women on ERT should consult prescribing doctor. High doses may cause abdominal pain, nausea, headaches, and dizziness.
Blue cohosh ( <i>Caulophyllum thalictroides</i> )	Mild estrogenic, spasmolytic effect.	0.3–1 g of drug or 0.5–1 mL of liquid extract.	None.	Should not be used during the first 3 months of pregnancy due to estrogenic effects.

*Note:* The above substances have not been approved by the Food and Drug Administration for the treatment of this disorder.

*Key:* EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid; ERT, estrogen replacement therapy.

Secondary dysmenorrhea is usually due to endometriosis or other pelvic pathology. A pelvic examination followed by special imaging may help

identify the site, extent, and type of lesion (also see [Chapter 31](#) and [Table 55-5](#)).

## Menopause

Natural menopause represents an age-related ovarian failure. Progressive decline in pituitary gonadotropins (FSH and LH levels) results in shorter menstrual cycles with fewer ovulations and a decrease in progesterone. This progressively leads to failure of the follicle to respond due to low levels of hormones and correspondingly results in less estrogen production. As a feedback loop, this is followed by increased levels of LH and FSH in response to decreased estrogen. Most of the circulating estrogen in postmenopausal women is due to conversion of androgens to estrogens in primarily fat cells and the skin. During this transitional phase, referred to as the climacteric or perimenopausal period, the frequency of bleeding eventually is less often and irregular; however, prior to this, there is often a phase of increased bleeding that is irregular and unassociated with ovulation. This type of anovulatory bleeding is the most common cause of “abnormal” bleeding in the perimenopausal female. Menopause may also be induced through surgery, medication (usually chemotherapy), radiation, or trauma to the ovarian blood supply.

When menses have not occurred for one year, the female has reached menopause. This occurs on average at age 50 or 51 years in the United States. Any vaginal bleeding that does occur in a female who apparently has reached menopause or has not had any vaginal bleeding for six months should be further evaluated. Premature menopause is defined as occurring before age 40 years and is of unknown origin. There have been associations to smoking, nutritional deficiencies, or high-altitude living.

Clinical manifestations of menopause include:<sup>25</sup>

- Decreased circulating levels of estrogen appear to affect the CNS via the hypothalamus. As a result, 95% of perimenopausal and menopausal women experience “hot flashes” manifested as flushing and sweating episodes. These episodes are sudden in onset, last several minutes, and are felt as a sensation of face and neck hotness that extends to the anterior chest. The skin temperature may increase as much as 5°C and may result in wetting of clothing through excess perspiration. Physiologic responses that also occur include an increase in heart rate perceived sometimes as palpitations. There may be associated symptoms of headache, dizziness, and nausea during the episodes. It is important to distinguish these occurrences from thyroid storm (i.e., sudden increases in thyroid hormone). Approximately 80% of women experience these episodes for more than one year, with as many as 20% of women having symptoms for more than five years.

Sleep is also affected. Many women have night sweats and also have difficulty falling asleep (prolonged sleep latency phase) and often awaken early without being able to fall back to sleep. It is important to distinguish this type of sleep disturbance from a similar problem seen in endogenous depression. Given a growing concern regarding estrogen replacement therapy, a search for alternatives in the management of hot flashes has begun. A randomized controlled trial demonstrated that a selective serotonin reuptake inhibitor (SSRI) (paroxetine controlled-release [CR]) was effective in treating menopausal hot flashes.<sup>26</sup> SSRIs are usually used in the treatment of depression. There also appears to be an increased risk for Alzheimer's disease in postmenopausal women not taking estrogen replacement therapy.

- Estrogen deficiency leads to a decrease in bone mass accelerating the osteoporosis process.
- Estrogen deficiency leads to an increased risk of cardiovascular disease and death including coronary artery disease and stroke. Increases in low-density lipoprotein (LDL) levels and decreased levels of HDL are seen.
- Tissue that is estrogen-sensitive will undergo atrophy. Common manifestations are:
  1. vaginal atrophy resulting in vaginal itching, burning, and painful sexual intercourse
  2. decrease in collagen content of the uterus, bladder, and rectum resulting in prolapse of these structures and/or an increased incidence of recurrent urinary tract infections and rectal or urinary incontinence
  3. decrease in collagen also results in thinning of skin and decreased elasticity
  4. thinning of scalp hair with an increase in facial hair

Based on the severity of the clinical manifestations and the perceived effect on quality of life and risk for death, estrogen replacement therapy (ERT) should be considered. It is known that exogenous estrogen replacement can decrease flushes and sweating, vaginal and other related atrophy, and skin/hair changes when taken for a period of one to five years. Longer use (10 years and beyond) has a significant effect on decreasing risk for osteoporosis and cardiovascular disease (decreased by 50%). There still remains much controversy regarding the risks versus benefits of oral contraceptive use and hormonal replacement therapy. A recent review summarizes what is known at this time about oral contraceptives:<sup>27</sup>

## Benefits

- Ovarian cancer is reduced by at least half.
- Endometrial cancer is reduced (presumably due to progestin-mediated suppression of estrogen-induced proliferation of endometrial cells).
- Acne is substantially reduced.
- The severity of dysfunctional uterine bleeding may be reduced, thereby reducing associated anemia.

## Risks

- The relative risk for myocardial infarction has been estimated at between 1.4 to 5 and 2 to 5. Differences may be due to the factor of either smoking and/or undiagnosed hypertension.
- Venous thromboembolism increases by a factor of 3 to 4 for women using low-estrogen oral contraceptives. New studies of combination oral contraceptives using low-dose estrogen with third-generation progestins indicated an increased risk. The risk of thromboembolism is much higher for women who have thrombophilia (deficiency in protein C or protein S or having the factor V Leiden or prothrombin G20210A mutation).
- There appears to be no increased risk for hemorrhagic stroke among women who are not hypertensive and no increased risk for hepatocellular carcinoma.

One significant change over the last few years is the caution given to the use of HRT in the treatment of postmenopausal complaints or as a cardiovascular protector. The Women's Health Initiative Randomized Trial, a randomized, double-blind, placebo trial of more than 16,000 postmenopausal women over five years suggests that combined estrogen plus progestin may increase the risk of ovarian cancer.<sup>28</sup> Endometrial cancers rates were similar to placebo. A second part of the study evaluated combined therapy (estrogen and progestin) in preventing the risk of fracture through an increase in bone mineral density. The researchers concluded that there was an increase in BMD and a decreased risk of fracture; however, when weighed against the risk of other diseases, there was no net benefit.<sup>29</sup>

A Women's Health Initiative project evaluating estrogen/progestin therapy and stroke provided data that support an increased risk of ischemic stroke in generally healthy postmenopausal women.<sup>30</sup> A memory study portion of the Women's Health Initiative concluded that estrogen/progestin combination therapy did not improve cognitive function in postmenopausal women 65 years or older and in fact may cause a small increased risk of clinically meaningful cognitive decline.<sup>31</sup> A part of the same study indicated increased risk for probable dementia.<sup>32</sup>

Nutritional recommendations are given in **Table 55-4**. Recent interest is in the use of phytoestrogens (plant estrogens derived from soy or clover) to prevent or reduce hot flashes. The isoflavones in the extracts may have additional benefits related to cholesterol levels and bone loss. Soy-derived isoflavones have been recommended for the treatment of hot flashes in menopausal women. A recent randomized, double-blind, placebo-controlled trial found that daily administration of 72 mg of soy-derived isoflavones was no more effective than placebo in reducing hot flashes.<sup>33</sup>

## Vaginal Bleeding

Vaginal bleeding is usually due to uterine bleeding. The causes of vaginal bleeding are limited and are usually the result of trauma or atrophic vaginitis found in elderly women. Uterine bleeding should be correlated with the woman's menstrual history in an attempt to place her in a stage of menstrual development. Uterine bleeding may occur (1) when no ovarian function is occurring as in premenarcheal and postmenopausal stages, (2) when normal ovulation occurs, (3) anovulatory (more common in the first years following menarche or perimenopausal years), and (4) during pregnancy. Chronologically, a woman's reproductive system's development may be divided into the following five stages:<sup>34</sup>

**Table 55-4** Nutritional Support for Menopause

Substance	How Might It Work?	Dosage	Special Instructions	Contraindications and Possible Side Effects
Vitamin E	Unknown.	800-1,000 IU/day	Take for 3 months to determine effectiveness.	Generally safe at recommended dose.
Vitamin C	May reduce symptoms of hot flashes.	1,200 mg of vitamin C and 1,200 mg of bioflavonoid hesperidin.	None.	Bioflavonoid Some individuals are sensitive to vitamin C and may have diarrhea; high levels of vitamin C may deplete the body of copper.
Black cohosh	Has a weak estrogen-like effect to help reduce hot flashes. May decrease levels of luteinizing hormone.	Highly concentrated extract at 40 mg 2 times/day in a 40%-60% alcoholic extract.	Because long-term studies have not been conducted, it is recommended to limit to 6 months of usage.	Not to be used in pregnant or lactating women. Women on ERT should consult prescribing doctor. High doses may cause abdominal pain, nausea, headaches, and dizziness.
Dong Quai	Adaptogenic effect on female hormonal system.	Powdered root as herbal extract, capsules or tablets, or tea at 3-4 g/day.	None.	Not recommended in pregnant or lactating women. May cause sensitivity to ultraviolet light (decrease exposure to sunlight).

Note: Other possibly helpful substances include the phytoestrogens (plant estrogens derived from soy or clover) for management of hot flashes.

Note: The above substances have not been approved by the Food and Drug Administration for the treatment of this disorder.

1. premenarchal
2. menarche
3. the reproductive years

- 4. perimenopausal
- 5. postmenopausal

This categorization is useful in considering the most likely causes in each stage of development. Bleeding in stages 1 and 5 is abnormal and warrants investigation. In premenarchal years, the most common cause is direct trauma and/or sexual abuse. In postmenopausal years, any bleeding that appears to be uterine should be suspected to be cancerous in origin. Irregular bleeding during menarche and perimenopausal stages is often the natural consequence of fluctuations in hormonal balance. However, one-fifth of abnormal bleeding during menarche is due to a bleeding diathesis. During the reproductive years, the major concerns are that there may be excessive bleeding and that there may be bleeding during pregnancy. Also, it is important to recognize the classic presentation of cervical cancer, which includes painful intercourse, postcoital bleeding, and foul smelling vaginal discharge. Alterations in the degree and timing of bleeding related to the menstrual cycle are defined by specific terms as follows:

- polymenorrhea—more frequent than every 20 days
- oligomenorrhea—less often than every 42 days
- menorrhagia—bleeding lasting longer than 8 days
- metrorrhagia—bleeding between periods

The time limits listed above are generalizations and may vary with other text definitions by a few days.

The major differential pivot point is whether bleeding is ovulatory or anovulatory. Ovulatory bleeding is cyclic and is associated with dysmenorrhea and some premenstrual symptoms. In general, the cause of abnormal ovulatory bleeding is usually a pelvic lesion such as endometriosis, fibroids, an intrauterine device (IUD), pelvic inflammatory disease (PID), or pelvic tumors (see [Table 55-5](#)). Anovulatory bleeding is irregular and usually painless; it is often heavy. Endocrine dysfunction or contraceptive use is often the cause. Anovulation often is due to lack of production of LH during the midcycle. The type of bleeding may suggest an underlying cause. If bleeding is bright red with associated clots, a nonmenstrual flow is suggested. Bleeding during pregnancy may be serious. Spotting is common in the first trimester; however, it may represent spontaneous abortion (50%), ectopic pregnancy, or a low-lying placenta. Past the 20th week of gestation, serious causes are likely, including placental abruption, placenta previa, marginal separation of the placenta, and vasa previa. Referral is indicated in all cases of vaginal bleeding during pregnancy.

<b>Table 55-5 Tumors and Cancer in Females</b>
--

--	--	--

Disorder	Diagnostic Features and Considerations	Management Considerations
<b>Endometriosis</b>	<p>Endometriosis is a condition characterized by uterine tissue (glands and stroma) located outside the uterus. Most commonly the tissue is found on the serosa of the ovaries or the peritoneum, although endometriosis may be found almost anywhere in the pelvic cavity and sometimes beyond. The etiology is believed to be from regurgitation during normal menstruation with the tissue traveling retrograde through the fallopian tubes instead of out the vagina. Endometriosis is found in an estimated 15% to 20% of women of reproductive age (the highest rates in infertile women); primarily in the age group 25–29. Classically, there is a triad of dysmenorrhea that has worsened coupled with dyspareunia (painful intercourse), and infertility. The pelvic pain is associated more with the depth of infiltration versus the extent of the disease. A pelvic examination may reveal involvement of the uterosacral ligaments, the cul-de-sac, with a fixed retroversion of the uterus, or tenderness only. Diagnostic ultrasound or magnetic resonance imaging (MRI) may be used to detect the extent of lesions; however, laparoscopy is needed for a definitive diagnosis. Colonoscopy is recommended if there is associated rectal bleeding.</p>	<p>Although painful, endometriosis is a benign, self-limited disorder; it does not progress to cancer. There are two general approaches dependent on whether pregnancy is still desired. Medical approaches may attempt to decrease estrogen influence through creating a pseudopregnancy using contraceptive pill approach, androgens (danazol), or gonadotropin-releasing hormone. Surgery may be used to remove lesions to correct infertility. For those not wishing to have children and having extensive disease, surgery involves a total hysterectomy with bilateral salpingo-oophorectomy.</p>
<b>Uterine Myomas (Leiomyomas, Fibromyomas, Fibroids)</b>	<p>Uterine fibroids are the most common uterine tumor occurring in about 25% of all white women and 50% of all black women. These myometrial tumors develop only in women having reached menarche; however, not after</p>	<p>Asymptomatic fibroids are not treated. Symptomatic lesions may be medically manipulated using various hormonal approaches to manage the abnormal bleeding or use of either gonadotropin-releasing hormone agonists or danazol (an andronergic agonist) to decrease the size of the</p>

	<p>menopause. They are often multiple and are estrogen sensitive. Signs and symptoms are dependent on the location. Small tumors are often asymptomatic. Larger tumors that are subserosal tend to cause signs/symptoms due to compression of the bladder or rectum such as urinary urgency or constipation. Those that are submucosal cause menstrual irregularities or bleeding. Infertility may also be due to fibroids. A pelvic examination is the initial evaluation tool followed by diagnostic ultrasound, computed tomography (CT), or MRI for confirmation. Occasionally, calcified uterine fibroids are seen radiographically on an anteroposterior (AP) lumbopelvic film.</p>	<p>fibroids. These drugs carry with them common side effects (in particular, danazol has a virilization effect). Surgery is used for those symptomatic women who have large masses or for those who are infertile (secondary to the fibroids). Surgical options include myomectomy (shelling-out the lesion) for those women wishing to still conceive or hysterectomy for those who do not.</p>
<b>Meigs' Syndrome</b>	<p>Meigs' syndrome involves the development of ascites and right hydrothorax (pleural effusion) secondary to a large, benign fibroma. It is theorized that the fibroma has an inadequate lymphatic drainage. Meigs' syndrome occurs primarily in middle-aged women.</p>	<p>Surgical removal.</p>
<b>Cervical Cancer</b>	<p>Cervical cancer is the third most common gynecologic cancer. It is often considered a sexually transmitted disease due to the association with risk factors such as early-age first time intercourse, multiple sexual partners, venereal disease, and infection with human papillomavirus (HPV). However, smoking is also associated with a higher risk. The average age of onset is about 50 years; however, cervical cancer may occur in younger women. Early cancer is asymptomatic. The first signs are usually painful intercourse, postcoital bleeding, or a foul smelling discharge. As the cancer progresses, other signs or symptoms may develop. Screening for cervical cancer is important given the initial</p>	<p>Based on the staging of the disease, various forms of therapy are available. Preinvasive disease may require only conization biopsy. To prevent spread to lymphatics, radiation therapy may be required and, in fact, is used often in advanced disease. More radical surgery such as hysterectomy is reserved for more advanced disease. Bilateral pelvic lymph node dissection and removal of all adjacent ligaments may be required. The 5-year survival rate is quite high for early-stage disease (80% to 90%); however, for late-stage disease, the 5-year survival rate is dismal with the best possible rate at 15%. This reemphasizes the need for regular Pap smears in an effort to detect early-stage disease. A vaccine (Gardasil) against HPV is now available.</p>

	<p>asymptomatic phase. Papanicolaou (Pap) smears are the initial screening test. Although the false negative rate can be as high as 40% dependent on lab, it is extremely important that Pap smears be a routine part of a women's check-up; in particular, those at high risk. If abnormal cells are found, further investigation proceeds systematically with colposcopy-directed biopsy. If equivocal,</p>	
	<p>a conization biopsy is required. A newer approach is to include an HPV DNA test (Digene Hybrid Capture test) with the Pap for women over age 30. The HPV DNA test is designed to detect certain specific groups of HPV more likely to cause cancer. If both the Pap and HPV test are normal, retesting is performed in 3 years.</p>	
<b>Ovarian Cysts</b>	<p>During the proliferative phase of the menstrual cycle, ovarian follicles enlarge and are transformed into Graafian follicles. Only one precedes to rupture at ovulation. The remaining follicles may continue to enlarge into fluid-filled follicular cysts or the ovulated follicle may fail to transform into a corpus albicans and fill with fluid becoming a corpus luteum cyst. When multiple cysts are found on both ovaries, the diagnosis is polycystic ovary syndrome. Affected females have complex hormonal dysfunction and are not able to ovulate even in an environment of high levels of gonadotropins. Sudden abdominal pain may occur with rupture, adnexal torsion, or hemorrhage.</p>	<p>For masses found on pelvic exam or with diagnostic ultrasound, a repeat evaluation in 4 to 6 weeks helps determine those cysts that will spontaneously resolve versus those that will persist or progress. Management varies dependent on size, number, and complications associated with cysts. Oral contraceptive treatment may reduce the size of cysts. Surgical excision may be necessary for symptomatic patients or those with other cyst complications.</p>
<b>Vaginal Cancer</b>	<p>Vaginal cancer is rare, occurring mainly in the 60-65 age group. Increased risk is found with a history of human papillomavirus infection, cervical or vulvar cancer, and diethylstilbesterol. Most vaginal cancers are squamous cell</p>	<p>Poorly differentiated lesions that have spread carry a poor prognosis of 15% to 20% 5-year survival. Small, differentiated lesions may carry a 5-year survival as high as 70%. Primary tumors are usually treated with radiation. Surgical procedures such as radical</p>

	<p>carcinomas. Spread of the tumor may be direct to local tissues, through inguinal or pelvic lymph nodes, or hematogenously. The most common finding is abnormal vaginal bleeding (usually postmenopausal) and sometimes a watery discharge. A punch biopsy is used for diagnosis. Screening for metastasis includes radiography.</p>	<p>hysterectomy and vaginectomy with lymph node dissection may be needed for more advanced disease.</p>
<b>Fallopian Tube Cancer</b>	<p>Fallopian tube cancer is rare, occurring mainly in the 50-60 age group. There are no well-defined risk factors. Most patients have vague pelvic or abdominal complaints. Some have a triad of pelvic pain, watery discharge, and adnexal mass.</p>	<p>Diagnosis is via surgical exploration and, if found, surgical removal and postoperative radiation therapy are standard.</p>
<b>Ovarian Cancer</b>	<p>Ovarian cancer is made up of a number of different groups that include benign and malignant lesions. The categorization of these lesions is based on basically four main cell types: (1) surface epithelium (germinal), (2) germ, (3) sex cord stromal, and (4) nonspecific. Benign lesions are more common than malignant. However, ovarian cancer causes more deaths than all other gynecologic cancers. It ranks as the second most common gynecologic cancer, however, first as a cause of death by gynecologic cancer. Ovarian cancer is seen more often in industrialized countries, especially where high-fat dietary intake is found. Risk factors include multiparity, infertility, late child bearing, and late onset of menopause. A personal or family history of endometrial, breast, or colon cancer also increases risk. A small percentage of women who have the BRCA gene are at higher risk. Oral contraceptives are protective. Seventy-five percent of women have advanced disease at the time of diagnosis. Vague symptoms may include dyspepsia, a sense</p>	<p>Localized tumors are surgically removed. More advanced disease requires a combination of approaches including radical surgical procedures combined with chemotherapy. Response to chemotherapy is often monitored with CA 125 levels. The 5-year survival rate is variable from 5% to 40%. Use of BCP may be protective.</p>

	of bloating or gas pains, lack of appetite due to a sense of fullness with small amounts of food, or low back pain. Physical findings may include finding an abdominal mass on pelvic examination. Severe abdominal pain may occur with torsion of the mass. Germ cell or stromal tumors may create	
	signs/symptoms secondary to the development of hyperthyroidism or androgen stimulation leading to feminization or virilization. Sonography may help; however, surgery may be needed for suspicious masses. Laboratory testing is nonspecific; however, beta-subunit-human chorionic gonadotropin, lactate dehydrogenase (LDH), alpha-fetoprotein, and the cancer antigen 125 (CA 125) should be evaluated.	
<b>Endometrial Cancer</b>	<p>Endometrial cancer is most often found in postmenopausal women, peaking at ages 50 to 60. It is the most common gynecologic cancer in the United States and is more common in industrialized countries where there is a high dietary fat intake. Risk factors include obesity (3 to 10 times higher risk); and, where unopposed estrogen is common such as estrogen replacement therapy, polycystic ovary disease; and estrogen-producing tumors. Those with a history of breast or ovarian cancer or pelvic radiation therapy are at higher risk. Eighty percent of cases represent adenocarcinoma, with sarcomas accounting for only 5%. Sarcomas are generally more aggressive. Abnormal uterine bleeding is the most common initial complaint, occurring in 90% of women. Many are postmenopausal. In fact, one third of postmenopausal bleeding patients have endometrial cancer. Pap</p>	<p>Like most cancers, staging based on histologic differentiation is necessary. Prognosis is based on the staging, the patient's age (poorer prognosis with advancing age), and metastatic spread. For early-stage cancer, total hysterectomy, bilateral salpingo-oophorectomy, and peritoneal cytologic examination are used. For later stages, pelvic and para-aortic lymphadenectomy is often added. The 5-year survival rate is 70% to 95% for early stages and varies from 10% to 60% for late-stage disease.</p>

	smears may show abnormal cells. However, endometrial tissue sampling is the definitive test (>90% accurate). Following a positive tissue sampling, investigation with laboratory, x-ray, and electrocardiogram is necessary to determine extra-uterine involvement.	
<b>Vulvar Cancer</b>	Vulvar cancer is a geriatric cancer seen primarily in women over 70 years old. It is not common, accounting for only about 3% to 4% of all gynecologic cancers in the United States. Risk factors include having a premalignant lesion, human papillomavirus, or chronic vulvar pruritis. Those patients with cervix or vaginal cancer are also at higher risk. The most common presentation is a palpable, often visible, vulvar lesion with pruritis. Dermal punch biopsy is used for diagnosis.	The 5-year survival rate is based on staging, with as little as a 15% survival with widespread involvement to as high as 90% for local involvement. Treatment is radical excision and unilateral or bilateral inguinal and femoral lymph node dissection.

The examination is limited to determination of endocrine causes or a bleeding tendency. An evaluation for thyroid dysfunction is prudent. Pelvic examination should be performed by chiropractors with training or referred to a medical physician in a search for a bleeding source such as a tumor. Laboratory evaluation may be helpful in determining whether the patient is anemic.

After performing a thorough history and brief examination, the patient should be given an explanation as to the different types of bleeding and what is specifically suggested in her case. Referral should be made, with a letter explaining the doctor's rationale or recommendations.

If a structural lesion is not found to be the source of bleeding, an attempt at controlling the bleeding and normalizing the cycle is made. The standard form of treatment is prescription of oral contraceptive pills (OCPs) or nonsteroid anti-inflammatory drugs (NSAIDs). Both OCPs and NSAIDs can reduce bleeding by up to 50% (NSAIDs usually are a little less effective).<sup>35, 36</sup> NSAIDs have a strong vasoconstrictive effect. A side benefit is possible reduction of any associated dysmenorrhea. A small number of women may have an increase in bleeding.

## **Vaginal Discharge**

The first line of distinction with vaginal discharge is to determine if the discharge is physiologic or nonphysiologic. Physiologic discharge is not

offensive in odor and is rarely associated with vulvar discomfort. Laboratory evaluation usually reveals few polymorphonuclear (PMN) leukocytes with predominantly Gram-positive bacillus found on culture or staining.

Physiologic discharge is associated with ovulation, premenses, use of birth control pills, and sexual excitement. Nonphysiologic discharge often has an offensive odor with associated vulvar discomfort that may include local dermatologic involvement. Laboratory evaluation will generally indicate a high PMN count with specific findings on bacteriologic testing.

Nonphysiologic categories include dermatologic, allergic, or toxic irritation from douches, vaginal sprays, perfumes, or contraceptive products (creams, jellies, foams, and suppositories), infection primarily from sexually transmitted diseases, neoplasms, and, on rarer occasions, anatomic problems such as a fistula or proctitis, or foreign body such as a tampon or intrauterine device.

Questioning regarding contraceptive and hygiene practices will often reveal the source of discharge with elimination, modification, or substitution as the primary solution. Infection should be suspected when there is an active sexual history, when discharge is accompanied by skin lesions, or when there is painful urination or intercourse. Generally, there are three primary causes of localized vaginitis, including:<sup>37</sup>

- 1. Bacterial vaginosis (anaerobes plus *Gardnerella*)—*Gardnerella*** accounts for approximately 50% to 60% of vaginal infections. Clues include a mild to moderate gray/whitish discharge with mild itching. Laboratory testing includes a positive “whiff” test (a fishy odor is smelled when the discharge is mixed with 10% potassium hydroxide [KOH] on a clean slide). Examination of the slide microscopically may reveal vaginal epithelial cells covered with coccobacilli (clue cells). There are few PMNs. Treatment is usually with metronidazole (Flagyl).
- 2. Trichomoniasis (*Trichomonas vaginalis*)—Trichomoniasis** accounts for approximately 15% to 20% of all vaginal infections. It is found most commonly when the pH of the vagina changes to a more alkaline environment (e.g., menstruation, abortion, post-delivery). This infection is generally sexually transmitted. One-fourth of patients are asymptomatic, one-fourth have pruritus, and one-half have both pruritus and discharge. The discharge is generally profuse and foul smelling, often being called “fishy” in odor. Diagnosis is made with a wet mount of vaginal secretions to identify the organism. A pelvic examination may reveal punctuate hemorrhages of the cervix (“strawberry cervix”). Treatment is with metronidazole (Flagyl).
- 3. Candidiasis (*Candida albicans*)—Candidiasis** accounts for approximately 15% to 20% of all vaginal infections. Unlike the other infections, it is often a cause of extreme pruritus, especially at night. There are many predispositions including diabetes, contraceptive use, steroids (including corticosteroids), antibiotics, and late pregnancy.

Sexual transmission is less common. Although the discharge is scanty, it has a cottage-cheese or curd-like appearance, often being thick and white. Marked pruritus leads to an erythematous, edematous, excoriated vulva. Diagnosis is via a KOH preparation or Gram stain. Treatment is often with over-the-counter medications such as clotrimazole or miconazole. If frequent and recurrent, prescribed treatment is usually with oral ketoconazole or fluconazole.

Gonorrhea and chlamydia are not direct infections of the vagina, but rather infect the endocervix. The discharge may lead one to think there is a local vaginal infection.

## **Infertility**

Infertility is defined as a year of attempted conception without success and is clinically separate from recurrent spontaneous pregnancy loss. The time frame of one year is used because within one year 85% of couples attempting conception will be successful.<sup>38</sup> Approximately 6 million couples are affected in the United States. There are reasons for infertility evaluation prior to one year. This would be in patients older than age 35 years or those who have diagnosed or suspected pelvic pathology.

The evaluation for infertility involves the following procedures:

- Semen analysis.
- Assessment of ovulatory function (often used are urinary luteinizing hormone and midluteal phase serum progesterone level). Urinary ovulation prediction kits replace the basal body temperature approach, and endometrial biopsy has been replaced by midluteal progesterone levels).
- Assessment of the uterus with a hysterosalpingogram (HSG) or sonohysterogram.
- Assessment of fallopian tube patency using either HSG or laparoscopy.
- Estimation of FSH on cycle day three in women 35 years or older or those with prior ovarian surgery. (Elevated FSH levels are associated with a poor ovarian response to hormonal stimulation.)

Management is dependent on cause and other factors. Two possible management approaches are in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI). These are reserved for specific patients, and due to cost and complexity are still not commonly used. Also, IVF carries with it an increased risk of multiple births.

The primary identifiable causes of infertility include:

- Ovulation disorders (25% of cases) such as oligomenorrhea, amenorrhea, and hyperprolactinemia: Medical options include clomiphene citrate, gonadotropins, metformin, laparoscopic ovarian diathermy, and IVF.
- Tubal disease (20% of cases) such as obstruction from prior infection: Medical management includes tubal reparative surgery and IVF.
- Endometriosis (5% to 10% of cases): Treatment with danazol, GRH, or progestins does not seem to improve fertility; therefore, laser ablation of endometriosis is recommended.
- Male factors (20% to 25% of cases) such as oligospermia or azoospermia.
- Unexplained infertility (30% of cases): Medical options include clomiphene citrate, intrauterine insemination with or without gonadotropins, and IVF.

### **Some Specific Pregnancy-Related Concerns**

Pregnancy is a natural process that in many cases is uncomplicated. Concerns ranging from decisions to screen for prenatal abnormalities, fetal development abnormalities, and other serious complications with pregnancy are beyond the scope of this overview. The primary focus of this discussion is on issues where the chiropractor can play a role in monitoring and counseling and musculoskeletal issues associated with pregnancy.

The U.S. Preventive Services Task Force and other groups<sup>5-14</sup> have made specific recommendations for screening, follow-up visits, and counseling for the pregnant patient. The general purposes of screening include:

- To monitor for signs of hypertension and developing preeclampsia and eclampsia (see [Chapter 24](#)).
- To detect diabetes and monitor for gestational diabetes development.
- To screen for anemias.
- To screen for diseases that may affect the pregnancy or fetus such as rubella, hepatitis, chlamydia, and, in high-risk groups, HIV.
- To make recommendations regarding amniocentesis (generally recommended in women age 35 years or older) or laboratory testing of specific indicators of disorders such as Down's syndrome and spina bifida (e.g., serum alpha-fetoprotein).
- To counsel on issues such as alcohol, smoking, and other drug cessation; adequate nutrition (specifically folate supplementation) and calcium (for high-risk eclampsia patients); and avoidance of high-risk sexual behavior.
- To encourage breastfeeding, lap-shoulder seatbelt usage, infant safety, and car seats.

Postpartum concerns include the development of a hyperthyroid state and postpartum depression. Hyperthyroidism may develop in the first few weeks following delivery, and it should be suspected in any patient with increased blood pressure, palpitations, and anxiety (see [Chapter 50](#)). Postpartum blues are common in the first few weeks following delivery. It is due to fluctuating levels of estrogen and other hormones. Patients are often emotionally labile and appear irrational in their reaction or response to minor relationship issues. Postpartum blues will resolve over a number of weeks once hormonal levels have stabilized. Postpartum depression, however, occurs within the first few months up to one year following delivery. It is a poorly understood condition, but likely represents a version of endogenous depression often requiring medication due to the not uncommon result of infant abuse or neglect (see [Chapter 20](#)).

The American College of Sports Physicians (ACSM)<sup>39</sup> and the American College of Obstetricians and Gynecologists (ACOG)<sup>40</sup> have made recommendations for exercise during pregnancy. Generally, women who already have an established exercise routine are advised to continue, with appropriate cautions and with close attention to any warning signs such as shortness of breath, dizziness, loss of balance, etc. For those women who have not established an exercise program prior to pregnancy, the ACSM guidelines recommend an intensity level where the heart rate is at or below 150 beats/minute, exercise of short duration (less than 20 minutes), and avoidance of ballistic movements. For the pregnant woman starting an exercise program, the ACOG recommends the following:

- Avoid dehydration and hypoglycemia by ensuring adequate caloric and fluid intake.
- Avoid extreme environmental conditions and dress appropriately to allow for heat dissipation.
- Avoid exercise in the supine position after the first trimester (decreased cardiac and venous return).
- Avoid vigorous exercise because of the preferential distribution of blood flow to the periphery and away from the uterus.
- Exercise regularly; intermittent exercise is not as effective or safe.

Absolute contraindications to exercise during pregnancy include ruptured membranes, premature labor, vaginal bleeding, suspected fetal distress, intrauterine growth retardation, preeclampsia, kidney disease, valvular or ischemic heart disease, multiple pregnancy, acute infection, or incompetent cervix.<sup>41</sup> Relative contraindications to exercise during pregnancy include hypertension; moderate to severe anemia; poorly controlled diabetes; excessive obesity; underweight; smoking; excessive alcohol intake; a history of premature delivery, preeclampsia, or significant pulmonary disease; twins after 24 weeks' gestation; and previous sedentary lifestyle. There are no apparent effects on length of labor with

exercise; however, 85% of exercising women will have a normal spontaneous vaginal delivery as compared to only 50% to 55% for those women not exercising.<sup>42, 43</sup> Also, regular exercise appears to decrease musculoskeletal complaints. Even as little as 45 minutes of physical activity per week has an effect of decreasing lumbar pain in pregnancy.

Musculoskeletal concerns during pregnancy are primarily related to mechanical changes due to the growth and position of the fetus and hormonal changes that result in less ligament stability (i.e., relaxin). Following are some common problems and management issues:

- It is not uncommon for the pregnant female to develop a mechanical compensation to the anterior position and weight of the fetus and develop an increased thoracic kyphosis and anterior head positioning. These factors, plus the more direct effect of the weight of the breasts in some women, may contribute to mechanical strain to the cervical and thoracic areas. Development of myofascially related problems is common and warrants stretching of the anterior musculature (i.e., pectorals) and strengthening of the interscapular musculature (i.e., rhomboids and middle trapezius).
- With the anterior displacement of the gravity line that occurs with the frontal position of the fetus, anterior tilting of the pelvis with hip flexion results. This may place hyperextension forces to the knees, stretching the posterior capsule. It is important for the patient to consider this recurvatum position when standing and to shift weight as often as possible to avoid bilateral, chronic stretching. Maintaining good muscle tone about the knee through a standard knee exercise program may also help.
- A shift from the weight-bearing function of the calcaneus to the metatarsals occurs due to the shift in the center of gravity anteriorly. In addition, the extra weight incurred during pregnancy adds to the challenge of the foot ligamentous and fascial structures. Adjusting of the joints of the foot and ankle, and/or arch supports may be beneficial for these problems.
- Increasing anterior weight causes an increase in the lumbar lordosis. The hyperlordosis may contribute to the development of symptoms related to facet compression including some referral of pain into the lower extremity. Abdominal strengthening early in pregnancy and modified abdominal contractions during pregnancy may assist in providing more anterior support.
- Hip pain is common for the simple reason of increased weight bearing coupled with the later trimester effect of relaxin on the ligamentous support of the hip. Proactive approaches include a strengthening program for the hip musculature, in particular the abductors, and extra cushioning and support for the hips during sleep.

Low back pain is common in pregnant women.<sup>44</sup> There is some literature support<sup>45</sup> for the role of chiropractic treatment of the pregnant patient with low back pain. Adjusting of the pregnant female is safe if precautions are taken to protect against compression forces to the abdomen, consider positional effects of blood flow, and ensure comfort. Compression by the fetus and abdominal organ combination may block venous return and lead to a relative hypovolemic response due to position change to a seated or standing posture resulting in either presyncope or syncope.

Two excellent reviews of adjusting procedures for women and pregnant females include those by Bartol<sup>46</sup> and Esch and Zachman.<sup>47</sup> The primary modifications are to support the abdomen without causing compression, avoid excess compression to the breasts, and avoid prolonged recumbency in the supine position. Abdominal support and redistribution of forces off of the abdomen can be accomplished through the use of appropriately positioned pillows. Another excellent alternative for avoidance of abdominal compression is appropriately delivered knee-chest table adjusting. Alternatives to standard adjusting approaches include “soft er” approaches such as Activator, massage, and reflex therapy. Certainly, in the last trimester and during labor, many practitioners focus on sacral mobility and reflex pain modulation through sacral reflex or acupressure/acupuncture points.

## **Breast Pain or Discharge**

Breast pain (mastodynia) is usually due to local tissue involvement; however, it may represent referral or extension of pain from the chest wall, or it may emanate from cardiac or gastrointestinal origins. It is important to first make this distinction before proceeding to an evaluation of breast involvement. The breast is composed of epithelial-lined ducts organized into lobules surrounded by Cooper’s ligaments. These ligaments extend throughout the breast and connect to both the skin and the chest wall. Most local pathology involves the ductal epithelium through hyperplasia, dysplasia, or neoplasm. The breast is sensitive to hormonal stimulation, in particular estrogen. As a result, the vast majority of “normal” breast discomfort is a result of this ebb and flow of estrogen related to menses. Discomfort is generally cyclic and bilateral. The associated pain, tenderness, and swelling are usually premenstrual in onset. The degree of discomfort may vary depending on pain threshold and the degree of fibrocystic changes. Fibrocystic “change” is manifested as multiple, well-defined nodules most seen in the upper outer quadrant and often bilateral. This fibrocystic involvement is by far the most common cause of breast discomfort seen from ages 25 years through 60 years.<sup>48</sup> Management of fibrocystic disease includes some conservative options including caffeine (xanthine) restriction and vitamin E supplementation. Medical approaches

are hormonal, involving androgens such as danazol or antiestrogens. Noncyclic breast pain in the premenopausal female or any breast pain in the postmenopausal female should be further investigated for possible fibrocystic disease, mastitis, or malignancy. This requires referral to a specialist.

Nipple discharge is a common concern. About 7% of patients with nipple discharge have carcinoma. There are some key factors that help distinguish benign physiologic causes versus those warranting concern. When there is bilateral nipple discharge that is seen only with nipple compression, never occurring spontaneously, and if the discharge is greenish or milky, there is rarely a concern. Usually this type of discharge is bilateral and is coming from multiple ducts. With this type of discharge there are several common causes:

- eczema or other dermatologic disease
- birth control pills, tranquilizers, rauwolfia alkaloids, or the patient is recently menopausal
- pregnancy, prolonged lactation, nonlactational galactorrhea, or elevated prolactin levels or other endocrine dysfunction

Serous or bloody discharge may occur with cystic mastitis, fibrocystic disease, Paget's disease of the breast (intraductal infiltration by ductal carcinoma), or Bowen's disease. This is more often represented by spontaneous discharge that is unilateral and arises from a single duct. When this scenario is present, further investigation by a specialist is requisite.

## Breast Cancer

Breast cancer is a significant cause of mortality in women, second only to lung cancer as the leading cancer-related cause of death in women. Important statistics to consider when discussing breast cancer follow:<sup>49</sup>

- Women account for 99% of all cases of breast cancer.
- In 60% of all cases, the only identifiable risk factor is being female.
- Women 50 years and older account for 70% of all cases; the risk in women 80 to 85 years of age is 15 times higher than that for women 30 to 35 years old.

**Figure 55-2** Position of patient and direction of palpation for the clinical breast examination. (A) The figure shows the lateral portion of the breast; (B) the medial portion of the breast. Arrows indicate vertical strip pattern of examination.

- Although those with genetic mutations in the BRCA1 gene (and less commonly the BRCA2 gene) have a significantly higher risk of developing breast cancer (50% to 80% over a lifetime), these women represent only 3% of all breast cancer cases.<sup>50</sup>
- An appropriate in-office breast examination can detect, at minimum, 50% of asymptomatic cancers.<sup>51</sup> (See **Figures 55-2** through **55-4**.)
- Twenty-one percent of women aged 40 years or older who are multiparous or had their first child after age 30 years account for 16% of new breast cancer cases each year.

**Figure 55-3** Palpation technique. Pads of the index, third, and fourth fingers (inset) make small circular motions, as if tracing the outer edge of a dime.

- One-third of women who develop breast cancer will succumb to it; therefore, the survival rate for breast cancer is approximately 60%.
- Most recurrences develop within two to six years following the initial diagnosis.
- Fifty percent of survivors will develop metastasis, with 40% to 60% of metastasis occurring in bone and 7% to 15% in soft tissue.

A large database regarding a woman's risk of developing breast cancer has been developed. Generally, there are those factors that have been strongly associated with breast cancer risk and those that may or may not play a role but are important to consider. Certainly significant risk factors are being female and increasing age (the most important). A list and a brief discussion of other major risk factors and a list of potential risk factors follow.<sup>52</sup>

## Major Risk Factors

- **Family history:** Genetics contributes to about 5% of all breast cancers; however, it accounts for 25% of cases seen before age 30 years. Familial clustering is suspected when the patient has three or more affected first-degree or second-degree relatives on the same side of the family; or when fewer than three are affected, breast cancer is diagnosed before age 45 years, ovarian cancer has been diagnosed in one or more family members, a genetic mutation is detected in a family member, or the patient has an ethnic risk such as Ashkenazi Jews.
- **Previous history of breast cancer:** When there is a previous diagnosis; in particular, lobular carcinoma in situ (LCIS) or if the cancer was diagnosed before menopause, the risk of having another primary tumor is three to four times greater.
- **Benign breast disease:** Benign breast disease that necessitates a biopsy increases the likelihood of subsequent cancer, especially those with proliferative lesions or cellular atypia; in fact, 40% of those with proliferative disease and a family history of breast cancer in a first-degree relative develop carcinoma. Also, a history of biopsy before age 50 years is associated with a higher likelihood than a history of biopsy performed in older patients.
- **Menstrual relationships:** Menarche before 12 years of age or menopause after age 55 years allows for breast cells to be exposed to estrogen longer; women who have reached menopause or have a hysterectomy before age 45 years have half the incidence of breast cancer compared to those reaching menopause after age 55 years. Early menarche, extremely lean body mass at age 10 years old, and taller adult height increase risk;<sup>53</sup> being multiparous or giving birth for the first time after age 30 years (risk doubles); pregnancy before age 20 years reduces the incidence of breast cancer.

**Figure 55-4** Levels of pressure for palpation of breast tissue shown in a cross-sectional view of the right breast. The examiner should make three circles with the finger pads, increasing the level of pressure (superficial, intermediate, and deep) with each circle.

- Hereditary/genetic factors: Mutation of the BRCA1 gene increases lifetime risk up to 85%; chance of acquiring a second primary breast cancer is 65% and risk of developing ovarian cancer is between 40% and 60%.<sup>54</sup> BRCA1 is located on chromosome arm 17q and is involved in encoding a tumor suppressor protein; BRCA2 (located on chromosome 13) is associated with similar risks for breast and ovarian cancer. Although the risk is extremely high for these patients, they account for only a small percentage of all women with breast cancer.
- Hormonal replacement therapy (HRT): There is strong evidence that there is a causal relation between both endogenous estrogen levels and the use of postmenopausal estrogens and progestins and the incidence of breast cancer in postmenopausal women. Contraceptive use prior to menopause does not appear to be a significant risk.<sup>55</sup> A recent study<sup>56</sup> indicates that the assumed safer combination of estrogen/progestin actually carries more risk than estrogen alone. Some differences in data indicate that perhaps HRT promotes the growth of less aggressive, slower growing tumors. A recent study<sup>26</sup> indicated that HRT was associated with risk for invasive breast cancer when the woman had a more favorable histology. It is known that there are significant differences in prognosis between the two carcinomas. Eighty-five to ninety percent of carcinomas that metastasize are invasive tumors including infiltrating ductal and

lobular carcinomas versus the less common medullary, papillary, tubular, and mucinous tumors that have a lower rate of metastasis.<sup>57</sup>

## Potential Risk Factors

- Alcohol consumption: The relative risk of breast cancer increases slightly if one or two drinks (33 to 45 g) are ingested per day in the under-30-years age group; apparently this risk may be reduced with adequate folate intake (greater than 300 mg/day).<sup>58</sup>
- Smoking: Smoking is a risk factor in some women; in particular, those who have cytochrome P450 1A1 polymorphism.<sup>59</sup> However, the risk is relatively low.
- Fat intake: Although previous accusations of a high-fat intake as a cause of breast cancer have been discounted,<sup>60</sup> there may be a relationship between a high-fat diet and high linoleic acid.<sup>61</sup>
- Weight gain and obesity: Weight gain after age 18 years appears not to be associated with premenopausal breast cancer; however, it is positively associated with incidence after menopause, accounting for approximately 16% of all cases. When HRT is taken alone, it accounts for only approximately 5%; however, both weight gain and HRT taken together account for as much as one-third of postmenopausal breast cancers.<sup>62</sup> Estrogen levels in the postmenopausal female are not from ovarian production but result from androgen conversion to estrogen and the amount of adipose tissue. Estrone and estradiol are converted into estrogen via an enzyme found in adipose tissue, thereby increasing the level of active estrogen.
- Recently, attention has been focused on the contribution of low levels of vitamin D to many disorders; breast cancer included. A meta-analysis in 2013<sup>63</sup> determined that there was a dose-response. For every 10 ng/mL increase in serum 25(OH)D concentration, there was an associated 3.2 % reduction in breast cancer risk.

A potential positive factor is length of breastfeeding. A large epidemiological review of 47 studies in 30 countries indicates that the longer women breastfeed, the more they are protected from breast cancer.<sup>64</sup> The authors suggest that the shorter time that women breastfeed in developed countries versus underdeveloped countries may in part explain the higher incidence.

Tools for evaluating a patient's risk are available through the National Cancer Institute at <http://cancer-trials.nci.nih.gov>. An interactive tool and an in-office program are available free of charge.

## Types of Breast Cancer

Breast cancer is not a single entity. There are many different types, primarily categorized by invasiveness and location. Following is a brief description of each:

- *Noninvasive.* Noninvasive carcinomas account for approximately 10% of all breast cancers. They are considered as a group to be early-stage cancer or precancerous in most cases. There are two main types: (1) ductal carcinoma in situ (DCIS) arising from milk ducts, and (2) LCIS. DCIS is divided into comedo and noncomedo. Comedo is more aggressive, while noncomedo is slower growing over longer periods of time. DCIS is seen as clusters of microcalcification on mammogram. Nipple discharge or a palpable mass may be seen on exam. LCIS is more common in premenopausal women. LCIS is less often diagnosed from a clinical exam and more likely found on biopsy.
- *Invasive.* Ductal carcinoma accounts for 80% of all cases of breast cancer. There are many types including adenocarcinoma, tubular carcinoma, mucinous or colloid carcinoma, and medullary carcinoma. Each carries a different degree of risk. Invasive lobular carcinoma accounts for approximately 10% of cases.

Staging of breast tumors includes tumor, lymph node, metastasis (TNM) staging mainly used for research, and a clinical division using four stages. A zero stage is used for lesions found in situ that are noninvasive. Stage I is a lesion that is less than 2 cm and has no lymph node involvement. Stage II is an intermediary stage with small lesions with lymph node enlargement or larger lesions without lymph node enlargement. Stage III is more advanced, larger than 5 cm, with lymph node involvement. Stage IV indicates metastasis.

Signs and symptoms may be subtle and require vigilant attention to both observation and examination on a regular basis. Signs include:

- Detection of an abnormal lump on a monthly breast self-exam (BSE)
- A change in breast tissue size or shape
- Spontaneous bloody discharge from the nipple
- Skin changes including crusting, ulceration, or eczema
- Venous distention seen as an irregular pattern referred to as the “peau d’orange” or orange-peel appearance
- Any redness, warmth, or edema of the breast or axilla

Any abnormal breast examination findings (including breast exam and evaluation for axillary or supraclavicular lymphadenopathy) warrant a referral for mammography or a fine-needle aspiration (FNA). Biopsy can be performed as a core biopsy or surgical biopsy. If a surgical biopsy is performed, removal of the lesion and some surrounding normal tissue is the standard approach. A 2007 study by Lehman et al.<sup>64</sup> indicates that at the

initial diagnosis of breast cancer, MRI evaluation of the contralateral breast can detect breast cancer missed on mammography or clinical examination.

Mammography remains a controversial topic, with disagreement on the application of the existing evidence.<sup>66</sup> A Cochrane review<sup>67</sup> in 2011 estimated that one in 2,000 women will have their life prolonged by 10 years of screening; however, another 10 women will be exposed to unnecessary treatment for breast cancer. With regard to mortality rates, they concluded that the evidence does not demonstrate a reduction in mortality. Also, most estimates are that about 30% of breast cancer is overdiagnosed (largely due to screening mammography).<sup>68</sup> This amounted to approximately 1.3 million in the United States over the last three decades; 70,000 women in 2008. Although the recommendation is for women to make an informed decision with their physician, such a decision is difficult when national groups for over 40 years have not entirely agreed. A brief history follows:<sup>69</sup>

- 1971—The Health Insurance Plan study reported that although breast cancer screening reduced mortality rates for women in the age range of 50 to 64 years, it did not for women in the age range of 40 to 49 years.
- 1997—The National Institutes of Health Consensus Development Conference summarized their findings by stating that no single recommendation can be made for all women regarding screening mammography yet in the same year. The American Cancer Society made the recommendation that all women in their 40s undergo annual mammography and the National Cancer Institute recommended performing mammography every one to two years.
- 2002—The U.S. Preventive Services Task Force (USPSTF) reversed its recommendation and recommended mammography screening for women 40 years and older.
- 2009—The USPSTF made a recommendation against “routine” mammography among women aged 40 to 49 years with the advice that women make an informed decision with their physician. What is misinterpreted is that this is a recommendation for screening mammography. For patients at higher risk or with a palpable lump, it is still recommended to obtain a mammogram.

In a 25-year 2014 follow-up study of the Canadian National Breast Cancer Study, the conclusions by the researchers were that annual mammography in women ages 40 to 59 years did not reduce mortality from breast cancer beyond that for those screened by physical examination or usual care, and that over 22% of mammography-detected invasive breast cancer was overdiagnosed, meaning it eventually was determined not to be.<sup>70</sup>

It is likely that early detection has less benefit than previously assumed due to the fact that cancers detected often are curable at a later time due to advances in treatment, and that many tumors may recede on their own or grow so slowly that the woman dies of another cause.

Following is a summary of recommendations:

- Most groups agree that a recommendation can be made for biennial (every two years) screening mammography for women aged 50 to 74 years.
- Annual mammograms beginning at age 40 years—recommended by the American Cancer Society, the American College of Radiology, and the American Congress of Obstetricians and Gynecologists.
- Mammograms every one to two years for women ages 40 to 49 years—recommended by the National Cancer Institute.
- Individualized screening plans for women 40 to 49 years of age—recommended by the American College of Physicians.

Mammography ratings are based on the BI-RADS system (Breast Imaging Reporting and Data System) published by the American Radiology Society. It is a quality assurance approach using a scale of 6:

- 0 = incomplete
- 1 = negative
- 2 = benign
- 3 = probably benign
- 4 = suspicious abnormality
- 5 = suggestive of malignancy
- 6 = known biopsy-proven malignancy

Then by matching whether there is a palpable mass based on age, whether there is reproducible nipple discharge, or whether there is asymmetrical thickening, further testing is dictated using diagnostic ultrasound, needle biopsy, ductogram, or surgical excision.

Newer imaging approaches include:

- Scintimammography: uses an injected radioactive tracer called technetium sestamibi to attach to breast cancer cells and mark their presence.
- Tomosynthesis (3D mammography): is a variation of standard mammography that allows the construction of a 3D image generated by taking more images, requiring slightly more radiation. Studies are still needed to confirm the advantage of these images in a risk/benefit ratio analysis.

Although laboratory testing is possible, most tests are reserved for those with established breast cancer or those at high risk. Testing to determine a

hereditary tendency or evaluating for BRCA1, BRCA2, or an altered tumor suppressor gene p53 is not used as screening except for those at high risk. Testing for those with breast cancer includes:

- An evaluation of estrogen receptors (those tumors that are positive are generally less aggressive)
- Detection of cancer cells in lymph nodes and blood vessels close to the tumor site
- Tumor grading (the lower the grade, and therefore the more differentiated, the less aggressive; the higher the grade, the more likely to metastasize)
- TRUQUANT BR RIA (test for serum levels of the antigen CA27-29; found in tumors that metastasize; high levels seen in tumors that recur)
- Oncotype Dx,<sup>71,72</sup> a diagnostic assay that analyzes a panel of 21 genes related to breast cancer to determine the risk of recurrence in women with newly diagnosed, early stage disease. Through the measurement of these genes it is possible to determine which women need chemotherapy beyond hormonal therapy. This approach may reduce the need for chemotherapy in as much as 23% of women with early stage breast cancer.

There are a number of treatment options dependent on type of lesion, risk factors, and the woman's preference.<sup>73</sup> General approaches include using selected estrogen response modifiers (SERMs) such as tamoxifen (Nolvadex, Soltamox) or raloxifene (Evista) for estrogen-receptor (ER) positive tumors. This approach is used for premenopausal women who have had their breast cancer removed or for those at high-risk as a preventive (50% effective in this group). Aromatase inhibitors are used for postmenopausal women with HER2/neu-positive results.

For those with stage I or II breast cancer, breast conserving surgery (BCS), which involves lumpectomy followed by radiotherapy, is the most common choice. For women who choose mastectomy over lumpectomy, a new study indicates that, instead of the standard five-week daily treatment, treatment may take only three weeks. Some doctors are even trying five days. Options also include chemotherapy and tamoxifen for prevention of recurrence. New findings indicate that women with breast cancer may survive longer with fewer numbers of recurrences by incorporating a strategy that combines the use of tamoxifen (a selective estrogen-receptor modulator) with a newer medication, letrozole (an estrogen synthetase [aromatase] inhibitor). Because tamoxifen is both an antagonist and a partial agonist of estrogen receptors, at some point the agonist action impairs any potential anticancer ability. As a result, after five years the beneficial effects are lost, and the guidelines are to discontinue use at that time. The result was recurrence. Researchers in a recent study placed

women who had completed the five-year tamoxifen therapy on five years of letrozole.<sup>74</sup> The results indicate a significant degree of reduction in the frequency of recurrence. Although the increase in osteoporosis was higher in this group versus the placebo group, it was not substantial (5.8% versus 4.5% respectively). Herceptin (Trastuzumab) may reduce recurrence rates by as much as 50% in women who have HER2 protein-related breast cancer.<sup>75</sup> It is intended for those patients who have received one or more chemotherapy regimens for metastatic disease, or is used in combination with paclitaxel for those patients who have not received chemotherapy. Modified radical mastectomy is recommended for some patients, leaving the pectoral muscle intact and involving reconstruction with a saline implant or tissue flap. The survival rate for both procedures appears to be the same; however, those having BCS are more likely to have recurrence in the same breast. Tsangaris et al.<sup>73</sup> provide a more extensive discussion of treatment options with tamoxifen. Axillary node dissection is being recommended less often with local breast cancer due to the complications of nerve damage and arm edema. Lymphatic mapping with sentinel (main node involvement) lymphadenectomy is now recommended. For later-stage cancers, radical mastectomy is still the treatment option of choice. Radical mastectomy is also chosen as a prophylactic measure for women at extremely high risk of cancer based on hereditary likelihood and other risk factors.

Prevention may be possible to some degree; however, many of the risk factors are nonmodifiable. Some possible prevention strategies have less to do with preventing cancer and more to do with early detection and early treatment.

- Early detection is more likely with monthly breast examination, annual in-office breast examination, and mammography when there is a questionable finding or every one to two years in women over age 40 years.
- There are conflicting reports regarding the effect of physical activity and breast cancer risk. However, it does appear that higher levels of adult physical activity provide a modest degree of protection.<sup>76</sup>
- Dietary factors may have a bearing on survival of women with breast cancer. Interestingly, a recent study<sup>77</sup> indicated that there was no advantage to a low-fat diet after the diagnosis of breast carcinoma was made; however, there was an increased survival for women eating more protein, but not red meat. It has also been shown that a diet high in fruits and vegetables, specifically high in alpha-carotene, beta-carotene, lutein/zeaxanthin, total vitamin C, and total vitamin A, may reduce premenopausal breast cancer risk.<sup>78</sup>

## Eating Disorders

Disordered eating is a common problem in females. The majority of problems occur with the female athlete or with women in occupations where a thin appearance is required (e.g., acting or modeling). The two primary disorders representing the extremes of disordered eating are anorexia nervosa (AN) and bulimia nervosa (BN). AN is a disorder associated with self-imposed weight loss due to a distorted body image and other psychologically related problems. The vast majority of individuals are young, affluent white females (85%). Eighty percent of AN patients develop the disorder within seven years after menarche if, in fact, menarche develops. The female is often a perfectionist, coming from a family and environment of high expectations. The AN patient is sometimes identified as either restrictive dominant (i.e., avoiding eating) or binge-purge dominant (i.e., engaging in bulimic activities). The diagnosis of AN is based primarily on patient attitudes and self-perception with some indicators of malnourishment to support the diagnosis. Clinically AN criteria include the following<sup>79</sup>

- Weight is maintained at least 15% below that expected as normal based on height and gender.
- Intense fear of gaining weight even though obviously underweight
- Distorted sense of self
- Absence of at least three consecutive menstrual cycles (without any other known cause)

AN patients may have associated problems. In 50% of AN patients there is a tendency toward bulimic activities including compulsive exercise to lose weight, misuse of laxatives or diuretics, and purging activities such as vomiting. Due to nutritional deficiencies, some patients may have a hypo-functioning thyroid. Cardiovascular problems include bradycardia and hypotension manifested occasionally as orthostatic hypotension or syncope. Skin changes include facial lanugo, often giving a “furry” appearance, and also a yellowish discoloration (hyper-carotenemia) of the skin. When bulimia is also present, additional findings may occur, as discussed below. Due to the associated amenorrhea, the diagnostic search will often include laboratory testing, as discussed under the amenorrhea section of this chapter. Treatment is aimed at dealing with the nutritional aspects and the psychologic impairment that maintains the disorder. Referral to an eating disorders clinic is requisite. Management is beyond the expertise of most general physicians.

Bulimia nervosa (BN) is characterized by a binge-purge cycle in an effort to avoid weight gain. Although BN is seen in about half of AN patients, it is also its own disorder, with many individuals being of normal weight or slightly above normal. Bingeing usually occurs when the individual is depressed, bored, or lonely. Binge meals are often the “forbidden” foods that are high in fat or carbohydrate. Many bulimics report being obese

during childhood or adolescence; they diet as a first approach to weight loss. The most common bingeing activities include self-induced vomiting or laxative/diuretic abuse. This activity is so common it is seen in as many as 20% of college students, with about 4% reporting weekly binge/purge actions. Other BN patients use extreme amounts of exercise in an attempt to burn off anticipated weight gain. BN patients are more aware of their actions as being aberrant compared to the purely AN patient. The purging activities are easier to keep private and, given that extreme weight loss is not always seen, the disorder is silent to others. The only clues are indirect and reflect, in most instances, the secondary effects of self-induced vomiting. These signs include:

- Parotid or salivary gland swelling, giving a puffy-cheek appearance
- Bruising of knuckles from hitting incisors during self-induced finger vomiting
- Pharyngitis from reflux of gastric acid, detected as a chronic hoarseness that is unrelated to respiratory infection
- Dental erosions from gastric acid reflux
- Conjunctival hemorrhages from retching

Patients may have problems with esophageal irritation including Mallory-Weis syndrome and strictures. Cardiac and renal problems may occur secondary to problems with hypokalemic, hypochloremic metabolic alkalosis.

If a patient is suspected of having the disorder, subtle questioning should attempt to determine how often purging activities occur. If there appears to be enough evidence to warrant concern, referral to an eating disorders clinic is requisite.

## Incontinence

Urinary incontinence (UI) is an involuntary loss of urine that is not an inevitable result of aging. Statistics vary based on living environment, time frame, and definition; however, estimates are that urinary incontinence affects approximately 30% to 50% of older adults.<sup>80</sup> The prevalence specifically in community-dwelling individuals older than age 65 years is approximately 15% to 30%. Women are twice as likely to be affected. Generally, the most frequent causes of UI in women are stress UI and urge incontinence. Focused questioning for UI addresses the following areas:

- Frequency and amount of voiding
- Situational questions regarding the onset of UI (mechanical stimulation of voiding from coughing, laughing, sneezing, or jumping is likely

stress incontinence, whereas UI without mechanical stimulation is more often due to detrusor instability)

- Any associated signs/symptoms of urinary tract infection
- Bowel movements, in particular constipation (a distended distal colon with stool may affect bladder function through a pressure effect)
- Diagnosed conditions that may be the cause of voiding difficulty (e.g., congestive heart failure, diabetes, pelvic surgery for various conditions) or the medications used for the condition may exacerbate voiding problems
- Drug history (some medications may cause retention and lead to overflow incontinence [e.g.,  $\alpha$ -agonists and stimulants such as ephedrine found in nasal decongestants] while others may act as diuretics [e.g., prescription and herbal diuretics, alcohol, and caffeine])
- Previous diagnosis and/or management of UI
- Patient's desired goals of management

The evaluation may be limited for the chiropractor given that a rectal examination for both sexes, and a pelvic examination in women, is necessary for a complete evaluation. If these examinations are not part of the skills of the practitioner, referral for these evaluations is requisite. In addition to a urogenital examination, the following should be included in the work-up of UI:<sup>81</sup>

- Palpation for suprapubic tenderness, lower abdominal masses, and bladder distention
- Neurologic testing of the perianal area and lower extremity may be warranted when complaints of pain or numbness are reported
- The cough test (a screening test for stress incontinence in which the patient is asked to cough to determine if there is loss of urine)
- Maintenance of a frequency-voiding record by the patient
- Urinalysis to determine if glucosuria, blood, or infection may indicate an underlying pathologic cause
- Referral for more extensive testing includes an estimation of post-void residual, uroflowmetry, and pressure flow studies

Based on the type of UI, treatment options vary. Refer to [Chapter 34](#) for a more extensive discussion of treatment options. Generally, if stress incontinence is the cause, Kegel exercises are beneficial. If detrusor instability is the cause, bladder training, habit training, pelvic muscle exercises, and biofeedback are important nonsurgical, drugless approaches. Pelvic floor electrical stimulation (PFES) has been used for half a century as a treatment approach to stress incontinence. PFES stimulates pudendal nerve afferents activating pudendal and hypogastric nerve efferents, resulting in contraction of smooth and striated periurethral muscles and the striated pelvic floor muscles. Researchers in a recent randomized controlled

trial assigned women to an eight-week behavioral training program, behavioral training plus PFES, or gave women a self-help booklet.<sup>82</sup> There was significant improvement in those treated with behavioral training (69%) or behavioral training plus PFES (72%) but no significant difference between the two groups. Those using the self-help booklet also had improvement (52%). Drug therapy involves antimuscarinic medications including oxybutynin and tolterodine.

## Physical Abuse

Partner abuse is unfortunately a common feature of many relationships. The statistics are staggering, with the minimum prevalence data indicating 30% to 35% of all couples having had at least one episode of violence.<sup>83</sup> Some estimates are as high as 50% to 60% of couples. Abuse during pregnancy is also troubling, with estimates between 17% and 45%. Other saddening statistics include the following:<sup>84</sup>

- Thirty percent of all female homicides are perpetrated by a husband, a boyfriend, or an ex-partner.
- Of all women who seek care in the emergency department, 21% are battered women.
- Around 4 million women are physically assaulted each year.

Unfortunately, once an anger reaction has crossed over the verbal boundary to violence, it is more likely to recur. Unbelievably, until the last few decades of the twentieth century, abuse by a woman's husband was considered a personal option and the woman was not protected under law.<sup>85</sup> It was not until 1971 that the first shelter for battered women was established in London.

There appear to be cycles of abuse behavior. Initially there is a tension-building phase that escalates into the violence phase. Ironically, often following the violence phase is a honeymoon phase where the abuser apologizes and promises to change and demonstrates renewed love interest. This often misleads the abused partner so that plans to leave are postponed in the hope of reconciliation. It is also not uncommon for the abuser to then shift blame to the abused, minimize the occurrence, or even deny it ever happened. Despite the high prevalence of abuse, physicians rarely recognize the signs. This is in part due to the abused patient's attempt to hide these signs. The signs may be subtle or if obviously due to trauma may be explained away by the abused patient. Some physical signs that are suspicious include:

- Bruises are of different colors (old versus new abuse).

- Battering is more commonly in a central pattern at the head, neck, breast/chest, or abdomen, except for bilateral peripheral injuries (indication of defense attempts).
- Imprints of hands or shoes are on the skin (especially with rib fractures).
- Other types of suspicious injury include missing teeth, fractured mandible, choke marks on the neck, and scalp wounds including areas where hair has been pulled out.

Psychologically there are numerous possible consequences for the abused individual including chronic depression, sleep disorders, somatization disorders, anxiety disorders, and alcohol and drug abuse, among others.

In interviewing female patients, it is recommended that questions regarding abuse be asked in the past tense to prevent an avoidance response. If abuse is suspected, documentation is required. If a photo record of abuse is acceptable by the patient (indicated by a signed release form) it should be part of the patient record. In California, if abuse is even suspected, it is a requirement that a telephone or written report to the police be made. Many other states have similar requirements. In addition to reporting the suspected abuse and providing for appropriate care for injuries, it is equally important to provide resources for the abused patient including a shelter resource if it is determined that returning home is unsafe. All healthcare practitioners should have at hand contacts at centers for abused women. Social services and/or shelters will provide information regarding development of a safety plan. If the patient refuses help, the doctor must respect that the patient has the right to personal choice no matter how difficult it may seem. However, the doctor should be cautiously persistent if possible.

## Osteoporosis

Although osteoporosis (loss of bone mass; see [Chapter 30](#)) is seen in both genders, the female-to-male ratio for vertebral osteoporosis and fracture is 6:1.<sup>86</sup> This is primarily due to the lack of estrogen stimulation seen in the postmenopausal female. Bone loss in early menopause is between 1% and 5% per year. This bone loss is relative to the premenopausal bone mass status of the female. Bone mass development occurs primarily before and up to the early twenties; therefore, any interruption or dysfunction in bone accumulation leaves the individual with less bone prior to menopause. Common factors are related to diet and exercise. Not enough calcium and too much or too little exercise are the primary risk factors in the adolescent group. The focus for the young female athlete is to determine menstrual status. Amenorrhea (as part of the female athletic triad) results in loss of

estrogen stimulation for bone formation and, as a result, bone loss may equal that of early menopause.

It is important to screen all females, and in particular those with indicators of osteoporosis, on x-ray for known risk factors for osteoporosis including the following:<sup>86</sup>

- white or Asian background
- early menopause
- family history
- lean body habitus
- lack of exercise, or excessive exercise in the young
- glucocorticoids, phenytoin, aluminum antacids, lithium, loop diuretics, tetracycline, warfarin
- heavy alcohol consumption; smoking; low calcium intake or vitamin D deficiency; high phosphate, fiber, or sodium intake; more than four cups of coffee per day; carbonated drinks (several a day); and possibly a high-animal-protein diet (although a low-protein diet may also place the female at risk)
- high homocysteine levels

The resulting screen of the above factors will establish a baseline level of risk for osteoporosis or progression of osteoporosis. Given that osteoporosis is essentially a silent disease until fracture or deformity occurs, it is important to screen all females.

When osteoporosis is suspected, the primary initial evaluation tool is x-ray. Spinal x-rays may detect existing osteoporosis; however, only with bone loss between 30% and 50%. There are classic radiographic findings with osteoporosis; however, their appearance indicates advanced involvement. These findings include cortical thinning (pencil-thin cortex) and trabecular changes. Trabecular resorption may leave the remaining stress-surviving trabeculae more visible, in contrast to a background of radiolucency. Changes in the vertebral shape with osteoporosis include vertebra plana (pancake vertebra), wedged vertebra, and biconcave (fish, hourglass) vertebra.

More sensitive techniques include single- and dual-photon absorptiometry (SPA and DPA, respectively), quantitative computed tomography (QCT), dual-energy x-ray absorptiometry (DEXA), and possibly ultrasonography (US). Although DPA, QCT, and DEXA measure both types of bone, DEXA is now the measurement tool of choice. Laboratory evaluation is valuable only in the differential evaluation. Most bone-related lab levels, such as calcium, phosphorus, and alkaline phosphatase, are usually normal unless there has been a recent fracture.

Osteoporosis treatment includes both prevention strategies and treatment strategies for those with documented osteopenia or osteoporosis:

- For all women, establish a lifestyle habit of maintaining an adequate amount of calcium and vitamin D combined with an appropriate level of exercise; also recommendations for avoidance of known contributors to osteoporosis acceleration including smoking, alcohol, caffeine, carbonated drinks, etc.
- When a secondary cause of osteoporosis or a compression fracture is found or suspected (i.e., cancer, Paget's disease, hyperparathyroidism, or osteomalacia), medical consultation is necessary.
- If a compression fracture appears radiographically unstable, refer for medical consultation (see [Chapter 6](#) for details).
- For all older women, establish a prevention program for falls including an environmental evaluation, exercise program, and nutritionally supportive regimen.
- For all osteoporotic patients, a comprehensive program is needed that includes patient education, appropriate exercise, and appropriate nutrition coupled with psychosocial support.

The amount of calcium intake is generally recommended to be 1,000 mg for premenopausal women and 1,500 mg for postmenopausal women. For the elderly or homebound patient it is important to consider the need for vitamin D supplementation. The recommended daily allowance is between 400 and 800 IU. A cup of milk will provide only 100 IU of vitamin D. This is a significant factor that is often overlooked (see [Table 30-2](#)).

Medical options for postmenopausal women include the following:

- ERT or HRT (hormonal replacement therapy)
- bisphosphonates such as alendronate (Fosamax)
- selective estrogen receptor modulators (SERMs) such as raloxifene
- calcitonin

Exercise prescription for the osteoporotic patient should meet two goals. First, it is important to stimulate bone production and prevent loss. Second, it is important to strengthen muscles to provide support and to provide proprioceptive training to prevent falls. The increases in bone mass seen with exercise are mild to modest, in the order of 1% to 3%. However, it must be kept in mind that simply preventing further bone loss is a major goal of an exercise prescription. The general rule of thumb for causing bone mass response is that the exercise must provide mechanical loading either through pull of muscle on bone or with weight bearing. Some important considerations follow:

- Walking does not seem to provide enough stimulation for increased bone mass; it must be combined with resistance exercise.<sup>87</sup>

- Non-weight-bearing exercises including swimming and cycling are relatively ineffective approaches.<sup>88</sup>
- Resistance exercise must exceed that provided by daily activities.<sup>89</sup>
- The effects of exercise are site-specific (e.g., running does not provide a stimulation for bone in the upper extremities).
- Impact activities that apply relatively large loads on bone quickly are the most osteogenic and are the most risky; therefore, a progression of exercise up to the level of these types of activities is the final goal.

## The Female Athlete

A major milestone for females and sports occurred in 1972 with Title IX legislation.<sup>90</sup> This legislation mandated equal opportunity for females, providing for equity in sports programs at educational institutions and equal access to athletic competition and recreational exercise. It has led to an explosion of participation in many sports, including those previously male-dominated sports such as soccer, rugby, basketball, bodybuilding, bowling, and golf, among others. With this increased involvement, the number of injuries to females related to athletics has skyrocketed. There are many theories as to why this increase seems out of proportion to similar injury patterns in males. Some of the most obvious have to do with gender-specific training. Other factors relate to the anatomic and physiologic differences between males and females. These observations have spawned an interest in gender-specific research that increasingly demonstrates more similarities and fewer differences when body size and weight are factored in.

Prior to puberty, the differences between males and females are negligible. Due to the fact that girls reach puberty earlier than males, there is a small period in which females mature more quickly, have greater coordination, and in many cases are taller than their male counterparts. Prepubescent males and females are equal in body fat composition.<sup>91</sup> The male body fat decreases 11% on average through adolescence. Females increase body fat on average 25% during this same period. Postpuberty, there are some recognized differences between males and females:<sup>92</sup>

- The average female is 3 to 4 inches shorter than her male counterpart.
- Adult women have 8% to 10% more body fat than men on average. Percent body fat differs with each sport; endurance athletes average between 12% to 18%, white elite runners as low as 6% to 8%, and team sports (e.g., soft ball, volleyball, and swimming) 18% to 24%.
- Women have shorter limbs relative to body length when compared with men. This is most evident in the upper extremity where the humerus is shorter in women than in men. Women also have a more narrow shoulder width.

- The wider, shallower pelvis observed in women has been cited as a major cause of an increased quadriceps (Q) angle at the knee. The effect on the Q angle and its association with increased patellofemoral problems has not proven to be as major a concern as has been implied from earlier research.<sup>93</sup>
- Cardiopulmonary differences include the following: women have fewer red blood cells (RBCs), lower hematocrit and hemoglobin, smaller heart and stroke volume, smaller vital capacity and residual lung volume, and lower  $\text{VO}_2$  max.
- As absolutes, the average female is two-thirds as strong as the average male; upper body strength is only 30% to 50% and lower extremity strength 70% that of the same size male. However, when body mass and relative strength are considered, the female has about 55% of the male's upper body strength and is about equal in lower body strength.
- Statistically, there are no objectifiable differences between joint laxity compared with males, although clinically it has been observed that the knees and shoulders of females seem to be "looser."

Regarding the menstrual cycle, there appears to be no significant correlation between menstrual phase cycle and exercise performance.<sup>94</sup> However, injury rates appear to increase in athletes with premenstrual symptoms. Also, there has been some association suggested between estrogen and possible laxity of the anterior cruciate ligament.<sup>95</sup>

Specific concerns that should be addressed on preparticipation examinations and with all athletic females are as follows:<sup>96</sup>

- Shoulder laxity: Women who participate in upper body sports such as tennis, swimming, and volleyball should be instructed to focus on both strengthening the shoulder rotator cuff and serratus anterior and also trunk strengthening to decrease the stress to the shoulders. Given that women are generally weaker in upper body strength, focus on a generalized upper body-strengthening program will also be beneficial.
- Knee laxity: It has been observed that patellar instability is more common in females. This may be due in part to more of a tendency toward underdevelopment of the back surface of the patella and lateral condyle of the femur, decreased vastus medialis strength, tighter iliotibial band (ITB), or a high riding patella. This tendency, combined with a position of recurvatum (hyperextension) seen more commonly in females, may predispose toward either tracking problems, patellar subluxation, or patellar dislocation. Focus the patient on vastus medialis strengthening, ITB stretching, orthotics for pronation, and proprioceptive training. Anterior cruciate ligament (ACL) laxity or looseness is a concern for females, given a relatively high rate of injury when compared to males participating in similar

sports. Although there are many theories, it appears that the main effective strategy for decreasing injury is training. It is clear that the vast majority (78% in one study) of ACL injuries are noncontact, often occurring when landing from a jump.<sup>97</sup> This is even more true in sports such as basketball and volleyball. One study<sup>98</sup> divided these noncontact injuries into three types and documented the percentage of incidence. Together they accounted for most ACL injuries in the study and individually are essentially equal in occurrence (26% to 29%). The three types are:

1. planting and cutting
2. straight leg landing
3. one-step landing with the knee hyperextended

ACL injury rates were reduced among a group of women by almost 90% simply by modifying the plant-and-cut maneuver to a three-step stop with an emphasis on avoiding knee extension. Another study<sup>99</sup> indicated that the incidence of knee injury in female athletes is significantly reduced with a training program for jumping and landing. Noncontact ACL injury may be related to both genu recurvatum and hyperpronation. Intercondylar notch size is probably not a factor.<sup>100</sup>

- Stress fractures: Tibial and other stress fractures are more common in females who are amenorrheic and/or osteoporotic. Of particular concern is the “dreaded black line” seen radiographically at the tibia in dancers. Nonunion is particularly difficult with this fracture. Standard stress fractures should be managed with partial weight-bearing, aquatic and non-weight-bearing exercise, and an increase in calcium supplementation to 2 g/day for several weeks.
- Nutritional concerns: The primary nutritional concerns in the female athlete are iron deficiency and calcium insufficiency. Iron deficiency is seen in 20% to 25% of female athletes. The incidence is high in elite cross-country skiers, followed by female distance swimmers, then all collegiate athletes; the greatest deficiency is seen in adolescent female swimmers (47%).<sup>101</sup> These subsets of athletes should be screened as well as any athlete developing early fatigue, chest complaints, dizziness, or presyncope/syncope events. Vegetarian runners are more at risk than those consuming meat. Menstrual loss is the main cause; during menses loss of 1.2 to 2 mg of iron per day is common. This translates into a 1- to 2-mg drop in hemoglobin levels. Nonmenstruating women require 10 mg of iron per day, while menstruating women require at least 15 mg of iron per day. Calcium supplementation is discussed under the osteoporosis section.
- Pelvic floor laxity and incontinence: Either urethral sphincter insufficiency or loss of detrusor tone in combination with an increased intravesical pressure exceeding urethral pressure will result in

incontinence. It is seen primarily in high-impact sports (high-impact aerobics, running, basketball, track and field, and volleyball) and in those activities associated with increased abdominal pressure (gymnastics, weight lifting, martial arts, and others). Management is discussed under the incontinence section in this chapter and in [Chapter 34](#).

- Female athletic triad syndrome: The triad of disordered eating, amenorrhea, and osteoporosis is found in some female athletes; in particular, in the high-level amateur and professional. Each is discussed under its own section above. Females who are affected generally have low body fat, inadequate caloric intake, disordered eating, and/or are involved in a high-intensity exercise/sport. The amenorrhea (and subsequent development of estrogen-deficient osteoporosis) is believed to be a form of hypothalamic amenorrhea where decreased or abnormal secretion of gonadotropin-releasing hormone (GnRH) is due to either (1) adrenal activation inhibiting hypothalamic release of GnRH, or (2) increased caloric demand with inadequate caloric intake that leads to an “energy drain” that then may cause a relative hypothyroid state.

## **Appendix A**

# **How to Incorporate Literature Evidence into Practice**

This appendix will not satisfy the detail necessary for an understanding of statistics or even research design and so therefore will disappoint scientists and teachers of evidence-based methods. However, the intention is not to train clinicians on how to conduct research or to remind researchers how to construct or conduct research but rather is designed for the clinician as a foray into the world of the scientist to understand their methods and logic and how to begin to resolve the apparent disconnect between these two worlds.

The three components of evidence-informed practice must include not only the literature evidence, but also the practitioner's expertise and the patient's preferences. This is often biased toward a focus on the literature for scientists, and toward the practitioner's belief in his or her expertise for the field-doctor. The patient's preferences are perhaps biased toward the individual from whom he or she seeks help, but are also influenced by the information given by that practitioner. Because patient outcomes are somewhat unique to that context, evidence-informed knowledge and measurement must include both the literature evidence for a given topic and also the practice environment of each practitioner. Measurement in practice is not confined by the

restraints of randomized controlled trials (RCTs) and other studies. Imposed by the practice context, using a less scientifically restrictive approach is allowable and preferable. This is because with no intention of extrapolation outside that practice, it reflects the context of that environment where future patients will be managed and where data are relevant. How then can one practice scientifically without being a scientist? Let's look at how a scientist views patients.

## **The Scientist Mindset**

### **Here is the scientist's perspective:**

- Attempt to systematically eliminate any bias in drawing conclusions and determine how much *chance* may play a part in the results.
- Address as many variations as possible through research design to include multiple patient populations, practice environments, and other variables to allow general application. At the same time, make patient groups homogenous so that comparison is appropriate (meaning comparing groups requires that both groups are similar in demographics and other elements regarding their condition, comorbidities, pain levels, acuteness, etc.).
- Scientists and researchers believe that clinical "expertise" is often the product of the classic representation of the "biased" environment. In other words, as a practitioner you see what you want to see and forget what does not support the perception of success.

To be sure, there are some flaws to most human observations. These can be generalized into two broad categories: (1) bias, and (2) misinterpretation of chance occurrence.

## **Bias**

Bias has many forms, but the most common is having an expectation based on prior experience, or on trying to get a specific result. This applies both in practice and in research. Here are some examples: • Bias can occur in the reader who believes a positive report from a research study because he/she wants to find support for his/her belief, and therefore discounts the results of studies that do not support his/her belief system.

- When bias enters into a study it is called an error. Bias can enter at all levels of a research study including the participants, examiners, staff, and reviewers. Bias in the selection of patients, bias in patient recall of events, bias based on preferences of patients, and so forth.

In practice, to be honest about our successes, we must first understand the caveats of human perception; our tendency toward a bias to believe in what we do. “Recall” bias is often focused on successes, so you remember those events that support your belief in the value of what you do; not in itself a bad thing, but not unbiased.

Consider the following:

- You may not count those patients who received benefit through referral to other healthcare providers.
- You may tend to selectively forget those patients who don't improve and attribute that result to their lack of compliance or attitude. Perhaps you do not count them

as a non-responder because they never returned to convey that information.

## **Chance**

The possibility that chance is the reason for an occurrence is more likely if it is seen rarely or by a single individual and less likely if it occurs frequently and is observed by many; for example your practice versus a large study, respectively. Chance occurrence is more common than we humans intuit. Researchers can measure this occurrence and calculate the probability that chance is the potential reason for a result. In general, the more individuals in a study and the more studies that support the same findings, the less likely it is that chance will play a role. Chance occurrence is reported in numbers such as  $p$  values and 95% confidence intervals (CI); more on that later.

## **Placebo and Nocebo**

We are less concerned with placebo in our practices than in scientific studies because a positive placebo effect still results in a successful outcome; the patient's expectation and requirement of you are met. Scientifically we want to avoid placebo in order to determine the truth about an intervention's direct cause of an effect. In practice, this becomes less relevant but must nonetheless be recognized and appreciated when tallying our successes. The ethical dilemma is this: Is a patient avoiding a known intervention that is safer, cheaper, or, of course, more effective? Nocebo is the reverse—a sham or inert substance or treatment that produces harm. New studies are indicating that some sham treatments result in adverse events.

# The Clinician Mindset

The clinician's perspectives that may be contrary to the scientist's perspectives include the following: • Do the best you can for the patient even if your choice of treatment does not match the literature.

- Each patient is unique and no amount of literature support for a given conclusion can cover all possible scenarios (i.e., patient variation; the real world).
- The major concern by clinicians—and an excuse for studies being ignored if they don't represent what the clinician wants to hear—is that the clinician may believe that the scientific perspective is the epitome of disconnect to the individual patient.

The danger is that the clinician will adopt a “desert island” approach where he or she stays isolated in practice without updated knowledge or comparison to others' experiences and opinions. This is defensible only when you have no choice; you use the best available tool to accomplish the task based on your experience. When you have access to a greater fund of knowledge, is it ethical to limit your scope of treatment, and become that person on the desert island?

Is what appears in studies enough to guide our clinical decisions? What are the potential limitations of applying strong literature conclusions that are scientifically sound? Good science is based on large groups of individuals where the potential for chance can be diminished statistically, yet these large groups are in fact averaged, so the group or that average may not represent the patient in front of you. Scientific studies cannot tell you how each patient will respond to you specifically, because of these unique elements: • Your office space

- Your procedures

- Your demeanor
- Your patients' beliefs and attitudes
- Your techniques and expertise

Common questions and concerns clinicians voice about using only scientifically validated evidence from the literature or when adopting the scientific mentality are: • If I question everything, what can I trust?

- If I question everything, how can I have confidence in what I do?
- If I don't try to stay up to date with techniques that promise high-tech advances, how can I provide the best care for my patients?
- Do I have to wait for evidence?

The solution is through the understanding that an evidence-informed practice allows, and demands that one generates, some of the evidence upon which one makes decisions. You become the clinician/scientist. The clinician/scientist mentality is simply a change in focus that requires that, whenever possible, one: • Applies scientific principles to observations in practice (i.e., recognizes the potentials for biased observation) • Applies literature recommendations (i.e., pilot studies) when possible even if this is not your customary management approach, to test out the literature

- Writes case reports
  - Participates in research and research design

You may ask: What's in it for me?

- You can map out your patients by presentation and determine your effectiveness with each type.
- Your successes are marketable.
- Your weaknesses are remediable when you are part of a group that compares.

Before we illustrate some simple approaches to measurement, analysis, and change for your practice, let's review some basic scientific principles.

## **Evidence**

Let's start with a world; a perfect world. In a perfect data-driven world, we would know all about all. We would have data on billions of individuals that would include all the demographic information, genetic information, disease/disorder information, and data on how all problems were managed and the success or failure of those methods. We therefore would know an individual's risk and the risk relationship to a multitude of environmental and genetic risk factors and triggers. We would even know the detail of what is the best diagnostic test and most available test for a given context such as a country, region, or area. We would know the exact treatment method used to manage operationally defined disorders to the point of understanding what specific surgical, drug, or conservative treatment approach works in the majority of patients who are, in fact, the mirror-image of the patient in front of me; the whole person in front of me. Because this perfect data-driven world is not attainable, this appendix is about how to take only fragments of understanding and piece together an approach that is the best educated guess to what may work for our patient.

We could rely on our experience, but what if you are a novice with little experience or none in the specific area of concern for your patient? How would you approach this problem? You would look for what others know. You may ask colleagues, you may search the Internet using a broad search engine such as Google or Google Scholar. google. Even then, how much can you trust the information you find? Regardless of your choice of resource(s), you will still

ask the same questions to know whether you are close to the truth: • Does the information from a colleague, an article, or a blog reflect relevant information for my specific patient?

- On what is the opinion or conclusion based?
- What are the prejudices or biases of those resources? Like any other search, we want information that is based on an attempt to look at what is fact and not based entirely on observation, opinion, or interpretation. That is where science comes in. That makes it sound like science is perfect. It is not. Scientific knowledge is always building on past observations, including misinterpretations or errors. That being said, the best we can do is to aggregate all available resources and weigh each one, and science should rank high on that list. How we attribute weight to that information is not a equal one-to-one proposition. And, how we value the information, how practical and usable it is, is not always a reflection of how scientifically rigorous the research has been.

It is relatively easy to rate the weight of information based on scientific rigor. For example, a randomized controlled study would certainly rate higher than one that is not, because that is the highest-order study for ruling out chance and bias if conducted properly. A prospective study, in general, is better than a retrospective study (more on this later). A case study of one to several patients is clearly not as strong scientifically as a larger study involving more participants. But regarding value, the weighting must be in the context of the patient in front of you and the confluence of the literature conclusions in an aggregate summary. Then each clue, whether historical or by clinical examination, must now be placed on a scale on the side of likely having the disorder in question versus not.

For example, a given historical clue may be placed on the side of having the disorder but only amount to the weight of a BB, whereas the value of an orthopaedic clue may have the weight of a bowling ball, or vice versa (**Figure A-1**). Or something may be intermediate, like the weight of a billiard ball. That being said, the value of the test may be different from the scientific rigor rating, especially if the study population matches the patient in front of you compared to studies where the population does not. Also, remember that risk factors are not diagnostic clues. They have value in rating risk, which is an association, but do not necessarily help in making a diagnosis.

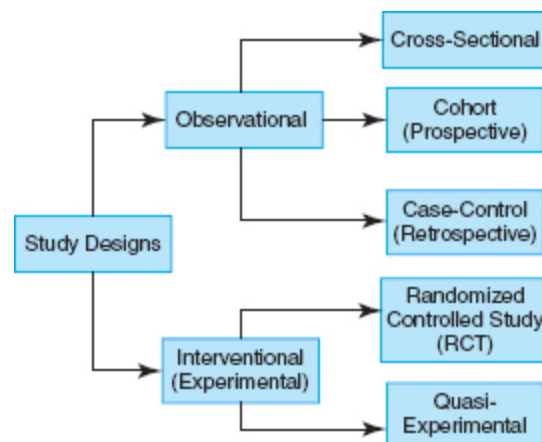

The broadest and most important distinction of research studies is determining their intent. There are basically two types of research studies (**Figure A-2**): **1.** Observational: A study can be designed to find an association or risk to a particular disease or disorder. These are observational studies without intervention.

**2.** Interventional: A study can be designed to determine the effect of an intervention on patients with a known disorder.

These studies can: (1) examine a patient group at one point in time, called a cross-sectional study; (2) follow a group of patients forward in time, called a prospective (or longitudinal) study; or (3) back through time, called a retrospective study. We will begin by looking at interventional studies to determine how we approach the literature with regard to the effectiveness of an intervention.

**Figure A-1** The scientific weight of different types of studies.

**Figure A-2**

## Treatment Effects

*How do you know if the treatment works, and if so, how well it works?* To understand how the results of research can be utilized in practice, the clinician must be numerate. Numeracy is similar to literacy but instead of interpreting the meaning of words, it means to interpret the meaning of numbers. Note that this does not equate to doing the math and calculating the statistics, but it means that clinical

application of the end result of the calculations is achievable and hopefully communicable.

What numbers mean depends on the interpreter. Of course it is human nature to convey our own bias and certainly use numbers in the most convincing light for what we mean to achieve. The variables are the study, the researchers who conduct the study, the patient, and the middle man—you, the doctor. Like it or not, the doctor becomes the inevitable translator of statistics for the patient. You need to be “bilingual”: know the results for a group of patients (the study), and attempt to translate that information into results for your patient. You need to convey why you feel your care can help and also include reasonable options for the patient. Most would admit that second on the list for not reading a research article (the first being time) is that when you encounter the numbers, you just want to gloss over them and get to the conclusion, hoping that the researchers and editors of the publication have done their job and given you the bottom line. But you are rarely confident that you truly understand the meaning and relevance of the statistical terminology and numbers.

If you don't see one of the following terms in the abstract of an article on an intervention or risk factor, you will have your first warning sign about the scientific validity of that study: Absolute Risk (AR), Relative Risk (RR) and Recurrence Rate Data (RRD), Number Needed to Treat (NNT), Odds Ratio (OR), Effect Size (ES), and mean differences. This is the vocabulary list of statistics, the words one needs for understanding the results found. It may sound daunting but the math used is almost always simple addition, subtraction, or division, which is now automated through online calculators, is easily accessed, and for the most part, mathematically related. By using examples and discussing results first, we will effortlessly learn the language used to express the results utilized in study papers. You should then be able to generally determine what a study is saying,

despite the possibly confusing terminology, and determine whether it is worth reading, how important and valid the information is, and whether it is usable for your purposes.

Understand the patients' dilemma. They want to be in control of their health management choices, yet most are not trained in the language of statistics to make sense of that information if it is offered in terms such as  $p$  values, confidence intervals, and so on; in other words, they are not numerate. We need to assist patients in making decisions regarding their health. Although we are always sensitive to our patients' desires to be actively involved in their health management choices, we understand that they are relying on us to give them information in a manner that is usable. How we explain the benefits and risks of a given treatment, even to a colleague, is in need of edit and translation before explaining the same information to a patient.

*Where do clinical questions about an interventions success come from?* It may be a question based on lack of experience, but it just as often may reflect curiosity; an attempt to learn something new about something you already know. The question can also come from your patient. It probably will center on whether they will improve or if there is a risk to treatment. So what is the patient going to ask? What are the chances I will get better with this treatment and how long will it take? What are the chances of responding to a standard treatment such as medication, surgery, or no treatment?

Suppose a patient approached with a question about a report he or she heard on the news about a "miracle cure" for some disorder. Let's use an example. A news headline states that a new drug reduces cancer death by 33%. Thirty-three percent reduction of cancer, but compared to what, no treatment or another treatment approach? In other words, 33% of these cancer patients will survive and 66% will not without treatment? Or does this mean the new treatment is compared to another existing treatment? What if the newer

treatment is far more expensive and has more side effects? How this study was conducted would, like most studies, be based on two main goals of science: is there a difference between groups, and are there associations when evaluating risk?

Let's say that an oncologist needed to explain the study to one of his or her patients. Here is how it could be expressed.

- "You have one-third the risk of death with the newer treatment compared to the standard treatment."
- "The risk of death is about two-thirds that of those in the standard treatment group."

Or you could use a combination of the above two statements:

- "Your risk of death is reduced one-third with the newer treatment compared to standard treatment so that now you have only two-thirds the risk of someone using the standard treatment."

The first statement is called relative risk reduction (RRR), the next statement about having two-thirds the risk of someone on standard treatment is called relative risk or the risk ratio (RR), and it is just that, calculated by dividing the rates of death with the new treatment by those of the standard treatment. This indicates a comparison to another treatment, not comparison to natural history. What's missing? If the actual death rate for those on the standard treatment was only 5.7% and the death rate in the group with the newer treatment was only 3.8%, then we know the death rate using standard care for this cancer is not very high to begin with. The ratio between groups magnified the effect of the new treatment to 66%, which is a true

comparison but as a ratio. The actual difference in death rates between the two groups is only 1.9%.

Let's discuss another set of hypothetical examples (**Figure A-3**). If the risk of death is 10% in the standard group compared to 6% in the new treatment group, the absolute difference is 4% AND this is also a 40% reduction in risk! If the risk of death is 1% in the standard treatment group and it is 0.6% in the new treatment group, it is still a 40% reduction AND this equals an added advantage of helping only 0.4% more people! So what makes the difference? The actual (not relative) outcome rate (event rate) difference is called the Absolute Risk Reduction (or Risk Difference). The relative risk and relative risk reduction calculations are blind to the actual numbers because they are only ratios between numbers. For example:

**Figure A-3** 40% RR in three different-sized groups.

- 10 is 10% of 100
- 1 is 10% of 10 and
- 0.1 is 10% of 1

The ratio remains the same (10%) but clearly the actual numbers are magnitudes of difference lost when calculated

as ratios. The problem is that RR and RRR create a magnification of effect often enlisted by researchers or pharmaceutical marketers attempting to sway the reader into thinking the effect of a newer treatment is greater than it really is greater than its actual clinical value would be. There are clearly some ethical considerations in the medication advertisements that illustrate attempts to exaggerate effects. It is disturbing to realize that to be considered effective, researchers have to show only that a new drug has a *statistically* significant difference (not due to chance) but not a clinically significant difference if compared to placebo.

Next, let's discuss some other terminology for events that occur with two treatment groups compared in a study. The term Exposed Group Event Rate (EER) is also called Treatment Event Rate (TER) and Intervention Event Rate (IER), and refers to the new treatment approach group. The term Control Group Occurrence (CGO), also called Control Event Rate (CER), refers to the comparison group. **Figure A-4** is a more detailed expression of how a two-by-two table is constructed and the resultant RRR, ARR, and NNT are mathematically derived. Although interesting and valuable, much of this is automated through online calculators so that you could take the results of studies and plug in the numbers without doing the math.

Let's review a study that uses these designations, comparing clopidogrel (Plavix) to aspirin for patients with risk of ischemic events. The ischemic events included myocardial infarction, stroke, or vascular death. The control event group used aspirin. For them, the CER was 5.83% versus the EER for the clopidogrel group of 5.32%. The  $RRR = (5.83 - 5.32)/5.83$ , which equals 8.7% in favor of clopidogrel. The absolute risk is  $ARR = 5.83 - 5.32$ , which equals only 0.51%!

	+ Outcome	- Outcome
+ Intervention	A 10	B 50
- Intervention	C 26	D 34

CER = control group event rate =  $c / (c+d) = 0.43 = 43\%$

EER = experimental group event rate =  $a / (a+b) = 0.17 = 17\%$

		Relative risk reduction (RRR)	Absolute risk reduction (ARR)	Number needed to treat (NNT)
		CER-EER		
CER	EER	CER	CER-EER	1/ARR
43%	17%	60%	26%	4
		*95% CI $\Rightarrow$	10.3% – 41.7%	2 – 10

\*95% confidence interval (CI) on an NNT =  $1/(\text{limits on the CI of its ARR}) =$

$$\pm 1.96 \sqrt{\left[ \frac{\text{CER} \times (1 - \text{CER})}{\# \text{ Control Pts}} \right] + \left[ \frac{\text{EER} \times (1 - \text{EER})}{\# \text{ Exper Pts}} \right]} = \pm 1.96 \sqrt{\left[ \frac{0.17 \times 0.83}{60} \right] + \left[ \frac{0.43 \times 0.57}{60} \right]} = \pm 15.7\%$$

**Figure A-4** Sample calculations—risk reduction.

These questions were adapted from the Oxford Centre for Evidence-Based Medicine and applied to physical therapist practice.

The NNT is the inverse of the ARR (1/ARR) and represents the number of patients needed to be treated to avoid *one* adverse outcome (e.g., an ischemic event). In the previous example, the NNT is equal to  $1/0.0051$ , which equals 196. Almost 200 patients would need to be treated with clopidogrel, *as compared to aspirin*, to avoid one adverse CV event. Does this make sense considering the high cost of the new drug?

Here is another study comparing endarterectomy versus aspirin for cervical artery stenosis. The CER was 26%, whereas for surgery the EER was 9%. Using standard calculations and statistics, RR = 35%; RRR = 65%; and ARR = 17%. The NNT = 5.9, meaning five to six patients need to be treated with surgery to prevent one stroke. The questions arise: Is it worth it? What are the costs and what are the risks of the treatment?

The use of statins is very popular for the reduction of cholesterol. What are the results, though, regarding reducing cardiovascular risk and death? Although Crestor

(statin) sales were \$4.5 billion (\$3-\$5/day for patients) with 80 million meeting the criteria, it was proposed the following criteria should also be included (effectively increasing eligible patients significantly):

- Patients over age 50 years if male; age 60 years if female

- One risk factor (smoking or hypertension)
- Elevated C-reactive protein (CRP) ( $> 6.5$  mol)

The researcher (also the developer of the test C-reactive protein used as one of the indicators) claimed a reduction of 55% in myocardial infarction, 48% in stroke, and 45% in angioplasty. The real numbers for Crestor were that the CER in the placebo group was 0.37% (68/8901) and in the Crestor group the EER was 0.17% (31/8901). The RR = 54%; RRR = 46% ( $1 - RR$ ), but the AR = 0.2% with an NNT = 500. So the author/researcher was correct but selective in the statistic he or she used, which appears to be an intentional decision to promote the use of statins.

When determining effectiveness, several questions need to be answered. The first is, did a statistical difference occur? This is determined, and is reported as the  $p$  value. The  $p$  value is a measure of how often something would happen beyond chance. In other words, is it statistically likely that the vast majority of the difference is NOT due to chance? The next question is, what is the magnitude of that difference? This is measured, and is reported as the 95% confidence interval (CI). The CI is the range of difference not just a point value representing an average.

Like CIs for diagnostic tests, a result of 1 means there is no value. Unlike CIs for diagnostic tests, CIs for intervention and/or risk must not include 0 or go below 0. In other words, if there is no difference between two treatment outcomes or risks, divided into each other the result is 1. If it is less than 1, the intervention being tested is less effective or the risk being evaluated turns out to be potentially protective and not a risk. CIs inform the clinician about the range within

which the true treatment effect might lie. The greater precision (narrower range) results from larger sample sizes (i.e., assuming a larger number of events). It is calculated by finding the appropriate z-score, which is based on the degree of confidence. The CI is calculated as the standard deviation divided by the square root of the  $n$  and then multiplied by 1.96. The final step is to add and subtract it from the mean to determine the range.

The next question is, is it clinically relevant? This is determined by various means of measuring two issues: the *minimal clinically important difference* (MCID) and the *effect size* (**Table A-1**).

**Table A-1** Minimal Clinically Important Difference (MCID)

<b>Outcome Measure</b>	<b>Suggested MCID</b>	<b>Patient Population</b>
Oswestry	4-6	Patients with LBP
Roland-Morris	2-5	Patients with LBP (1-2 with mild disability; 7-8 with high disability)
Neck Disability Index	7	Patients with cervical radiculopathy
VAS (100 points)	18	Patients with chronic LBP
Pain (11-point scale)	2-3	Patients with chronic pain

**Table A-2** Effect Size Summary

<b>Number</b>	<b>Difference between Treatment and Placebo</b>
---------------	---

0.0	No difference
0.2	Small treatment effect
0.5	Moderate treatment effect
>0.8	Large treatment effect

The MCID is generally gauged by a comparison to a percentage or difference in points based on an outcome measure. This is by standard a 30% change; however, some researchers require a higher standard of up to 50% change. How is this change determined? This can be statistically determined in complicated formulas, but again, for the clinician, the quickest and most reliable way is by comparison to an outcome measure. These outcome measures are numerous but the most common for spinal conditions include the Roland-Morris Disability Questionnaire, the Oswestry, the Bournemouth Questionnaire, the Neck Disability Index, and the common measures of pain—the visual analog scale and the numerical rating scale. Some caution must be used when the baseline for these outcome measures does not indicate a high degree of disability or pain. As we have seen, a percentage change of let's say 50% may indicate only a change from a numerical rating scale (NRS) for pain of 2 to 1 (as compared to a more significant indicator of an NRS of 10 to 5). Therefore, the higher the severity indicated by the measure, the more reliable is the percentage change. The other determination is simply a point change relative to the outcome measure, as indicated in **Table A-2**. MCIDs can be used to simply look at the effect of treatment (intervention) in each group, or for a comparison between groups. When comparisons are made between groups, an effect size based on the mean differences between groups is more often utilized.

The effect size can be even trickier than the MCID. This statistic more often has to do with the difference between treatment groups. As a statistical calculation, the effect size is often described as a number with a point value of greater than 0.8 equal to a large treatment effect.

A summary approach is to compare several statistical values to see globally if there is an effect change that would likely be clinically valuable; i.e., valuable to your patient.

**Table A-3** summarizes an approach using the NNT, EF, and OR in gauging the significance of a change. Remember that this is always an important comparison to what often is reported as a *statistically important change* or difference, which may have little or no value in practice.

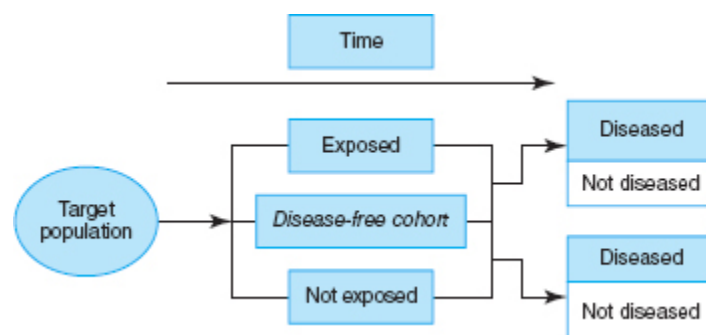

## Risk

When estimating risk, researchers are really looking for whether there is an association between an exposure and an event. Associations can be studied based on looking at risk factors such as smoking, hypertension, obesity, and so on. An association is not by definition the same as cause-and-effect, which requires more stringent study approaches including studying patients only forward in time rather than retrospectively. In studying risk, researchers attempt to compare the risk of an outcome in participants exposed to the risk factor compared to those non-exposed in observational (not interventional) studies (trials). For studies of risk factors versus interventions, there are two approaches, both observational (**Figures A-5, A-6**). One is the cohort or prospective study that follows people through time. The other is a case-control, retrospective study where researchers use a method that looks back in time to see if the patient with a specific disorder was exposed to a risk factor under investigation. The cohort study usually uses *relative risk* as a measure whereas the retrospective, case-

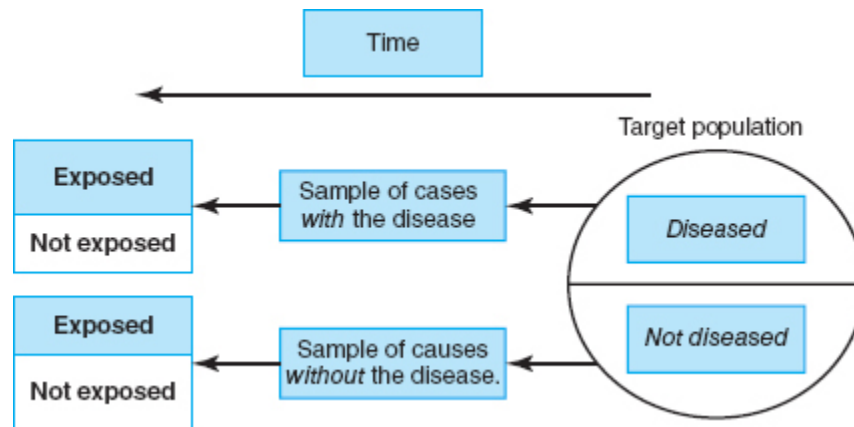

control study must use an *odds ratio*. So again with the prospective study you begin with disease-free subjects and see who develops the disease when exposed to a risk factor, whereas in a retrospective, case-control study, the individuals already have the disease, so you are looking back in their medical records to see how many of them were exposed to the risk factor. Here is a very important difference between these two approaches. In the cohort study, the item of interest is the *outcome* (**Table A-4**); who was exposed to the risk factor develops the outcome, whereas in the case-control retrospective study, the item of interest is the *risk factor*, because we already know which individuals have the disease (**Table A-5**).

**Table A-3** Summary Comparison

Statistic	Good	Poor
NNT (Number Needed to Treat)	A single-digit number	A larger number; the higher number the more patients needing treatment to affect 1 patient
ES (Effect Size)	>0.8	<0.2
OR (Odds Ratio)	>2	1

**Figure A-5** The cohort study.

**Figure A-6** The case control study.

If you want to determine if the researchers or even peer-reviewers of a study missed an important factor on how the statistics were calculated based on the type of data, make sure you check for the following statistics. For the statistics used to determine the difference between groups (improved/not improved, improved by how much, prevents/does not prevent, etc.), the following questions and solutions are used:

**Table A-4** Cohort (Prospective)

		Condition/Health Problem		
		Present	Absent	Risk
Risk Factor	Exposed	a	b	a/a+b
	Not Exposed	c	d	c/c+d

**Table A-5** Case-Control (Retrospective)

		Risk Factor		
		Exposed	Not Exposed	Odds
Condition	Case (those with)	a	c	a/c
	Those Without	b	d	b/d

- Are the data continuous such as blood pressure, ROM, temperature, lab values, etc.? A t-test should be utilized.

- Are the data dichotomous (meaning positive/negative, improved/not improved, etc.)? A chisquare test should be utilized incorporating a two-by-two table.

How do we determine the strength of these types of study results and conclusions? First, we need to look at a study's  $p$  value or confidence intervals. What does a  $p$  value indicate? It is the mathematical caution flag that indicates whether to proceed or not based on the study's accepted tolerance of whether the differences found are due to chance. A  $p$  value of 0.05, which is often used, basically indicates that the researchers and you are comfortable with the possibility that these values could occur 5% of the time by chance. Stated another way, you can be 95% sure that the findings are not due to chance. What about confidence intervals? They keep everyone honest by revealing the *range* of values in a study. The point values, such as relative risk, are a mean or average of all study participant outcomes. But clearly there is a range of findings in any sample of people including extremes. And just like the  $p$  value, a 95% confidence interval means that the true value is likely to be in that range 95% of the time and that conversely you can accept that 5% of the time it is not.

The confidence interval is one step closer to giving you a sense of the clinical significance of the findings. What is our clue that the range conflicts with the conclusion that there is a risk? If the ratio of the event being studied, the disease or the condition, is the same in both groups, numerically they will equal 1, meaning that if it occurred in 10 out of 100 patients in one group and the same in the other, dividing them into each other equals 1. If it is below 1, we must consider the possibility that this is not a risk factor, or at least in some patients it is not. And at the extreme it may be protective, especially if all the values were below 1.

So let's use a hypothetical example. What if you were studying the effect of diabetes during pregnancy on the

fetus and subsequently wanted to determine the effect on abnormal weight gain as a child? This is a prospective study; forward in time and hopefully that cohort of exposed fetuses (those who had mothers with diabetes) is compared to a group of fetuses whose mothers did not have diabetes. In **Table A-6** we see how that would be constructed in a two-by-two table. Note that the outcome of interest, the condition, would be abnormal weight gain, and this is our focus. We then compare those fetuses exposed to a diabetic mother with those who were not to determine the risk of abnormal weight gain. Let's say that each sample group had 1,000 study subjects. You can see quickly that the rate of abnormal weight gain is higher in fetuses born to diabetic mothers compared to those who were not. However, you also see that the overall problem being studied, the abnormal weight gain, is very low. Although we can say that the absolute risk is low, the relative risk or risk ratio calculated by dividing the risk of those exposed by those who were not, is high at 10. Said another way, the children born to diabetic mothers have 10 times the risk of abnormal weight gain compared to those not born to diabetic mothers in our hypothetical study.

Now let's use a real study that illustrates a hybrid where patients were studied prospectively but then evaluated as a follow-up retrospectively for the relationship between cardiac risk factors and having a diagnosis of lumbar disc herniation.<sup>1</sup> Note that this is not a cause-and-effect study, but a study of associated risk. This is a key limitation of studies that look back in time. This is a 16-year follow-up study of nearly 3,000 nurses.<sup>1</sup> Multivariate analysis was used, meaning statistically an attempt to tease out overlap among factors is being incorporated so that there is some confidence that the factor's independent association to the outcome, in this case disc herniation, is estimated. Among the cardiovascular risk factors evaluated were diabetes, hypertension, high cholesterol, and smoking. **Table A-7**

illustrates the relative risks and their association 95% confidence intervals for several of these CV risk factors. You can see the adjusted relative risk is above 1, which indicates an increased associated risk. None of the confidence intervals falls below 1, which means the range of values in this study population always indicates an increased risk. Also the *p* value is well within the 0.05 target. How can this be stated to a patient? As a diabetic there is an associated risk for disc herniation that is 52% higher than for people who don't have diabetes, or even though it might not seem obvious, having been or being hypertensive increases associated risk for disk herniation by 25%. This is stated as relative risk. As a side note, the proposed mechanism is an accelerated growth of atherosclerotic plaque to the arteries that supply the lumbar disc.

**Table A-6** Cohort (Prospective) 1,000 Subjects in Each Group

		Condition/Health Problem		
		Present	Absent	Risk
Risk Factor	Exposed	30	970	0.03
	Not Exposed	3	997	0.003
Relative Risk (Risk Ratio) = $0.03/0.003 = 10$				

**Table A-7** Multivariate Analysis

Factor	Relative Risk	95% Confidence Interval
Diabetes	1.52	1.17-1.98
Hypertension	1.25	1.11-1.41
High Cholesterol	1.26	1.10-1.44
Smoking (age >45)	2.14	1.34-3.42

$P$ value = 0.01 (for trend)		
------------------------------	--	--

Reproduced from Jhavar BS, Fuchs CS, Colditz GA, Stampfer MJ. Cardiovascular risk factors for physician-diagnosed lumbar disc herniation. *The Spine Journal*. 2006; 6:684-691.

In a case-control study we are interested to see who with the disease was exposed to the risk factor. Looking back through medical records is a shorter, less expensive approach, but because patients cannot be randomized as in a cohort study, you can look only at an association and not a cause-and-effect relationship. You can see that what has changed with a case-control study is our focus of interest, which is the risk factor. That's because we already know who has the disease. What we don't know is who with that disease or disorder was exposed to the risk factor. That changes the two-by-two table. Because researchers are allowed to choose the number of patients to study in a retrospective study, we can only estimate risk through the odds ratio. This is the ratio of odds between those who have the disease/disorder and were exposed to the risk factor divided by those without the disease/disorder who were exposed to the risk factor. Plugging in numbers, let's see how this works. Let's say this is a hypothetical study of workers with carpal tunnel syndrome who use computers, the risk factor (**Table A-8**). You can see here the odds for those with carpal tunnel, the cases that were exposed to the risk factor of computer use, are 9, whereas the odds of those in the no carpal tunnel group exposed to computer use are only 0.82. The ratio equals 11. This could be stated as the associated risk between computer use and carpal tunnel syndrome in our hypothetical study is eleven times higher than those without carpal tunnel syndrome.

There is an important aspect regarding odds ratio interpretation. For the comparison of two groups, if they have equal odds, meaning the denominator and numerator

are the same, numerically this will calculate to 1, which means there is no difference in associated risk. But remember if it is below 1 it may indicate either a decreased risk or protection.

Let's now use a real study of risk in a case-control study by Cassidy et al.<sup>2</sup> This is a measurement of association between visits to a chiropractor or a medical doctor's office prior to a VB stroke (**Table A-9**). We can see that the odds ratios are all above 1, which indicates some association for both visits to a chiropractor or MD's office and VB stroke. Note that the CIs are all above 1 and rather tight except visits to a PCP for patients under the age of 45 years. It is important to remember that as a retrospective study, all that can be established is an estimate of associated risk, not cause-and-effect.

**Table A-8** Case-Control (Retrospective)

		Risk Factor		Odds
		Exposed	Not Exposed	
Condition	Case (those with)	90	10	9
	Those Without	45	55	0.82
Odds	Ratio = $9/0.82 = 11$			

**Table A-9** Odds RatioHow Do I Interpret?

Parameter	Odds Ratio	95% CI
Visit to chiropractor within 30 days	1.37	1.04-1.91
Visit to PCP - Pt. under 45 y/o	1.34	0.94-1.87
Visit to PCP - Pt. 45 y/o and older	1.52	1.39-1.67

Reproduced from Cassidy JD, Boyle E, Cote P, et al. Risk of vertebrobasilar stroke and chiropractic care: results of a population-based, case-control, and case-crossover study. *Spine*. 2008;33(4 Suppl):S176-183.

So let's review some summary take-home points about studies that evaluate risk.

- They can be forward in time, called a prospective, cohort study or backward in time, called a retrospective, case-control study.
- Although both may estimate odds ratios, case controls can only use odds ratios because the actual relative risk cannot be determined. This is because the samples of patients in each group are not necessarily equal. In case-control studies the researchers can choose the number of patients and who the controls are.
- If there is no difference between the groups being studied, the relative risk or odds ratio will equal 1. Always look for the corresponding CIs and see if the range goes below 1 or in studies of protective factors, rises above 1, in which case you will have some doubt about the significance of the difference between groups.
- Cause-and-effect may be implied in a prospective study, especially if it is an RCT. However, a case-control study can estimate an associated risk only through the odds ratio.

We have one final step in reaching a conclusion about the literature evidence for what we are investigating. We have been determining the value of studies related to interventions and risk. If we weigh these on our scale of determining yes or no for their value, case studies amount to only BBs (**Figure A-7**). If we have stronger studies, especially prospective studies that are blinded and randomized, we have the weight of billiard balls. What about

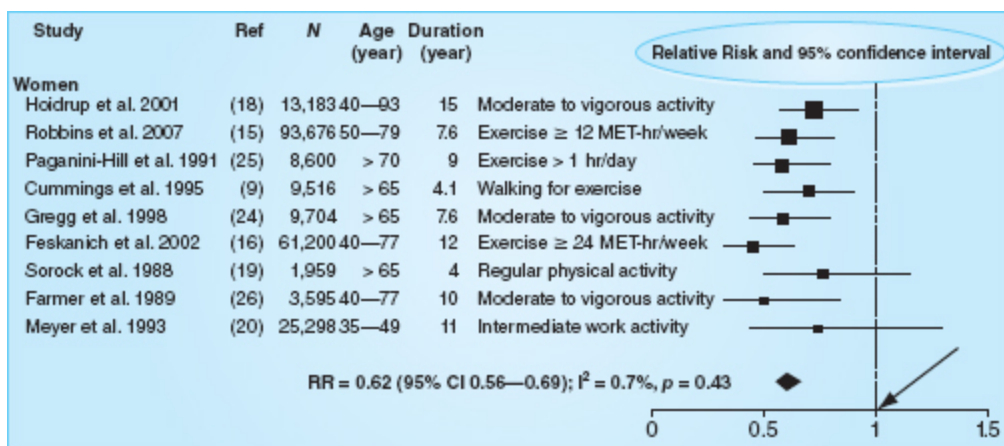

the bowling ball? These are the systematic reviews (SRs) that include all relevant RCTs and other high-quality studies. And when these studies are homogenous (i.e., same group of patients, same measures) we have a potential for a meta-analysis (i.e., statistical comparisons). To be clear, reviews may also be narrative, not applying rigid rules of search and rating but expressing the summary opinion of an individual or groups. These are not systematic reviews.

**Figure A-7** The scientific weight of different types of studies.

With a high-quality SR, a group of researchers, using stringent inclusion/exclusion search criteria (similar to a study of patients but here it is studies), rates the quality and conclusions of all relevant studies. If they are homogenous, they can generate what are called *forest plots*. A forest plot is a very efficient way of visualizing all studies on the same page. Note in **Figure A-8**, we see a number of studies that are represented by dots and lines. The dots (diamonds or circles) represent the point estimate of the study. The line represents the CI. We can immediately gauge whether or not studies consistently reach the same results compared to each other. Additionally, we can see how many of the studies' CIs stay above the central line. That central line is

our foul line. It is equal to 0 if there is a comparison of differences or mean difference among studies. When the comparison is a ratio such as relative risk, the center line is “1.” If the CI line crosses that center line, the range of the CI becomes less trustworthy because it has a foot on either side of the result. In other words, in a study of risk, it would indicate there was some risk in some participants but less risk in others. So for example, if studying the risk of smoking on lung cancer, it would imply both that there is risk in some participants but in some there was less risk (even the chance that this factor is protective).

**Figure A-8** Forest plot of risk.

Reproduced from *Annals of Epidemiology*, Alireza Moayyeri. The Association Between Physical Activity and Osteoporotic Fractures: A Review of the Evidence and Implications for Future Research. © 2008, with permission from Elsevier.

So far we have examined how researchers study and report the results of treatment but how can we be confident that their research represents a strong, scientifically based study. We need to know there was a comparison between groups of similar patients with similar prognosis and that there was a control group or placebo group. A strong study will be designed to compare treatments or compare the treatment to natural history. We know that, in general, the larger the group of participants in the study, the more we can trust the results, especially if reflected in a tight CI. If

the study is prospective (forward in time), it is stronger when randomized (meaning patients are randomly assigned to groups). It is even stronger if the patient is “blind” to which treatment he or she is receiving. When the treatment that the subjects are randomized to is also “blind” to those assigning randomization, those delivering the treatment, and those gathering outcome data, it is considered “double-blind.”

When reviewing a study on risk related to either a treatment or risk related to no-treatment, we need to know that the same comparison groups of participants discussed above are incorporated. This could be done prospectively, which is the stronger study, or retrospectively (i.e., patients usually selected from past medical records), which is weaker scientifically and can only establish associations of risk. Finally, we know that a systematic review is the strongest scientific resource, where comparisons of high-level studies can be summarized and sometimes visualized in a forest plot.

## **How to Create an Evidence-Informed Practice: Your Practice Your Practice**

So how is it possible for a non-scientist clinician to establish a research approach that generates evidence about his or her practice? Let's review a template that is easy to incorporate by simply using the data you usually collect, adding some other items, entering this into a simple spreadsheet, and learning a few tricks to organize that data to provide meaningful

## information. You then become an evidence-informed chiropractor.

Evidence-informed knowledge and measurement must include the practice environment of each practitioner, given that patient outcomes are somewhat unique to that context. The data generated are relevant because they reflect the environment in which future patients will be managed.

What is important to measure? You should never measure anything you are not willing to use for change. Evaluating patients' responses based on their complaint and diagnosis matched with the management tools that were utilized is obviously the most important information that effects change. Capturing data can be as simple as entering it into a spreadsheet where it can be manipulated and sorted to produce reports based on your focus of interest.

Comparative information should include the following: •

Demographic information including gender and age.

- Complaint information with regard to acute, subacute, or chronic complaints.
- Severity of the complaint.
- A measurement and documentation of a functional questionnaire at baseline and follow-up. This patient-completed form keeps judgment about effectiveness less biased, and therefore more scientifically valid.
- Frequency of care and compliance to that plan.
- Types of care, with a focus on the type of manipulation, and secondarily, columns for adjunctive care.

**Figure A-9** illustrates one approach to this. You can see that the patient is coded by his or her diagnosis. This is extremely important for comparing results of care.

Unfortunately, there is no standard. Even International Classification of Diseases (ICD) codes are not consistently used, and there is no code for all specific common problems. So either by using a coding system developed by

the practitioner or by operationally defining some ICD codes, a distinction of patient groups allows better delineation of patient types. For example, a patient with a cervical spine complaint could have the following codes or distinctions further subcoded by the type (i.e., acute, subacute, or chronic):

- Cervical pain only with no radiation
  - Cervical pain with radiation into the arm with no neurological findings
  - Cervical pain with radiation into the arm with neurological findings and special imaging confirmation versus those that do not have special imaging confirmation
- A separate column for each will allow sorting that may reveal differences based on whether the pain is acute, subacute, or chronic, and also might indicate a difference between those with or without neurological findings or imaging confirmation. Each may respond differently to care and may require different approaches.

If entered into a spreadsheet, making a copy allows manipulation of the data without disturbing the primary data sheet. Sorting can be by any column. For example, if you wanted to look at all patients with cervical pain and radiation with neurological findings and special imaging findings, you could group them together and look at their responses. In fact, you could average them into a point estimate. You could then visually, or through sorting, look for patterns with different responses based on the type of manipulation used or adjunctive care. **Figure A-10** illustrates how sorting by diagnosis allows the ability to average response rates for that diagnosis based on a pain scale or Oswestry score. Further sorting can illustrate if those who improved more had a specific chiropractic technique or combination of adjunctive approaches that proved more successful. **Figures A-11** and **A-12** illustrate how by highlighting data and then creating a graph, one can visually look at responses to care effects.

**Figure A-10** Sorting of data by diagnosis.

As your database grows, patterns will emerge, and different responses based on specific patient types become more meaningful. The intention is to find your “best practices” and to see where there is need for improvement or change. These are the areas where conversations with other practitioners or literature searching become valuable. If other practitioners use the same approach to clinical measurement and data collection as you do and they demonstrate better responses in areas than you do, sharing the differences can influence change and hopefully improve your results. So the best-case scenario is to establish a working group of like-minded clinicians and meet to share sanitized information (data free of patient information that would violate HIPAA). A final step would be to aggregate that data into a publication that reflected not only the data, but changes made by practitioners who shared the information and the results of those changes.

Change this data to represent improvement

## Diagnostic Tests

### Translating Terms and Numbers into Useable Information

Now let's switch to the other aspect of clinical practice, the tests we use to determine what is causing our patient's problem and the management approach we utilize. How do you know if the test you are using is of value? Although many diagnostic tests are taught and utilized, many have not passed the scientific rigor necessary to warrant their use. Let's look at the basic criteria by which a diagnostic test is tested, and from a scientific perspective how their value is determined. Although these can be discussed from a mathematical perspective, it is possible to use primarily a narrative explanation and when math is invoked, it will involve mainly simple addition, subtraction, and division. Ironically, we often approach a diagnostic test value like a simple math problem. For example, take a history indicator and a positive examination test finding, add them together (i.e.,  $a + b$ ) and you have the answer (i.e.,  $c$ ). The problem, as most clinicians intuitively know, is that the patient presentation is far too complex for this to work, except perhaps for the more classic presentations of a disorder. In fact, most of the time we can only get close to feeling

entirely correct about our diagnosis based not only on the complexity of patient presentation, but the unlikelihood that we can narrow down the cause to a single pain-producing structure. And, as is the case many times, conditions can overlap, such as shoulder impingement and rotator cuff tendinitis. Diagnosis is more commonly the act of weighing the factors on the side of having the disorder versus those on the side arguing against having the disorder. What makes this complex is that all factors do not carry equal weight in value. As mentioned previously, the weighing of factors leading to a diagnosis must account for differences in value so that some amount to the weight of a BB, others a billiard ball, and others a bowling ball. All factors are not equal in determining whether an individual does or does not have a disorder.

When it is time to interpret and apply the statistics regarding whether a patient has or does not have a disorder, we face two obstacles: (1) gathering and analyzing the studies used to study a test, and (2) extrapolation to our patient.

Let's step back. Why do we do tests? It may seem obvious: to discover the cause of our patient's problem. But we soon realize there are a host of peripheral factors that determine whether we perform a test. These include what we are taught, what managed care, Medicare, or other outside agencies require, whether it costs money, and frankly some of the time, whether it protects us legally. But what really determines the value of a test for your patient? It begins with what is known about the statistical value of the test. We will focus on the true value of testing without the interference of outside influences, motivators, past prejudices, and tradition.

One initial purpose of a test is to rule out a serious concern; one that would cause one to refer the patient. Another is to determine if you can move onto treatment without further testing. For instructors, there is a different

mindset. How do you determine which tests to teach? Is it the test list we were taught or the tests on a form that drive the instructor to want to prepare the student for either the real world or perhaps National Board testing? And why are those tests chosen by that group in the first place? How do we determine the value of the tests in relation to one another and how do we answer the student's question: should I combine tests into a cluster or is there one best test for this condition? There are any questions, but hopefully a few answers will satisfy most of them.

There are three main steps that determine the value of a test. The first is, are the test results valid? Secondly, what are the test results; and finally, if I use this test, will the results change anything in the management of my patient? For validity, we need to determine the type of patients used in the study. Are they representative of a spectrum of patients with the disorder from mild to severe, and are they representative of the types of patients I see? Is there a comparison to a gold standard? Is there, in fact, a gold standard? In other words, can this disorder be identified directly through visualization of the pathology through imaging, or of dysfunction through electrical testing or lab testing? Most importantly, is there an independent blinded comparison to that standard?

For studies that report results regarding the ability of diagnostic tests to find or exclude a disorder, a host of terms are used to describe values that seem mind-numbing in their scope and breadth. These include sensitivity, specificity, likelihood ratios, predictive values, and odds ratios, among others. It is a common clinician fear that if one does not understand the math behind the generation of these statistics, their use is not possible. Not true, as we will see.

For the value to my patient, we need to know if the test can be used in my office and whether the results apply to the types of patients I see to warrant extrapolation and

application. Most importantly, will the result change my management? Finally, what are the costs and risks, if any, of the test?

With the evaluation of a test, we look for two values: Is the test reliable? Is it valid? The reliability of a test has two components. The examiners evaluating a particular test may or may not agree with the result. Each examiner, when comparing the current interpretation to his or her past interpretation of a test, may not agree with his or her original interpretation. This comparison is called intra-examiner reliability. The comparison of an examiner's results to other examiners' results is termed interexaminer reliability. If the test result is dichotomous (meaning one value or another, such as true or false) the statistic used is the *kappa coefficient*. If the test result is continuous (such as the values for blood pressure, temperature, or range of motion) the statistic *intra-class correlation coefficient* (ICC) is used. So the estimate of the chance that an examiner will find the same result on the same patient when tested a second time is termed intra-examiner reliability, and interexaminer reliability is the estimate of how often a different examiner testing the same patient would arrive at the same result as the first examiner.

Validity has to do with whether the test is measuring what it is supposed to measure. This is determined by its comparison to a gold standard. Validity is the degree of trust you should give to the result the test is giving you. Is it sensitive enough to find the disorder, and is the test specific, meaning is it unique enough that when positive, it identifies that disorder? If a test has not passed the requirements of reliability and validity, it likely will have no demonstrable value. It may surprise you that many tests never have been put to the task of meeting these requirements. Even after failing one or both, some tests are still widely used due to tradition and habit. In the past, a surefire guarantee of utilization of the test was a plausible

mechanistic explanation of what the test was doing in relation to the pathology of the related condition, or by having someone naming the test after you. Great for writing test questions, useless for determining the value of the test on a patient.

As mentioned earlier, there are two ways of representing reliability, based on whether a test is simply positive or negative or whether there is a range of possible findings. Kappa is used for the dichotomous, or “one-or-the-other,” type of test result. The other type of result is the ICC, when the test result is a range of values. What we can do is take the numbers for kappa and ICC and translate these, based on a range, into usable language so that when we see the results, we automatically know whether we can trust that the test is interpreted similarly either among examiners or on repeated attempts by the same examiner. For example, a kappa of 0.21 to 0.40 is considered fair, and anything below 0.20 is considered poor (**Table A-10**). We should proceed with caution when considering adopting a test with such a rating. Lucky for us, the ICC produces similar number ranges and categories, making them relatively easy to remember and use (**Table A-11**).

**Table A-10** Interpreting Kappa

<b>Value of Kappa</b>	<b>Strength of Agreement</b>
<0.20	Poor
0.21-0.40	Fair
0.41-0.60	Moderate
0.61-0.80	Good
0.81-1.00	Very Good

So how is test performance measured—in other words, its ability to rule in or rule out a disorder? We tend to forget that there are really two contexts. One is the study itself—the tests in the study and the patients in that study. We then must find a way to translate the results of that study into a decision about the patient in front of you—the second context.

Test results that are dichotomous—positive or negative—are represented graphically in a two-by-two table. This deceptively simple-looking graphic serves as a source of frustration for many. The mathematical calculations and resulting terms are often confusing and tend to immediately turn off the clinician. Let’s simplify these through some examples. In the example in **Figure A-13** we have true positives and negatives and false positives and negatives, meaning some test results have been compared to a gold standard and found to be either accurate in finding the disorder or not. When the test is positive and the disorder is not present, this is a false positive. When the test is negative but the disorder is present, the test is a false negative. How these are combined determines their value to us and to our patient. These values include sensitivity, specificity, predictive values, and likelihood ratios. And it is important to know that these represent only the patients in the study. We will later find a way to take these values and help predict probability for the patient in front of us.

Table A-11 Intrepreting the ICC	
Value of ICC	Strength of Agreement
<0.40	Poor

0.40–0.75	Fair to Good
>0.75	Excellent

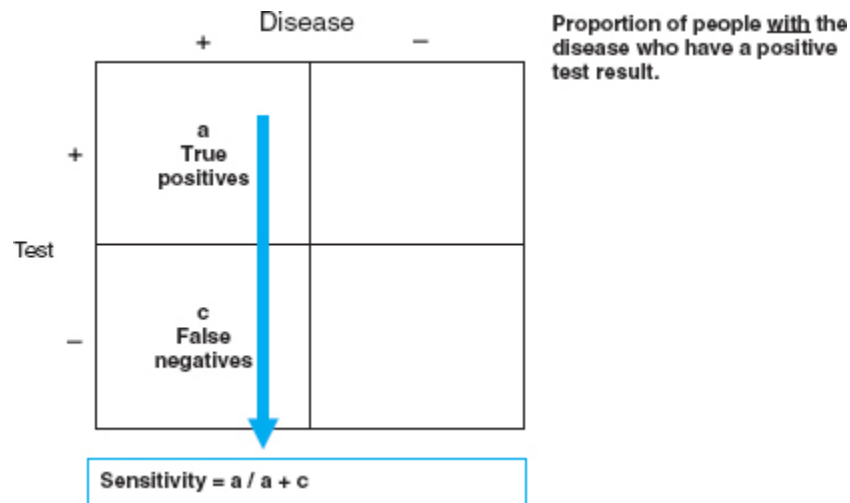

## Sensitivity

By taking the true positives and false negatives, we account for all the patients with the disorder who were tested.

Sensitivity is the proportion of the people with the disease or disorder who test positive (**Figure A-14**). Using an unrealistic scenario will allow us to use easily performed math. Let's say we have 100 patients who all have the disorder (**Figure A-15**). If the test is 84% sensitive, it means that it found 84 of the 100 patients with the disorder but missed 16.

		Disease	
		+	–
Test	+	True positives	False positives
	–	False negatives	True negatives

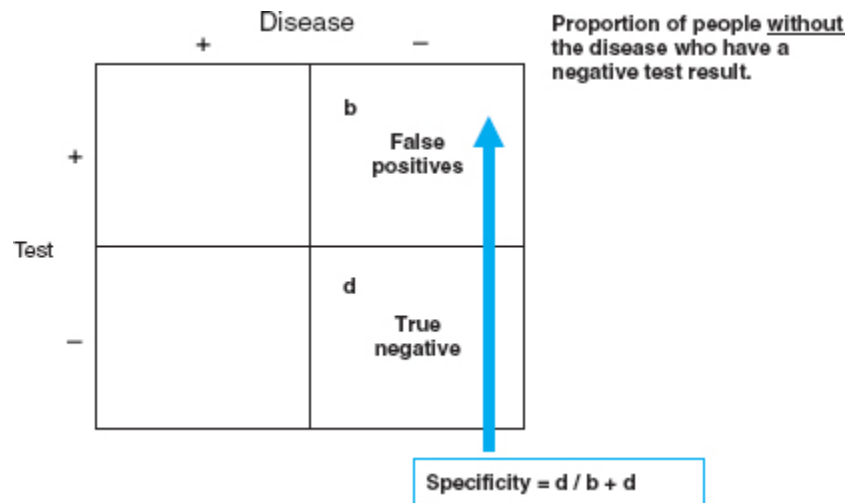

**Figure A-13** Two-by-two table for diagnostic test results.

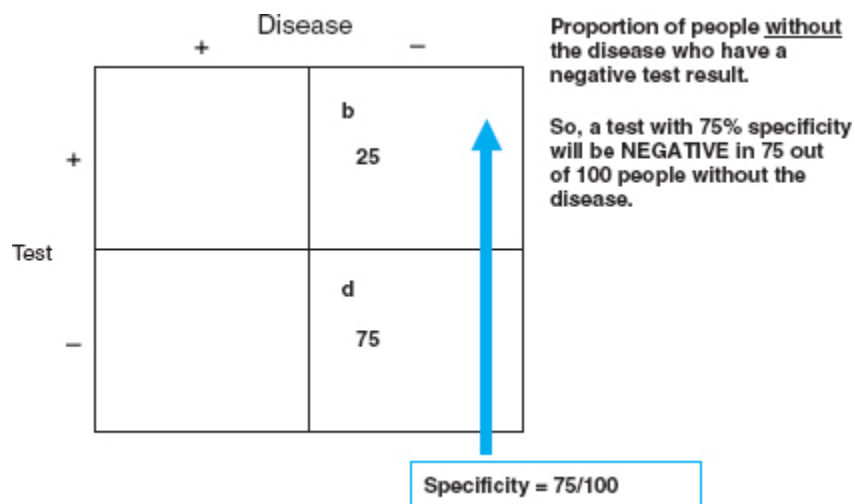

**Figure A-14** Sensitivity.

**Figure A-15** Sensitivity.

**Figure A-16** Specificity.

**Figure A-17** Specificity.

# Specificity

Specificity is a measure of the number of people without the disease who test negative. It combines the true negatives with the false positives to include all patients who do not have the disorder (**Figure A-16**). Again, using the same study where 100 patients have the disorder, a specificity of 76% would indicate that the test correctly identified 76 out of the 100 patients without the disorder but incorrectly implied that 24 had the disorder when they did not (**Figure**

**A-17**). So how is this useful in determining the value of the test? It must first be understood that the sensitivity and specificity of a test are not affected by the prevalence of the disorder (**Figure A-18**). In other words, it doesn't matter whether 5% or 75% of patients have the disorder. It will not change the sensitivity or specificity. We will soon introduce the statistics that do change with how many patients do or do not have the disorder.

**Figure A-18** Sensitivity and specificity are not directly affected by prevalence.

**Table A-12** Sensitivity and Specificity

SnNout  
A Highly SeNsitive Test, when Negative, points toward Ruling OUT the condition

SpPin  
A Highly SPecific Test, when Positive, points toward Ruling IN the Disorder

How do we translate a statistic such as a test is 92% sensitive and 65% specific into useful information? We can use an acronym (**Table A-12**). Using *SnNout* for sensitivity, we remind ourselves that a highly sensitive test, when negative, tends to point in the direction of ruling out the condition/disorder. We can then use the acronym *SpPin* for specificity, reminding us that a highly specific test, when positive, tends to point in the direction of ruling in a condition/disorder. The degree to which each test should be

weighted in ruling in or ruling out is clearly illustrated by the percentage value.

The next step is *predictive values*. These are affected by prevalence, so that the number of patients with the disorder does affect the values of positive and negative predictive values (**Figure A-19**). Now we can get a better sense of the value of the test in the study population of patients. Note that a positive predictive value is related to specificity, and a negative predictive value is related to sensitivity. This makes sense when we look at the meaning of SnNout for sensitivity and the negative predictive value and the meaning of SpPin for specificity and positive predictive values. An easy way to remember this is that the *p* in positive relates to the *p* in specificity and the *n* in negative is related to the *n* in sensitivity.

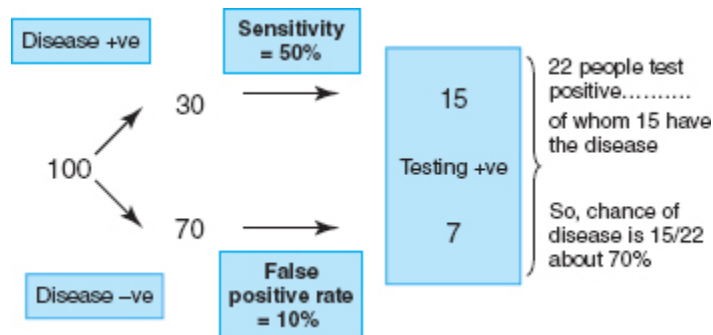

Let's use a practical example. You get a call from a patient, friend, or relative and she sounds concerned. She has just been to the doctor and was told that her test for a specific disorder was positive. You look up the most recent study and find out that the prevalence in the study population was 30% and that the test used has a sensitivity of 50% and a specificity of 90%. We already know that for the patients who were studied a positive test was quite good at ruling in that disorder. But let's see if we can improve and have some information regarding our individual. Let's look at this (**Figure A-20**). We have a prevalence of 30%, a sensitivity of 50%, and a specificity of 90%. To keep the math simple, let's assume the study had 100 patients. In that study 30 patients had the disorder and 70 did not. With a sensitivity of 50%, the test will be positive in only 15 patients. Now, we are more interested in false positives for those without the disorder. You will see why in a moment. The false positive rate would be 10% given the specificity is 90%. With 70 patients without the disorder and a false positive rate of 10%, 7 patients were correctly identified as not having the disorder. Adding the 15 true

positives and 7 false positives, we arrive at 22. The true positives divided by the total number of positives ( $15/22$ ) is about 70%. The chance of having the disorder is 70% if your individual matches the demographics and prevalence of the patients in the study that tested the test. This is the positive predictive value. Now let's simply change one thing, the prevalence, and reduce it to 4% (**Figure A-21**). If the test is positive, now what is the chance the person has the disease? Now with a sample group of 100 patients, only 4 have the disease and 96 do not. With a sensitivity of 50% only 2 patients are identified correctly. Adding the true positive and false positives together we arrive at 11.6 who test positive, 2 of whom actually have the disorder. Dividing those patients who actually have the disorder by the number who tested positive ( $2/11.6$ ) we arrive at a predictive value of only 17%. A lower prevalence seriously decreases the ability of the test to correctly detect the disorder even when sensitivity and specificity remain the same. Then back to your patient, friend, or relative with the positive test, the only way to truly know the predictive value for her test result is to match the results to the prevalence in the study population. In other words, if the patients in the study were referred to a specialty clinic but your patient is seen by a primary care physician, the prevalence would likely be higher in the study population than in the primary care setting. The predictive value of the test would not be guaranteed to be as high assuming the prevalence is lower in the primary care versus specialist context.

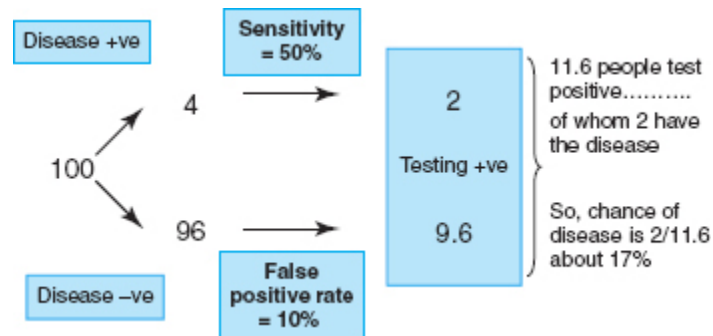

- positive predictive value  
 $131/181 = 72\%$
- negative predictive value  
 $93/105 = 89\%$

		Condition		
		Present	Absent	
Value	Pos.	131	50	181
	Neg.	12	93	105
		143	143	286

**Figure A-19** Predictive values are directly affected by prevalence.

**Figure A-20** Prevalence of 30%, sensitivity of 50%, specificity of 90%.

**Figure A-21** Prevalence of 4%, sensitivity of 50%, specificity of 90%.

We still need more to determine the value for a patient not in the study—the one in front of us. We need to find the connecting statistic between the study and a real patient. We need the likelihood ratio. By taking the estimated prevalence of a disorder in our patient or patient population and combining it with the likelihood ratio, we can arrive at a post-test probability that our patient does or does not have the disorder. Likelihood ratios are derived from values that

include sensitivity and specificity. Although there are no actual positive and negative LR<sub>s</sub>, their values in ruling in or out a disorder have been categorized by that designation. A positive LR is sensitivity divided by 1 minus specificity and a negative LR is 1 minus sensitivity divided by specificity. You can see in **Table A-13** a representation of the value of ranges of likelihood ratios with regard to whether they affect the probability in a large, moderate, or small degree for both positive and negative LR<sub>s</sub>. Basically an LR of 10 would change the probability that a patient had a disorder in the realm of 45%. Conversely, a negative LR of 0.1 would change the probability 45% that the patient does not have the disorder. Also, an LR approaching 1 has no value in discriminating between those with or without a disorder regardless of being positive or negative.

**Table A-13** Interpreting Likelihood Ratios

% Change in INCREASE Probability	+LR Power to RULE IN	Shift in Post-Test Probability	-LR Power to RULE OUT	% Change in DECREASED Probability
10 = 45%	10	LARGE	<0.1	<0.1 = 45%
5 = 30%	5–10	MODERATE	0.1–0.2	0.2 = 30%
2 = 15%	2–5	SMALL	0.2–0.5	0.5 = 15%

The value is further augmented by combining with a prediction of prevalence. This isn't the prevalence in the study but the predicted prevalence of the disorder in the general population, or if you are a specialist and that data are known, the prevalence for that subgroup of patients with this disorder in your patient population. Let's take a simple example of appendicitis. The general prevalence is 5%. This is called the pretest probability. By using a graphical tool called a nomogram (**Figure A-22**) we can draw a line starting at the pretest probability through the associated LR and the line will intersect on the far right in the post-test probability range (**Figure A-23**). Here we see that with a pretest probability of 5% and an LR of 3.4 for McBurney's

point tenderness, a positive test would result in only a 20% post-test probability that the patient has appendicitis.

---

## Confidence Intervals

What do confidence intervals add to the picture? Up to this point we have been discussing *point values*. These are the statistics that we referred to as sensitivity, specificity, predictive values, and likelihood ratios. But these represent a mean or average of all results of a study. We need to know the range of values, because when that range is large, it raises questions about the value of the data and the strength of conclusions that can be drawn from the data. The range is influenced by several factors, but one of the major ones is the number of occurrences of the disorder in the population, which is affected often by the number of participants in the study population. This reflects indirectly what is called the power of the study. The strength of the conclusions is highest when the range of the confidence interval is tight, meaning the numbers are close together. For example a CI of 7.8 to 12.9 is tight compared to a wider CI of let's say 7.8 to 128.8. The tighter value represents what is called more precision and strengthens the confidence that the point value can be trusted to represent the results. The wide range makes one question the size of the study population (meaning being too small) and number of occurrences. This indirectly affects the power of the conclusions.

What about the possibility that even though a single test performs only moderately with regard to sensitivity or specificity, its combination with other tests keeps it valuable as part of a cluster of exam findings? This is often the case with what are called clinical prediction rules (CPRs).

## Clinical Prediction Rules

Clinical prediction rules (CPRs) represent a scientifically developed, validated, and tested set of factors that have been shown to assist clinically, in the hopes of saving time and expense, while benefitting the patient. CPRs are used to predict patients' diagnosis or prognosis but given the variation in patients and their presentations, clinical judgment must be part of the decision-making approach. CPRs are used for screening and diagnosis, prognosis, and interventions. Although designated as a rule, they really represent more of an algorithmic approach to a patient with the hope that prediction of the intended outcome is better than clinician best-guessing.

A number of screening CPRs have been developed to help guide the clinician in making decisions regarding the need for x-rays or imaging in the event of neck, knee, and ankle trauma; probably even more relevant for on-field sports practitioners where imaging access is limited. For prognosis it is important to recognize that patients, payers, and the doctor are interested in prediction of success. Many of the interventional CPRs were developed by physical therapists—at least those related to the types of patients seen by chiropractors. They are more prescriptive, and when involving manipulation must be viewed with some caution given the manipulation utilized in the study may not represent that done by chiropractors.

**Figure A-22** Nomogram.

**Figure A-23** Nomogram for appendicitis.

When would one consider using a CPR?

- When you encounter problems you do not see on a regular basis.
- When you wish to demonstrate the scientific basis for your treatment, plan perhaps in defense of a management plan to a payer or for patient confidence in what you are proposing
- When you wish to be cost-effective. Many CPRs were developed based on this primary motivation.

Let's review the process of CPR development. The first step is to begin with a search of the existing literature. Then it is important to analyze the data and put together a

composite of validated predictors into a “rule” and conduct a derivation study. There are three progressive steps in the development of a CPR. These include: **1.** Derivation—the study from which CPR factors are derived

**2.** Validation—when the CPR is tested in a different population of patients

**3.** Impact analysis—when the CPR is applied in multiple settings in the real world to see if it is accepted and utilized; in other words, if it is feasible and practical, and ultimately of value To decide which factors out of many to pay attention to—the reliable indicators—researchers use a prospective cohort design with patients selected based on specific inclusion and exclusion criteria. Patients go through a standardized exam with a reference standard if a diagnostic CPR is being developed and a specific treatment approach if an interventional CPR is being developed, or wait a specific period of time if it is intended to be prognostic.

For interventional studies, a validated outcome measure with strong psychometric properties is selected. This outcome measure should have been demonstrated to have discriminative value in confirming a “minimal detectable change,” and possess a difference score that identifies a clinically important difference to the patient. For interventional CPRs, once the patients are dichotomized into successful versus unsuccessful, variables are compared with these two groups to determine univariate associations. Those with significant univariate associations are then combined into a multivariate analysis to determine the contribution of a group of predictors. Variables that become part of a group prediction of variables may not necessarily be the most significant individual predictor variables.

The process for diagnostic CPRs is to look at studies that measure validity (compare to a gold standard). Next, look at studies of reliability (intra- and interexaminer) and make

sure the kappa values are used if data are not continuous; interclass coefficient if continuous. If acceptable, examine the statistical analysis that includes sensitivity, specificity, and positive and negative predictive values, and establish likelihood ratios. Next, based on experience or prevalence values, determine pretest probability. Finally, use the likelihood ratios to determine post-test probability.

At this point groups of tests (or historical features) can be applied to a group of patients to determine if combinations of tests yield high likelihood ratios for prediction. With this analysis, it can be determined if a number of positive (or negative) findings can provide more prediction than single tests.

One approach, not part of the CPR process, that is a “quick-and-dirty” approach, is using the positive finding of one test’s post-probability as the new starting pretest probability. Another is to rank the test with regard to its value, not as a rule-in or rule-out test but in comparison to other tests for that disorder. This is accomplished using the Diagnostic Odds Ratio (DOR). Scientifically, far less sound but perhaps more useful for the busy clinician, the DORs allow the prioritization of several tests for the same condition. By calculating the DOR, the tests with overall better performance have higher numbers. The calculation is by simply dividing the + LR by the -LR. DORs do not, though, indicate the value of the test with regard to rule-out or rule-in; just its value compared to other tests. Sometimes this is close to the literature conclusion. See in **Table A-14** the DORs for test findings for cervical radiculopathy. Now look at what the literature suggests.<sup>3</sup> A cluster including:

- Upper limb tension test

- Restricted cervical rotation  $<60^\circ$
- Distraction
- Spurling’s

The + LR = 6.1 for three or more positives. History questions and standard neurological evaluation were not found to be sensitive.

## Correlation

The strength of the linear relationship or associations between variables is statistically their *correlation*. A correlation coefficient is represented by  $r$ . Correlation coefficients range from  $-1$  to  $+1$ . Graphically, this may be represented as a scatterplot (**Figure A-24**). As one decreases while the other increases, the coefficient is negative. Simple correlation coefficients are unit free. The closer a correlation is to  $1$  ( $-1$  if looking for an inverse relationship) the more strongly associated the data. If a scatterplot is constructed, the closer the points are (tightly clustered), the stronger the relationship. Scatterplots demonstrate relationships by showing form, direction, and strength. The line through the data is a regression line or a “least-squares line” (calculated by minimizing the vertical distances between the data points; the sum of squared deviations) and the straight line that is fitted to the data: the average trend of the data points. It is tempting to imply causation when it is only association that is demonstrated. Correlation belongs to a large class of statistics called regression.

**Table A-14** Diagnostic Odds Ratio Example for Cervical

Test	+LR	-LR	DOR
Upper limb tension test	1.3	0.12	10.8
Decrease of C-spine ROM less than 60°	1.7	0.02	8.5
Cervical distraction	4.4	0.62	7.1
Spurling's	3.5	0.58	6.0
Decrease of C-spine ROM less than 55°	1.5	0.27	5.5
Weakness of any arm muscle	1.9	0.4	4.7

Radiculopathy

Reproduced from Wainner RS, Fritz JM, Irrgang JJ, Boninger ML, Delitto A, Allison S. Reliability and diagnostic accuracy of the clinical examination and patient self-report measures for cervical radiculopathy. *Spine*. 2003;28(1):52-62.

**Figure A-24** Correlation scatterplot.

Regression describes the magnitude of change among variables. It is used to create therapeutic and diagnostic predictive models considering the role of several variables simultaneously (multivariate) and the weight each variable contributes to predicting the outcome of interest.

Several terms are used including “logistic regression,” “discriminate function analysis,” and “log-linear models.”

Here is an example: To determine the need for densitometry, one is looking at a host of possible contributors to the prediction of low bone mineral density (BMD) indicating possible osteoporosis. One study<sup>4</sup> evaluated numerous items and arrived at six items—RA, history of previous fractures, older age, non-estrogen use,

and low weight—that indicated low BMD. By assigning each a numerical weight based on the degree to which it contributed to prediction and summing the numeric weights, each variable that contributes to the predictive model is given its own coefficient.

## Another Example

When several variables are used to predict a certain outcome (as in prognostic clinical prediction rule) multiple regression is used. For example, for prognostic indicators for sciatica, multiple regression analysis demonstrated that the following contributed to the recurrence or persistence of sciatica:<sup>5</sup>

- Driving more than 2 hours/day
- Carrying heavy loads at work
- High level of psychosomatic problems
- Sciatica symptoms the year before

## Summary and Cautions

- Many CPRs serve as a starting point for what should be considered in looking at preventive, prognostic, or interventional approaches to patients but are not necessarily proven in larger impact studies.
- Most CPRs have only been taken through the derivation stage. Therefore, outside of the study population, one does not know if the CPR actually applies, given the variability of patient groups and the practice variables of doctors.
- For interventional CPRs, some do not compare to natural history when looking at the success of therapeutic interventions.

- For diagnostic testing, researchers gather together studies that look at:
  1. The diagnostic reliability and validity for the entity being considered.
  2. The variables that (through regression analysis) have been shown to help predict an outcome. These may be historical factors, diagnostic factors, or outcome measures.
- Then it is important to analyze the data and put together a composite of validated predictors into a “rule” and conduct a derivation study.

So if you are wondering if the data on diagnostic tests and clinical prediction rules have been gathered into combined resources, they have, and there are several opportunities to access this information. The best are the textbooks listed with other resources at the end of this appendix.

## **Appendix B**

# **Pharmacology for the Chiropractor: How Medications May Affect Patient Presentation and Management Outcomes**

Although a heated debate may ensue when asked about the inclusion of medication prescription to the scope of practice of the chiropractor, it is often evident that a baseline of pharmacology knowledge is in fact realistic and necessary to fulfill the role of a portal-of-entry physician. Many patients are taking medications prior to entering the chiropractor's office. As a result, a basic knowledge of common prescribed and over-the-counter (OTC) medication is useful. Following are some important reasons:

- The patient often asks questions regarding the side effects of his/her medication.

- The patient may present with signs or symptoms directly related to a side effect of a medication or from lack of compliance in taking a prescribed medication.
- The medication taken by the patient is used for the condition or symptoms the chiropractor wishes to address.
- In a review of a patient's medical history, it is important to determine current and past medications. Even if the patient has forgotten why the medication

was prescribed, a basic knowledge of commonly prescribed drugs will often offer a clue.

- Events may have changed in the patient's life that may influence the effect of medication. For example, certain foods, alcohol, fever, or illness may effectively increase or decrease the effects of the available drug.
- If laboratory studies are performed, drug interactions may have a significant effect on the results.

Here are just a few practical examples:

- A patient has a sense of difficulty breathing (sense of tightness) and multiple other complaints that range from musculoskeletal aches and pains to headaches. The patient is taking alprazolam (Xanax), which is often prescribed for anxiety, as an adjunct with antidepressants, or simply as a sleep inducer. Anxiety may have an effect on blood pressure, response to questions, and general well-being. Depression certainly may have an effect on patient complaints and their perceived response to care. Lack of sleep may have an effect on patient presentation as well.
- Another patient who takes lithium has a remarkable response one time to your care of midthoracic pain, yet another time is angry with you or simply nonresponsive. Knowing that lithium is used for manic depression may help in explaining the range of response if, in fact, the patient is not consistently taking his/her medication.
- A patient who has had chronic pain is taking large daily doses of naprosyn. The patient is complaining of constant heartburn and epigastric pain in addition to tinnitus. Understanding that naprosyn and similar medications are potentially ototoxic at high and prolonged use, and that these medications may lead to ulcers, and primarily gastric ulcers, may help to

explain the patient's symptoms and direct the appropriate course of management.

- A patient is taking Lasix for congestive heart failure. He is starting to complain of some cramping and muscle weakness. When a lab is ordered, the patient's serum potassium level is very low. Knowing the Lasix is nonpotassium sparing helps in the explanation and results in an immediate referral to the prescribing physician with a suggestion that potassium supplementation is requisite.
- A patient with migraine headaches seemed to respond to chiropractic care, but when on vacation was in an area where she did not have a chiropractor available. The patient took sumatriptan prescribed by her physician. It helped, but now, three days later, her headache is back, and worse. Knowing that many medications prescribed for migraine may be the cause of a "rebound migraine" is helpful in making decisions about management and explains why this would occur.
- A patient is taking coumadin because of deep vein thrombosis discovered one month ago. You are considering adjusting the low back with a side-posture adjustment. Understanding that coumadin is an anticoagulant may have an effect on the degree of force used in the adjustment or whether another technique will be used during the time the patient is on the medication.
- A patient who was diagnosed with temporal arteritis is on a course of corticosteroids for six months. During that time the patient has midthoracic pain that seems fairly severe. Knowing that the patient is on corticosteroids would certainly warrant taking x-rays to determine whether a compression fracture was the cause, and may explain why if found. If not found, there would still be a caution against any position or exercise that would cause loaded flexion, including

while adjusting, due to the osteopenic effect of long-term corticosteroid use.

Additionally, the patient is often taking many medications. With the senior patient, it is not uncommon to have obtained each medication from a different physician and each physician is unaware of the other's prescription. As a result, unforeseen interactions may occur. The chiropractor is in the advantageous position of being able to ascertain the complete picture of medications the patient is taking because the patient assumes the chiropractor is not involved in the regulation of these drugs.

The caveat for the chiropractor is that no advice regarding taking or withdrawing from, or increasing or decreasing dosage can be given without violating state scope-of-practice laws. However, when a problem is suspected or recognized, it is imperative that the chiropractor either sends the patient back to the prescribing physician with informative questions or contacts the prescribing physician to discuss the individual patient. It is extremely important to recognize that if a medication is stopped suddenly or the dose is decreased, a rebound effect or other reactions may occur that are potentially lethal. For example, sudden withdrawal of seizure medication may lead to status epilepticus (i.e., a seizure that continues and may lead to death).

It is important to understand that although a drug may have been developed for a specific system or condition, the same medication may be used as the primary or alternative drug for another condition. For example, although antihypertensive and antidepressant medications were designed for the associated condition, these medications are also used in the treatment of headache. Antihypertensive medications may also be used in the treatment of some cardiac disorders or reflex sympathetic conditions.

According to the IMS Institute for Healthcare Informatics, patients in the United States spent \$307 billion in 2010 for prescription drugs; an increase of 2.4% over one year.<sup>1</sup> In 2011, 78% of all prescriptions were for generic drugs. The CDC's National Center for Health Statistics survey<sup>2</sup> reported the following (**Figures B-1** through **B-3**): • The percentage of individuals taking five or more drugs increased from 6.3% to 10.7% from 1999 to 2008.

- Thirty-six percent of those age 60 years and older took five or more drugs over the preceding month.
- For those individuals 12 to 19 years of age, 30% took one drug over the previous month.
- For those age 60 years and older, 88.4% took one drug over the previous month.
- For those age 60 years and older, 90% of drugs are used to treat hypertension, high cholesterol, and heart disease—all modifiable through lifestyle changes.

The cost for the top ten drugs prescribed in the United States in 2010 was \$48 billion.

The top grossing drugs and their primary use in the United States were:

- 1.** Lipitor (atorvastatin)—high cholesterol
- 2.** Nexium (esomeprazole)—gastroesophageal reflux disease (GERD)
- 3.** Plavix (clopidogrel)—anticoagulant
- 4.** Advair Diskus (gluticasone and salmeterol)—asthma/COPD
- 5.** Abilify (aripiprazole)—schizophrenia, bipolar depression, clinical depression
- 6.** Seroquel (quetiapine)—schizophrenia, bipolar depression (combined with an SSRI) clinical depression
- 7.** Singulair (montelukast)—asthma/COPD
- 8.** Crestor (rosuvastatin)—high cholesterol

**9. Actos (pioglitazone)—diabetes**

**10. Epogen (epoetin alfa)—anemia due to chronic renal failure**

<sup>1</sup>Estimate is unstable; the relative standard error is greater than 30%.

**Figure B-1** Percentage of prescription drugs used in the past month, by age: United States, 2007–2008.

Reproduced from Gu Q, Dillon CF, Burt VL. Prescription drug use continues to increase: U.S. prescription drug data for 2007–2008. NCHS Data Brief. Sep 2010(42):1–8.

The most prescribed drugs in the United States were:

- 1. Vicodin (hydrocodone/acetaminophen)—analgesic**
- 2. Zocor (Simvastatin)—hyperlipidemia**
- 3. Prinivil and Zestril (Lisinopril)—hyperlipidemia**
- 4. Synthroid (levothyroxine sodium)—thyroid**
- 5. Norvasc (amlodipine besylate)—antihypertensive**
- 6. Prilosec (omeprazole)—GERD**
- 7. Zithromax (azithromycin)—antibiotic**
- 8. Amoxicillin—antibiotic**
- 9. Glucophage (metformin sodium)—diabetes**

## 10. Hydrochlorothiazide—diuretic (antihypertensive/congestive heart failure)

**Figure B-2** Percentage of use of at least one prescription drug, by age, sex, and race and ethnicity: United States, 2007–2008.

Reproduced from Gu Q, Dillon CF, Burt VL. Prescription drug use continues to increase: U.S. prescription drug data for 2007–2008. NCHS Data Brief. Sep 2010(42):1–8.

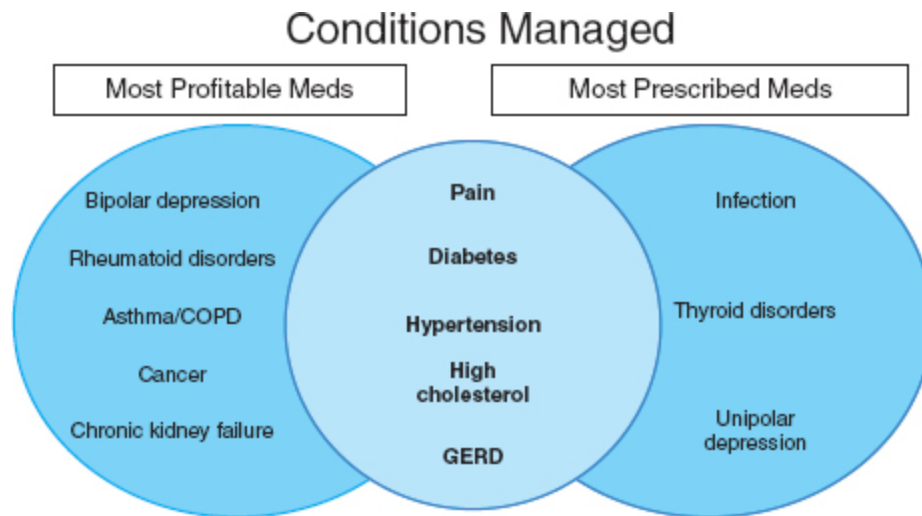

**Figure B-3** Percentage of prescription drugs used most often, by drug type and age group: United States, 2007–2008.

Reproduced from Gu Q, Dillon CF, Burt VL. Prescription drug use continues to increase: U.S. prescription drug data for 2007–2008. NCHS Data Brief. Sep 2010(42):1–8.

- 11.** Xanax (alprazolam)—anxiety
- 12.** Lipitor (atorvastatin)—hyperlipidemia
- 13.** Lasix (furosemide)—diuretic  
(antihypertensive/congestive heart failure)
- 14.** Ambien (zolpidem tartrate)—sleep induction
- 15.** Lopressor (metoprolol tartrate)—hyperlipidemia

When matching these two lists, it becomes apparent that there is clearly an overlap (**Figure B-4**). Among the overlapping conditions, all are modifiable through lifestyle changes including diabetes, high cholesterol, GERD, hypertension, and chronic pain. To a lesser degree, asthma, depression, and rheumatoid conditions may be affected through lifestyle. Not generally modifiable through lifestyle changes after being diagnosed are thyroid disorders, chronic renal failure, and cancer, although there may be some

opportunity for prevention for chronic renal failure and some cancers based on cause and type.

**Figure B-4** Conditions managed.

It would be prudent for the chiropractic physician, although not prescribing, to have at least a general sense of these most commonly prescribed medications and their mechanisms of action to determine possible side effects related to a patient's clinical presentation. Following is a very brief overview of drug categories, mechanisms, examples within those categories, and possible side effects and concerns.

It is easy enough, with searchable databases, to find a specific medication, its mechanism of action, side effects, and concerns regarding timing and cross-reaction with other substances including foods and dietary supplements. However, prior to being specific, it is possible to have a general sense of these elements by simply understanding the general classification of a medication, its intended actions, and assuming the medication is taken and not specifically injected, understanding the systemic effects of that medication (which often translate into side effects or adverse reactions).

Our approach then will be to discuss some very basic biologic factors that relate to medication interactions including absorption, metabolism, and excretion, move to a broad-based discussion of some classifications of medication, and complete the discussion with an overview of commonly prescribed medications for specific diagnoses or patient complaints.

Some general principles of pharmacology allow a better understanding of prescribing practices. The primary concern is prescribing the optimal amount of medication to be effective but not toxic or wrought with side effects. This dosage varies for several important reasons: • The amount of active drug in the body is determined by its metabolism in the liver and clearance from the kidneys. Obviously, liver or kidney disease may alter the available amount of drug in the system. Some special considerations include the infant and the elderly, for whom function of both organs is decreased compared to an average adult.

- The available amount of medication will vary with processes such as fever, other drugs, and metabolic conditions.
- Special concerns apply to particular groups, including pregnant females, the immunocompromised, the elderly, and infants. Some medications should not be used during pregnancy, and medication dosages for the other groups will vary based upon that group's specific factors.

A reminder that QID stands for four times/day; TID, three times/day; BID, two times/day; and QD is once a day. You can see how easily QID and QD could be confused and result in under- or overmedication.

Please refer to **Table B-1** for the basic terminology and definitions for medication usage. To find the location of a drug in **Table B-1** by the product name, refer to **Table B-4**.

**Table B-1** Summary of Basics Regarding How Drugs Affect Patients

<b>Principle</b>	<b>Definition</b>
<b>How Drugs Are Administered</b>	
<ul style="list-style-type: none"><li>• Oral (PO)</li></ul>	The disadvantage of self-administration is that the drug must survive the acidity of the stomach and be capable of passing through the intestinal lining to reach the bloodstream. Drug absorption is thus related to whether the drug is taken with meals or without, and to some restrictions on type of foods.
<ul style="list-style-type: none"><li>• Sublingual</li></ul>	Absorbed quickly, directly into the bloodstream through the capillary bed of the tongue. Does not have to withstand the acidic environment of the stomach.
<ul style="list-style-type: none"><li>• Rectal</li></ul>	Rate of absorption is not reliable. Useful for infants and for patients who are unconscious or vomiting.
<ul style="list-style-type: none"><li>• Parenteral (outside GI tract)</li></ul>	Injection: Can be given intravenous (IV), intramuscular (IM), and subcutaneous (SubQ). IV has the advantage of rapid and continuous administration. Also good for unconscious patients and for delivery of insoluble drugs. IM has the advantage of passing through capillary walls in muscle. May be rapid absorption if aqueous, while oil-based preparations are absorbed slowly. SubQ is more easily self-administered and is

	delivered to the capillaries beneath the skin for fairly quick distribution.
<b>Dosing</b>	
<ul style="list-style-type: none"> <li>• Safety Issues with Dosing</li> </ul>	Drug safety is presented in animal studies as EC <sub>50</sub> (Effective Concentration 50%)—the concentration of a drug that causes an effect in 50% of individuals; LD <sub>50</sub> (Lethal Dose 50%)—the concentration that is lethal to 50% of subjects; the therapeutic index—determines safety through the ratio of dividing the LD <sub>50</sub> by the ED <sub>50</sub> ; and Margin of Safety—the margin between the therapeutic and lethal dose of the drug.
<ul style="list-style-type: none"> <li>• Tolerance, Dependence, Withdrawal</li> </ul>	Tolerance occurs when a larger dose is necessary to achieve a previous therapeutic effect. This can occur due to metabolic reasons (e.g., drug is metabolized more quickly), at the cellular level (there is a decrease in the number of drug receptors [i.e., downregulation]), or for behavioral reasons. Dependence is when the patient must have the drug to function at a normal level. Withdrawal refers to removing a drug from a dependent patient.
<ul style="list-style-type: none"> <li>• Patient Profile</li> </ul>	It is extremely important to consider weight, gender, age, and in females, whether the patient is pregnant or not. Newer considerations are genetic inheritance of mutations that render a drug more effective or less effective.
<ul style="list-style-type: none"> <li>• Types</li> </ul>	Some drugs are given at a higher initial dose, called a loading dose. This is followed by a maintenance dose that is lower.
<ul style="list-style-type: none"> <li>• Abbreviations</li> </ul>	Once a day—QD; twice a day—BID; three times a day—TID; four times a day—QID
Drug Absorption	Drug absorption is affected primarily by the formulation state (gel cap, pill, solution, etc.) and by the route of administration.
Drug Distribution	The factor that affects distribution is the

	<p>membrane permeability. This includes some barriers such as the blood-brain barrier, blood-testes barrier, and the blood-placenta barrier. Another factor is whether the drug is lipophilic or not. Those that are passed through the gut wall easily tend to accumulate in fat. Other drugs may be bound and stored in other areas, such as bone. Calcium-binding drugs accumulate in bones and teeth.</p>
Drug Metabolism	<p>Drugs are metabolized primarily in the liver, and as a result are affected by liver disease and also may be toxic to the liver.</p>
Drug Excretion and Clearance	<p>Kidney function is important for the proper excretion and clearance of drugs. This is also a potential toxic factor for the kidneys. Proper kidney function is important for proper clearance. The older a patient is, the less effective this function becomes.</p>
Drug Actions	<p>Drugs bind to receptors and may act as agonists or antagonists that result in opening or closing channels (blockers), activated secondary messengers, inhibited normal cellular function (e.g., some antibiotics interfere with bacterial cell wall construction), or activated cellular function. Many of the newer drugs are enzyme inhibitors, such as cholinesterase inhibitors for Alzheimer's.</p>
Drug Interactions	<p>Drugs are generally described as interacting by addition, synergism, potentiation, or antagonism. Addition is the combined action of two drugs, equal to the combined response. Synergism results in a greater effect than a simple one, plus one additive response. Potentiation means that the drug has no inherent effect but enhances the effect of another drug. Antagonism is the opposite, whereby normally the drug has no effect but acts to inhibit the effect of another drug.</p>

## Food/Drug/Supplement Interactions

For chiropractors, it is particularly important to understand that recommendations in diet and advice regarding supplementation must be in the context of medications taken by a patient. There are several ways that this interaction can be affected:

- External effects based on how the drug is delivered (Type I interaction)

- Affect on absorption or transportation (Type II interaction)
- Distribution of the drug after absorption (Type III interaction)
- Excretion (Type IV interaction)

Our main concern with the latter three interactions is how they relate to timing with food/supplements, and the types of foods/supplements that interact with specific types of drugs. The effect may be less activity of the medication or more activity of the medication available for longer periods of time. Finally, medications can affect absorption or excretion of important vitamins and minerals leading to nutritional deficiencies and their consequences.

## **Absorption**

Because most drugs are absorbed in the stomach and small intestine, any substances ingested at the same time may affect this process. A general rule, not always applicable, is that medications are often taken one hour before a meal or two hours after a meal. Otherwise, food may decrease absorption or delay the time needed for absorption.

Following are some examples:<sup>3</sup>

- Soluble fiber, phytate, and oxalate found in some fruits, vegetables, whole grains, Metamucil, legumes, nuts, and cocoa may decrease the absorption of some medications.

- For patients taking coumadin/warfarin, foods that contain vitamin K may counteract the effects of the medication. These foods include dark green leafy vegetables, cabbage, avocado, liver, canola oil, soybean oil, and green tea. Also vitamin K, vitamin E, vitamin A, feverfew, garlic, ginger, ginkgo, inositol hexaphosphate, licorice, St. John's wort, turmeric, wheat grass, and fish oils may have the same effect, as does large amounts of alcohol ingestion (i.e., more than three drinks/day).
- Supplements containing fat-soluble vitamins (A, D, E, and K) and coenzyme Q10 need to be taken with 5 g of fat.

## Metabolism

Foods, drugs, and supplements may interact in a way that increases or decreases the metabolism of specific drugs. One of the major principles upon which this interaction is based is called the cytochrome P450 system.

To understand why certain medications are different in their absorption, metabolism, and excretion, it is first important to understand, at least basically, the cytochrome P450 group of enzymes (also abbreviated as CYP). This large and diverse group is one of the major sets of enzymes involved in drug metabolism. Largely proteins, they are found on the inner membrane of mitochondria and in the endoplasmic reticulum of cells. There are a number of substrates that include lipids and steroidal hormones, drugs, and toxic materials that can cross-react due to shared similarities. There are many isoenzymes of the CYP system that are named according to a standard format that has CYP indicating the gene family, followed by the subfamily number, and finally the gene coding. So, for example, for CYP3A5, *CYP3* indicates the gene family, *A* indicates the

subfamily, and 5 indicates the gene coding. There are, in essence, eight primary isoenzymes of importance for the CYP system.

It is a system affected not only by drugs but also by herbs that can inhibit the CYP system or increase activity of the CYP system. Under the discussion of specific medications related to system or disorder, the specific cytochrome interactions affected are listed, but here is a brief list of some important specific examples:<sup>3</sup>

- Although St. John's wort is commonly utilized in Europe as an alternative to some antidepressants, it is known to increase CYP3A4 enzymes used to metabolize many drugs (speeds up clearance) and therefore should not be taken with other medications, specifically other antidepressants. Also, with a similar action to monoamine oxidase inhibitors, there is a risk for sudden increase in blood pressure when ingesting foods with high tyramine content. Some of the foods included in this list can be remembered by thinking of a pizza parlor, because they include aged cheeses, pepperoni, salami, sausage, draft beer, and red wine; other foods include bananas, chocolate, soy sauce, sauerkraut, avocado, and fava beans.
- Ingesting  $\frac{1}{4}$  grapefruit or more per day slows down CYP3A4 enzymes. Known medications that are affected by grapefruit ingestion include NSAIDs, statins, some diabetes medications, antihypertensives, antibiotics, protease inhibitors, antihistamines, erectile dysfunction meds, and others.
- Certain medications slow the metabolism of caffeine, which may augment the effect of caffeine. These include Tagamet, Ciprofloxacin, and Luvox among others. Coffee may speed up the clearance of certain medications including theophylline, clozapine, estrogen, coumadin, and naproxen.

- As more individuals substitute meat with soy products it is important to note that soy interferes with tamoxifen and aromatase-inhibitor activity used for breast cancer therapy, and whole soy food interferes with thyroid medications.

## Nutrient Depletion

The effect of medications on absorption and increased excretion of vitamins, minerals, and other nutrients is well known, with some specifics to be aware of: • NSAIDs may interfere with the absorption of folate, iron, vitamins C and K, and melatonin.

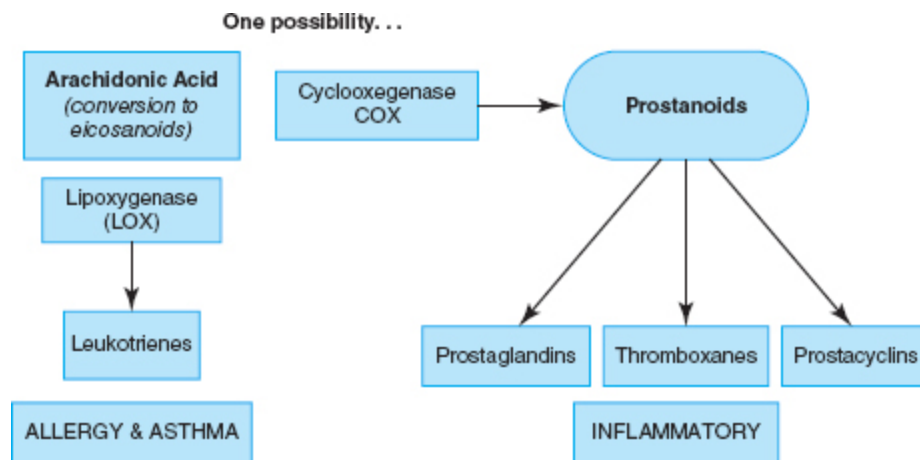

- Antacids and proton-pump inhibitors (e.g., Nexium or Prilosec) may decrease the absorption of vitamins C, B<sub>12</sub>, and D; calcium; iron; zinc; and folic acid. One major concern is osteoporosis.
- Some diabetes medications may interfere with vitamin B<sub>12</sub>, folic acid, thiamin, magnesium, and CoQ<sub>10</sub> metabolism.
- Some antihypertensives may interfere with the absorption of zinc, CoQ<sub>10</sub>, vitamin B<sub>12</sub>, copper, and melatonin.
- Statins used for the treatment of hyperlipidemias (e.g., Crestor, Lipitor) may interfere with the metabolism and availability of CoQ<sub>10</sub>. Muscle soreness or achiness is a common complaint with the use of these medications.
- Selective serotonin reuptake inhibitors (SSRIs) (e.g., Prozac) may interfere with sodium and melatonin absorption.
- Nonpotassium-sparing diuretics used for hypertension and congestive heart failure may cause potassium deficiency (requiring potassium supplementation) and sodium deficiency.

- Certain antiepileptic medications may require the need for sodium supplementation.
- Antirheumatic medications such as methotrexate require the patient to take folate supplementation.

Before we discuss specific medications based on use, a shortcut to identifying some medications is that they often have identifying suffixes due to similar chemical configurations. For example:

- Most tricyclic antidepressants have the suffix *-ipiline*.

- Antibiotics that are chemically similar have the suffix *-cycline*.

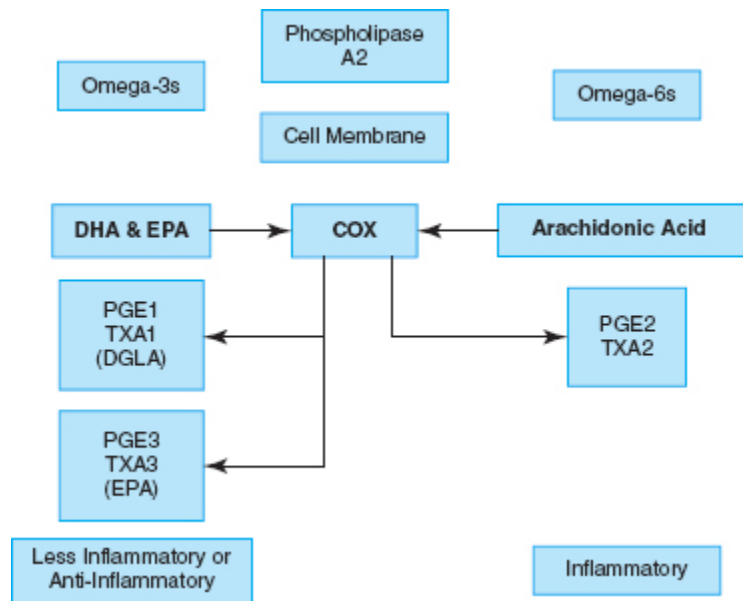

**Figure B-5** One possibility.

- Leukotriene receptor antagonists used in the treatment of asthma end in *-lukast*.
- Cholesterol-lowering drugs that block the production of cholesterol are generically called “statins.”
- Headache medications that are serotonin receptor agonists have the suffix *-triptin*.
- Drugs ending in *-mab* are monoclonal antibodies.
  1. Chimeric monoclonal antibodies end in *-ximab*, and those ending in *-zumab* are humanized monoclonal antibodies.

# Pain Medications

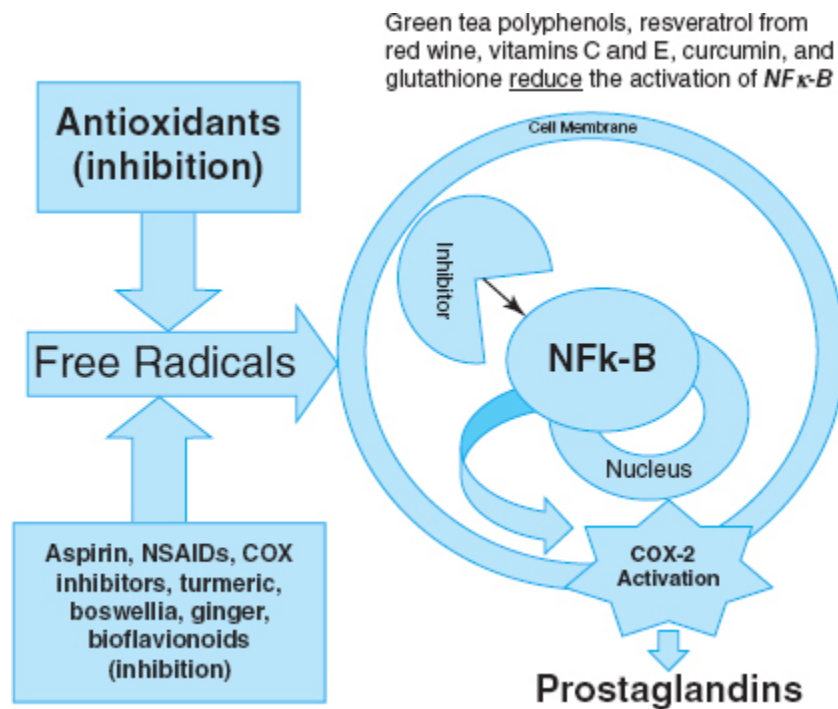

Let's start with a review of one of the pathways for eventual inflammation (**Figure B-5**). Arachidonic acid and omega-6 fatty acids are converted to a group of metabolites called eicosanoids. One pathway is to convert arachidonic acid to prostanoids through the action of the cyclooxygenase enzyme called the COX enzyme. These prostanoids include the inflammatory prostaglandins, thromboxanes, and prostacyclins. Another conversion of arachidonic acid by the enzyme lipoxygenase or LOX enzyme, leads to the production of leukotrienes, which are responsible for some of the inflammatory reactions seen in asthma and other allergic reactions. A balance occurs through competition with the COX enzyme. This is between arachidonic acid and omega-3 fatty acids represented by DHA and EPA (**Figure B-6**). Anti-inflammatory omega-3s are found in most green vegetables, wild game, most grains, grass-fed meat, and EPA/DHA fish oil. Metabolites of EPA and DHA are a different series of thromboxanes and prostaglandins, which are either less inflammatory or noninflammatory compared to the prostaglandins associated with arachidonic acid metabolism. Medications generally affect or take advantage of these pathways through competition or blocking. For example, corticosteroids inhibit phospholipase A2, which inhibits arachidonic acid release from phospholipids in the cell membrane. Aspirin, NSAIDs and cyclooxygenase inhibitors block the COX enzyme that converts arachidonic acid to prostaglandin E2, thereby blocking or decreasing inflammation. Additionally, nondrug ingestibles such as turmeric, ginger, bioflavonoids, and boswellia have similar actions.

**Figure B-6** Omega-3 and Omega-6 pathways.

Many other components influence these processes with sometimes overlapping actions, so the following can only be a generalization for clinical purposes. One example is cell-signaling molecules, which stimulate genes to induce the expression of the COX enzyme. The expression of the coding gene for COX-2 for the production of prostaglandins is transcriptionally regulated by NFκ-B. It is in the cytoplasm and is bound to its inhibitor (**Figure B-7**). Free radicals release NFκ-B from the inhibitor, which then moves into the nucleus to activate genes responsible for COX-2 activation and prostaglandin formation. Aspirin, NSAIDs, and corticosteroids inhibit binding of cell-signaling molecules such as NFκ-B, which reduces inflammation. Green tea, polyphenols, resveratrol, vitamins C and E, curcumin, and glutathione also reduce the activation of NFκ-B. It is possible that keratinoids and flavonoids also have similar actions. Without these inhibitors, NFκ-B activation induces COX-2 activation leading to inflammation.

**Figure B-7** NFκ-B metabolism.

Medications prescribed for musculoskeletal pain are not just analgesics but include anti-inflammatories, muscle relaxants, and adjunctive medications that include sedative, antidepressant, and antiseizure medications.

## Analgesics

Medications whose main function is pain relief are called analgesics. Analgesics are divided into opioids and nonopioids (**Figure B-8**). Opioids, previously referred to as narcotics, are derived from morphine and include morphine, oxycodone, methadone, and tramadol.<sup>4</sup> Their use is widespread either prescribed alone or in combination with other substances. Opioids bind to opioid receptors, mimicking endorphins with several receptors known including mu, kappa, and delta. There are basically three mechanisms for their actions, including: **1.** Inhibiting neurotransmitter release through blockage of  $\text{Ca}^{2+}$

2. Inhibiting glutamate release
3. Opening K<sup>+</sup> channels (hyperpolarized) to prevent pain transmission

Because abuse is a concern due to dependency, limited use of opioids is the rule. Adverse effects include confusion, nausea, vomiting, dry mouth, constipation, and urinary retention. Opioids are metabolized by CYP2D6 and therefore there are some inhibitors that should be avoided, including 5-HTP, adrenal extract, black tea, cat's claw, chamomile, chaparral, chromium, clove, DHEA, ephedra, evening primrose, fenugreek, ginger, ginkgo, gotukola, hops, kava, lemon balm, phenylalanine, sage, SAMe, St. John's wort, thyme, turmeric, tyrosine, valerian, and vitamin B<sub>6</sub>.

Nonopioids:

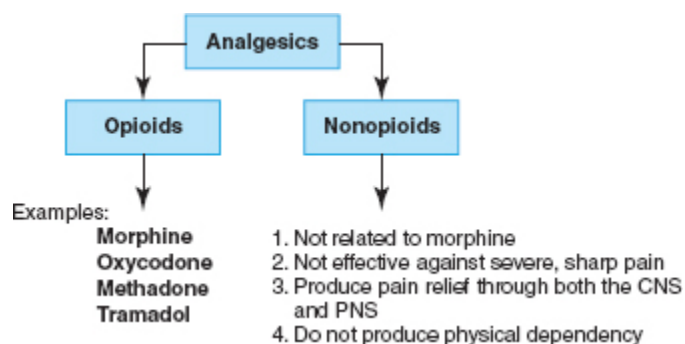

1. Are not related to morphine
2. Are not effective against severe, sharp pain
3. Produce pain relief through actions on both the central and peripheral nervous systems (opioid's effects are largely on the CNS)
4. Do not produce physical dependency

## **Anti-Inflammatory Medications**

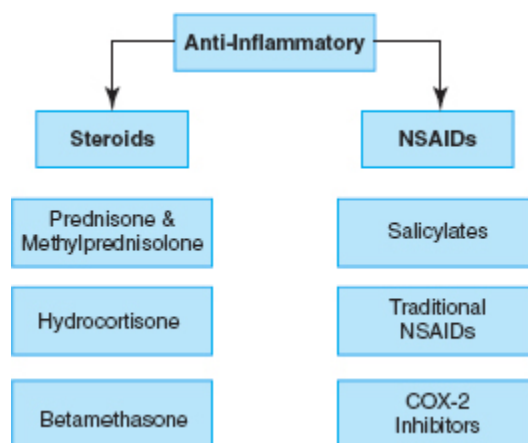

Anti-inflammatory medications are divided into steroids and nonsteroids. Steroids include prednisone and methylprednisolone, hydrocortisone, and betamethasone (**Figure B-9**). Nonsteroid anti-inflammatory medications (NSAIDs) include salicylates (i.e., aspirin) and traditional NSAIDs; the nonselective COX inhibitors, and COX-2 inhibitors. The majority of patients given analgesics are given NSAIDs. Here we discuss their general mechanisms of action.

There are different isoenzymes of the COX enzyme (**Figure B-10**). The COX-1 enzyme is considered

constitutive because it is found in most cells, whereas the COX-2 enzyme is considered inducible because it is mainly found in response to inflammation, and is found in activated macrophages. The nonselective COX inhibitors block both 1 and 2 isoenzymes. These include aspirin and most NSAIDs. Selective COX inhibitors block the COX-2 enzyme. This is most often represented by celecoxib (Celebrex). Note that the functions of these enzymes are not always detrimental and are often essential for proper function, so their blockage carries with it adverse reactions. The most common problem is interference with the enzymes whose role is gastrointestinal protection particularly of the stomach lining, but also for renal blood flow and platelet aggregation. As a result, gastric irritation and bleeding may occur, and because of an increase in thromboxane with an inhibition of prostacyclin by COX-2 inhibition, there is an increase in thrombus formation. This may lead to an increase in heart attack and stroke. Additionally affected are the kidneys, with an increased risk of renal failure. Other concerns are that NSAIDs can deplete vitamin C, folate, iron, and zinc. Related to the gastrointestinal bleeding and anticoagulant effects, it is important to avoid alcohol and to avoid supplements and products that have anticoagulant effects such as garlic, ginger, ginkgo, fish oils, and vitamin E, among others. NSAIDs are metabolized by CYP2C9 and therefore contraindicated are black tea, chamomile, chaparral, clove, ginger, milk thistle, St. John's wort, sage, thyme, and turmeric.

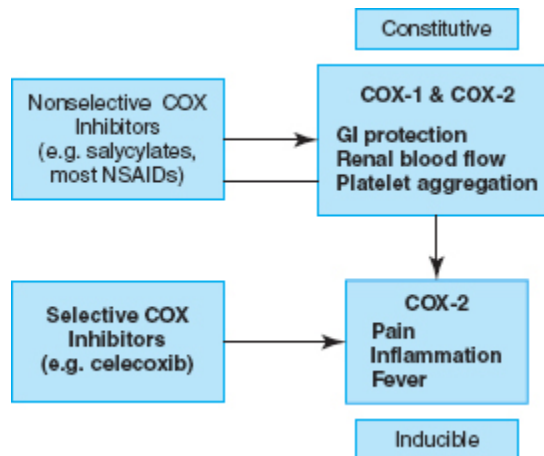

**Figure B-8**

**Figure B-9**

<b>Table B-2</b>		
<b>Synthetic NSAIDs</b>	<b>Analgesic/Antipyretic Dosing</b>	<b>Anti-Inflammatory Dosing</b>
Ibuprofen (Advil, Motrin, Nuprin)	200–400 mg every 6–8 hr	600 mg QID
Naproxen (Aleve, Midol)	200 mg every 6–8 hr	550 mg BID (or 275 mg every 6–8 hr)
Naproxen (Naprosyn, Anaprox, Naprolam)	200 mg every 6–8 hr	200–500 BID
Meloxicam	Not indicated for pain/fever	7.5–15 mg/day

(Mobic)		
Indomethacin (Indocin)	Not indicated for pain/fever	25–70 mg TID
Meclofenamate (Meclomen)	50–100 mg every 4–6 hr	200–400 mg/day

**Figure B-10**

In **Table B-2** we see a list of common NSAIDs. Note that ibuprofen, represented by Advil, and Motrin and naproxen, represented by Aleve, are the most common OTC medications used for pain. They have analgesic, antipyretic, and anti-inflammatory effects, but the dosing for anti-inflammatory effects is higher.

Not all synthetic NSAIDs are used for their effects of reducing pain, fever, and inflammation. In fact, we can see that the only approved COX-2 inhibitor, Celebrex, is dosed only for its anti-inflammatory effects (**Table B-3**). Drugs such as Vicodin, Percodan, Percocet, Darvocet, and Darvon are combination drugs (**Table B-4**). They represent combinations of either aspirin or acetaminophen combined with either oxycodone, codeine, or hydrocodone. In other words, they are combinations of an NSAID or acetaminophen with an opioid. The concerns are the gastrointestinal and vascular effects of NSAIDs combined with the dependency and narcotic effects of the opioids. For

chiropractors it is important to be aware of a commonly prescribed steroid for low back pain—the Medrol Dosepak. It is a card with twenty-one 4-mg pills. Patients start with six pills (24 mg) and take one less pill each day until finished. The pills are taken orally with a full glass of water before breakfast, after lunch, and after dinner.

**Table B-3**

<b>Synthetic NSAIDs</b>	<b>Anti-Inflammatory Dosing</b>
Oxaprosin (Daypro)	1200–1800 mg QD
Piroxicam (Feldene)	20 mg/day
Sulindac (Cloril)	200 mg BID: 400 mg/day
<b>Selective COX-2 Inhibitor</b>	
Celecoxib (Celebrex)	200 mg/day

## Acetaminophen

Acetaminophen is an aniline analgesic. It blocks the COX prostaglandin H<sub>2</sub> synthase enzyme at its peroxidase rather than the cyclooxygenase catalytic site. Higher concentrations of peroxide in activated leukocytes and platelets block the effect of acetaminophen on inflammation and platelet thrombosis. Acetaminophen is able to inhibit prostaglandins in the CNS, reducing pain and fever. It is neither an anti-inflammatory nor an anti-thrombotic medication. It is metabolized by CYP2E; therefore certain

supplements are contraindicated, including chaparral and dandelion.

Several concerns have been raised about chronic and/or large amounts of acetaminophen use. These center on three key issues:

- Exacerbation of asthma

- Elevation of liver enzymes
- Hearing loss

Another potential for confusion is that acetaminophen is labeled differently on different products, including but not limited to the following abbreviations and acronyms: AC, APAP, Acetaminoph, Acetamin, and Acetam.

Recently, there has been a concern about acetaminophen and asthma. Although this seems counterintuitive, the effect may possibly be through depletion of glutathione in bronchial mucosa, which could raise the risk of damage from oxidative stress. It appears that acetaminophen increases airway inflammation for those with asthma or for those predisposed to asthma, leading to an increase in severity and frequency of symptoms. Also, individuals may be more likely to develop asthma later in childhood if exposed to acetaminophen in utero or in the first year of life. Use of acetaminophen was associated with a 2.87-times increased risk of asthma.<sup>5</sup> Asthma symptoms related to acetaminophen exposure have been reported as high as 38% for 13- to 14-year-olds. Asthma prevalence in the United States showed a rapid increase in the 1980s when acetaminophen was being suggested for children in place of aspirin. There was a leveling off for that increase in the 1990s when acetaminophen use became the standard for fever management. This then seems a plausible explanation for an association with asthma increases given no other environmental changes occurred during that same period of time. Also, for 36 countries worldwide, the per-capita sales

of acetaminophen are a predictor for the prevalence of childhood wheezing.

Another concern associated with acetaminophen, and a warning issued in 2011 by the FDA, is liver damage. There was a strong recommendation to limit the amount of acetaminophen to 325 milligrams per tablet or capsule. They also required a boxed warning on all prescription acetaminophen products highlighting the potential risk for severe liver injury.

**Table B-4**

<b>Combined Analgesics</b>	<b>Nonopioid Medication</b>	<b>Other Medication</b>
Vicodin or Panacet 5/500	500 mg acetaminophen	5 mg hydrocodone
Percodan	325 mg aspirin	4.4 oxycodone
Percocet	325, 500, 600 mg acetaminophen	2.5, 5, 7.5, 10 mg oxycodone
Tylenol with codeine	300 mg acetaminophen	15, 30, 60 mg codeine
Darvocet N (50 or 100)	325 or 650 mg acetaminophen	50 or 100 mg propoxyphene
Darvon Compound-65	389 mg aspirin	32.4 mg caffeine, 65 mg propoxyphene
Fiorinal	325 mg aspirin	40 mg caffeine, 50 mg barbituate

Cautions include:

- Taking more than the prescribed dose of an acetaminophen-containing product in a 24-hour period

- Taking more acetaminophen than the maximum daily dose of 4,000 milligrams (4 grams)
- Taking more than one acetaminophen-containing product at the same time
- Drinking alcohol while taking the drug

In one study,<sup>6</sup> a placebo-control group had no elevation of liver enzymes after two weeks as compared to a group that took 4 grams of Tylenol daily for two weeks. Of this group, 33% to 44% had elevations of ALT; >3 times the upper limit. Those with the highest elevations were 10 times the upper limit of normal. Elevations returned to normal after discontinuing the Tylenol.

In one study<sup>7</sup> evaluating almost 27,000 men for hearing loss related to analgesic use, researchers concluded that regular use of aspirin, NSAIDs, or acetaminophen increases the risk of hearing loss in men, with the highest risk group being those 50 years of age and younger. A similar association was found for women in a study<sup>8</sup> published in 2012; however, the researchers found no association with aspirin but with ibuprofen and acetaminophen. In all studies, the relationship is dose-dependent, with those chronically taking these medications more than twice per week. Specifically, men were classified into three groups: under 50 years of age, ages 50 to 59 years, and those 60 years of age or older. Compared to men not regularly taking aspirin, NSAIDs, or acetaminophen, the risk increase was on average about 33% for those 59 years of age or younger for all of these medications. There was a substantially increased risk compared to men who did not take acetaminophen regularly, so that those men who did had a comparative increased risk of 99%.

<b>Disease-Modifying Antirheumatic Drugs (DMARDs)</b>
---

A special class of medications used in the management of rheumatoid and rheumatoid-like inflammation is DMARDs. A broad classification for these diseases also includes the inflammatory bowel diseases (Crohn's and ulcerative colitis). There are two classifications, biologics and nonbiologics. The older nonbiologics include drugs such as methotrexate, cyclosporine, and sulfasalazine. The biologics work off different principles. Delivery is either through self-injection subcutaneously (SQ) or through infusion therapy. Biologics are genetically engineered proteins used to address one of several aspects of immune regulation:

- Anti-TNF inhibitors—Cimzia, Enbrel, Humira, Remicade, and Simponi

- T cell inhibitors—Orencia
- IL-6 inhibitors—Actemra

## Muscle Relaxants

Muscle relaxants used as adjuncts to musculoskeletal pain management are the most heterogeneous group of medications (**Figure B-11**). They include “antispasticity” medications used for the spasticity associated with upper motor neuron disease and the more common “antispasmodics,” which are further divided into benzodiazepines (BZD) and nonbenzodiazepines. The original benzodiazepine was Librium. Marketed soon after was Valium. They are clearly known for their sedative effects. Benzodiazepines work primarily through augmenting the effects of the neurotransmitter gamma-aminobutyric acid (GABA). An alternative herb supplement is valerian root. Side effects for BZDs include rebound insomnia, nausea, and diarrhea. Special attention should be given to crossreactions with Tagamet, alcohol, and other sedatives. Because BZDs are metabolized by CYP2C19, certain supplements are contraindicated and certain foods

and teas need to be avoided such as black tea, chamomile, ginseng, chaparral, St. John's wort, thyme, turmeric, clove, ginger, gotukola, kava, milk thistle, and red yeast rice.

Like many medications in this category, there are many formulations and many delivery approaches, including orals and injectables. Because the effects on the CNS also include the limbic and reticular systems, they have effects related to sedation and sleep induction. Included in the BZDs are halcyon, Ativan, and Xanax, each with its own primary use such as decreasing anxiety, as a sedative, for pain, and antitremor and anticonvulsive effects. Some non-BZDS such as Lunesta, Sonata, and Ambien are best known for their sleep induction properties. Side effects may include dizziness, headache, dry mouth, and some GI disturbances. Metabolized by CYP3A4, interactions with certain supplements, foods, and teas should be monitored and potentially limited. Some are inhibitors and some are inducers. Inhibitors include black tea, cannabinoids, chamomile, Essiac herbal tea, ginger, ginseng, goldenseal, gotukola, grapefruit juice, kava, licorice, chaparral, clove, echinacea, milk thistle, peppermint oil, red yeast rice, sage, saw palmetto, St. John's wort, thyme, and turmeric. Inducers include chamomile, echinacea, garlic, goldenseal, hops, licorice, St. John's wort, and yucca.

**Figure B-11**

Table B-5 Nonbenzodiazepine Muscle Relaxants	

Generic Name	Brand Name
Carisoprodol	Soma
Cyclobenzaprine	Flexeril
Chlorzoxazone	Parafon-Forte Paraflex Strifon-Forte
Metaxalone	Skelaxin
Methocarbamol	Robaxin

**Table B-5** lists some non-BZDs used to reduce muscle spasm for patients with back pain. Note that they do not relieve pain, but they either relieve muscle spasm or are sedating. There are common side effects including drowsiness, dizziness, and severe allergic reactions (**Table B-6**). They interact strongly with other sedatives and alcohol. Commonly prescribed are Norflex, Skelaxin, and Flexeril. Some, such as Flexeril, may cause urinary retention in males, and some may be habit-forming. Many are metabolized by CYP1A2 and therefore may interact with some supplements, foods, and other substances including broccoli, cabbage, shiitake mushrooms, charbroiled meats, melatonin, chaparral, tobacco, herbal tea, and turmeric.

In summary, it is important for chiropractors to be aware of national guidelines and recommendations related to the medications prescribed for back pain.<sup>9</sup> Following are summaries of Clinical Practice Guidelines for NSAIDs and for muscle relaxants for chronic low back pain (LBP).

---

## Summary for the Clinical Practice Guidelines (CPG) by Country for the Use of NSAIDs for Chronic LBP

- Europe, Italy, and the United States: CPG recommendations were that there was evidence for use (short-term).
- CPG recommendations in Belgium concluded there was no evidence for NSAID use or for aspirin.
- The U.S. CPG concluded there was insufficient evidence to estimate the effectiveness of aspirin.
- COX-2 inhibitors were recommended in the United Kingdom only if acetaminophen was not effective.

---

### **Summary for the Clinical Practice Guidelines (CPG) by Country for the Use of Muscle Relaxants for Chronic LBP**

- Belgium in a 2006 review found only low-quality evidence to support the use of muscle relaxants in the management of chronic LBP; recommendation was that only short-term use be considered.
- European guidelines in 2004 found strong evidence for support of benzodiazepines for chronic LBP but conflicting results for nonbenzodiazepines.
- For the U.S. guidelines in 2007, there was no evidence generally for the use of muscle relaxants but moderate benefit was found for benzodiazepines.

**Table B-6** Common Side Effects of Nonbenzodiazepine Muscle Relaxants

<b>Concerns</b>	<b>Brand Name</b>	<b>Dosing</b>
May be habit forming	Soma	350 mg/8 hr
May lead to urinary retention in males	Flexeril	10 mg/6 hr
Drowsiness, dizziness,	Parafon-Forte	500 mg/3–4 times/day

and severe allergic reactions	Paraflex Strifon-Forte	
Drowsiness, dizziness, and severe allergic reactions	Skelaxin	800 mg/3-4 times/day
Drowsiness, dizziness, and severe allergic reactions	Robaxin	500 mg/2-3 tablets/QID

## Medications with Neurological Effects

Medications used for local problems have systemic effects. This is no more true than for medications that affect the nervous system. The principles upon which these medications work are based first on a division between central nervous system (CNS) and peripheral nervous system (PNS) effects. Secondly, medications primarily have an effect on neurotransmitters and/or their receptors. Blocking or slowing transmission, inhibiting, blocking, or stimulating receptors, or preventing breakdown or reuptake of the neurotransmitter are the primary strategies of medications developed to affect the nervous system. As a reminder, the autonomic nervous system, which governs most visceral function, also serves functions related to stress, an increased demand for increased metabolism (such as exercise), and pain. Following are some primary drug mechanisms in relation to their nervous system effects.

Acetylcholine is the neurotransmitter for both the sympathetic and parasympathetic preganglionic neurons. For both, the receptors are nicotinic. For the postganglionic parasympathetic nervous system, receptors are muscarinic. For the sympathetic nervous system, the postganglionic (junctional) receptors are referred to as adrenergic because

the neurotransmitter is norepinephrine. Acetylcholine is also the neurotransmitter for parasympathetic postganglionic neuron stimulation and sympathetic sweat gland stimulation. So the first obvious conclusion is that any effect on acetylcholine will have an effect on both divisions of the autonomic nervous system but clinically seem to have more effect on junctional or target tissue receptors post-synaptically. For example, the usual target organ effects of cholinergic parasympathetic activation are glandular secretion and peristaltic activity so that tears, mucus production, salivation, GI secretion, defecation, and urination are all facilitated by parasympathetic activity. Blocking these effects results in drying of secretions, constipation, and urinary retention. Parasympathetic activation also decreases heart rate and blood pressure. Receptors are divided into muscarinic and nicotinic. Muscarinic stimulation results primarily in cardiac and GI effects. Nicotinic receptor activation has effects on the heart and GI system, and nicotinic receptors in muscle are responsible for depolarization and subsequent muscle contraction.

Drugs affecting acetylcholine are called cholinergics. Cholinergics can be classified as cholinergic, anticholinergic, cholinesterase inhibitors, and nicotinic and muscarinic blockers and agonists.

- Cholinergics—used for glaucoma and urinary retention. Example, isoptocarpine. Side effects for cholinergics are nausea, vomiting, blurred vision, tremors, hypertension, and bronchial constriction.
- Anticholinergics—used for intestinal disorders such as irritable bowel syndrome, chronic obstructive pulmonary disease (COPD), and urinary incontinence. Examples are VESIcare and Detrol (urinary incontinence especially detrusor instability [unstable bladder]), and Spiriva (asthma and other COPD-

reducing bronchoconstriction). Side effects include dry mouth, urinary retention, depression, flushing, fever, and constipation.

- Anticholinesterases—used in treatment of Alzheimer's disease, glaucoma, and as a local muscle relaxant. Examples include Aricept (Alzheimer's), Humorsol (glaucoma), and Botox (headaches due to local muscle entrapment and Dupuytren's). Side effects include nausea, diarrhea, confusion, and headache.
- Muscarinic receptor blockers or inhibitors—used in the treatment of asthma, tachycardias, and incontinence. Examples include Atrovent and Apovent (asthma), Ditropan (urinary incontinence), Artane and Cogentin (adjunctive for Parkinson's), Colofac, Duspatal, Duspatalin (irritable bowel syndrome), Benadryl (antihistamine), scopolamine (motion sickness), and atropine (anesthesia and bradycardia). Side effects include urinary retention and blurred vision.
- Nicotinic agonists—used in the treatment of smoking addiction. Examples include Nicorette, Nicoderm, and Chantix. Side effects include altered taste, heartburn, and nausea.
- Nicotinic inhibitors—used for hypertension. Example is Inversine. Side effects include dry mouth, constipation, hypotension, and incontinence.

There are supplements and herbs that are purported to have cholinergic and anticholinergic effects. Some examples include:

- Cholinergic supplements: Pulsatilla, American hellebore, and betel nut

- Anticholinergic supplements: Jimson weed, sage, Angel's trumpet, barberry, belladonna, and *Datura wrightii*
- Nicotinic receptor blockers: Jimson weed, scopolamine, and belladonna

Sympathetically focused medications target primarily respiratory and vascular issues such as COPD, hypertension, and congestive heart failure. The influences of the sympathetic nervous system are through junctional receptor types found pre- and postjunctional. Following is a breakdown with specific effects for each receptor.

## Postjunctional Adrenoceptors

- *alpha-1 receptors* are largely responsible for constriction of small and large peripheral arteries, stimulation of the dilator papillae, constriction of many of the gastrointestinal tract sphincters, the bladder neck sphincter, and the vas deferens. So it is clear that blocking these receptors could help for several reasons: they decrease blood pressure through a decrease in peripheral resistance and prevent incontinence through bladder neck sphincter tightening, although this is more often a side effect of these medications inhibiting micturition.
- *beta-1 receptors* increase the pacemaker activity of the heart while at the same time increasing the force of contraction of the ventricles; additionally, if there is a sudden drop in blood pressure, activation of juxtaglomerular cells in the kidneys activates the rennin-angiotensin-aldosterone system. Blocking these receptors might be effective in decreasing blood pressure through decreasing cardiac force of contraction.
- *beta-2 receptors* are responsible for promoting smooth muscle relaxation for both blood vessels and bronchi, and they initiate glycogen breakdown. For asthmatics and those with constriction of bronchioles, promotion of smooth muscle may be effective, while their blockage for managing hypertension may allow

bronchial constriction with difficulty in breathing as a side effect.

## Prejunctional Adrenoceptors

- *alpha-2 receptors* (also called autoreceptors) are found on both sympathetic and parasympathetic presynaptic synapses and when stimulated, inhibit the release of norepinephrine.
- *beta-2 receptors* facilitate the release of norepinephrine.

Nonadrenergic, noncholinergic (NANC) neurons include dopamine, vasoactive intestinal polypeptide, and nitric oxide. These substances modulate primarily the activity of parasympathetic cells.

## Antidepressants

The basis upon which medical management has evolved follows the hypothesis development over several decades related primarily to the function of mainly three neurotransmitters: serotonin, norepinephrine, and dopamine. These neurotransmitters, also called the monoamines, are crucial to proper function related to, among others, emotion, sleep, appetite, sexuality, and reaction to stress. Medications increase one or more of these monoamines, decrease their breakdown (e.g., monoamine oxidase inhibitors), or normalize receptor sensitivity. Although the neurotransmitters are often increased within hours of ingestion, it may take weeks for the effects to be felt by the patient. This delay may be due to a hypothesized receptor sensitivity reaction. Upregulation may occur when decreased neurotransmitter is available

leading to increased receptor sensitivity or an increased number of receptors. Medications may decrease this hypersensitivity or decrease the number of receptors through downregulation. This may take several weeks, partially explaining the delayed effects of antihypertensive medications. The permissive hypothesis restates the cause of depression through a proposed *imbalance* of neurotransmitters versus their actual levels. For example, low levels of serotonin may allow proportionately high levels of norepinephrine to cause mania.

Following are examples of drug categories and mechanisms of action.

- *Tricyclics* (e.g., amitriptyline [Elavil, Endep] and doxepin HCl [Adapin, Sinequan]) and heterocyclic antidepressants (e.g., trazodone HCl [Desyrel], nortriptyline [Aventyl], clomipramine [Anafranil]). Avoid alcohol, grapefruit juice, and St. John's wort. There is an increased risk for suicide. Tricyclics are metabolized by CYP2C19; therefore it is important to avoid black tea, chamomile, chaparral, clove, ginger, ginseng, gotukola, milk thistle, red yeast rice, thyme, and turmeric.
- *Selective serotonin reuptake inhibitors (SSRIs)* (e.g., fluoxetine HCl [Prozac], paroxetine HCl [Paxil], and sertraline HCl [Zoloft]). SSRIs are metabolized by either CYP2C9 or CYP2D6 and as a result, certain supplements and some foods are contraindicated: **1.** CYP2C9: black tea, chamomile, chaparral, clove, ginger, milk thistle, sage, St. John's wort, thyme, and turmeric  
**2.** CYP2D6: 5-HTP, tyrosine, adrenal extract, vitamin B<sub>6</sub>, kava, black tea, cat's claw, chamomile, chaparral, chromium, clove, DHEA, ephedra, evening primrose, fenugreek, ginger, ginkgo, gotukola, hops, phenylalanine, sage, St. John's wort, SAMe, thyme,

turmeric, and valerian root • *Monoamine oxidase (MAO) inhibitors*. Inhibit the reuptake of dopamine, serotonin, and norepinephrine with the major affect on dopamine. With the older MAO inhibitors there is a caution regarding a sudden onset of hypertension. To prevent this, patients are instructed to avoid high tyramine foods such as aged cheeses, tap beer, licorice, soy sauce, miso, sauerkraut, homemade pizza, sausage, pepperoni, salami, fava beans, snow peas, tofu, soybeans, and meat substitutes, and to avoid tryptophan supplements and St. John's wort. There is also a recommendation to limit certain liquids including wine (2-4 oz/d), coffee and cola (<500 mg caffeine/d), and bottled beer (24 oz/d). Newer drugs such as Wellbutrin and Cymbalta are used in the treatment of depression, and Zyban has been approved as an aid for smoking cessation. Possible problems are seizures, hepatotoxicity, nausea, vomiting, headache, agitation, tremor, and anticholinergic effects. These drugs are generally CYP2D6 inhibitors and are metabolized by CYP2B6. As with many antidepressants, alcohol and St. John's wort should be avoided.

When stress reaction is managed medically, drugs such as Valium and Librium are also prescribed. These benzodiazepines inhibit the stimulation from the locus coeruleus to the amygdala, thereby decreasing norepinephrine release and subsequent sympathetic stimulation. These drugs are effective; however, due to their sedative and addictive properties they should be used with caution.

Lithium is still the standard for manic depression; however, patients with thyroid, kidney, or heart disorders should not take lithium. Other medications prescribed for manic depression include two anticonvulsants,

carbamazepine (Tegretol) and valproate (Depakote), and lamotrigine (Lamictal) and gabapentin (Neurontin). However, the role of gabapentin was apparently misrepresented, and although effective for other disorders it has not been shown to be effective for depression.

Some possible side effects of these medications include:

- drowsiness and sedation—tricyclics
- insomnia and anxiety—SSRIs
- orthostatic hypotension and cardiac arrhythmia—tricyclic and heterocyclic agents
- weight gain—tricyclics, heterocyclics, and MAO inhibitors
- delirium—interactions between tricyclic and heterocyclic compounds and SSRIs may cause what has been coined “serotonin syndrome,” which results in excess cerebral serotonin stimulation

### **Anti-Epileptic**

With the understanding that seizure activity represents, in part, hyperexcitability, the mechanism of action for many of the medications prescribed for epilepsy becomes more evident. The development of effective medications is based on the premise that neurotransmitters that are primarily excitatory need to be diminished or blocked and those that are inhibitory need to be enhanced. Following are some common examples: • Phenytoin (e.g., Dilantin) and carbamazepine (e.g., Tegretol) are part of a medication category termed glutamate antagonists. They block glutamate ionotropic receptors, rendering ion channels less permeable to sodium and/or calcium.

- Benzodiazepines and barbiturates used in the management of many disorders are used as therapy for seizures due to their glutamate inhibition by GABA through hyperpolarization.
- Sodium valproate is able to effectively block the conversion of GABA to glutamate by blocking the

transaminase enzyme responsible for this conversion.

- Ethosuximide is a specific T-channel blocker affecting the excitability of thalamic relay neurons. This then blocks these neurons from entering a burst-firing mode.

Note that anti-epileptic medications are used for other disorders based on these neuronal inhibitory effects including prophylactic management of chronic headache and neuralgias such as trigeminal neuralgia and post-herpetic neuralgias.

The major concern with medical management of epilepsy is the chronic effect on psychomotor and cognitive function. Phenytoin and phenobarbital are of particular concern with long-term usage. A possible problem with anti-epileptic drugs is CNS toxicity, including sedation, dizziness, imbalance, diplopia, and nausea. Usually these are transient. Morbilliform rashes occur in 5% to 7% of patients. Common side effects for the three primary drugs include: • Valproic acid (Depacon): tremor and weight gain

- Phenytoin (Dilantin): in young patients, gingival hyperplasia and hirsutism
- Carbamazepine (Carbatrol, Tegretol, Tegretol-XR) and oxcarbazepine (Trileptal): hyponatremia in patients who drink large amounts of fluids or are on diuretics

## **Psychomotor Stimulants**

Psychomotor stimulants are utilized in the treatment of several disorders including narcolepsy and attention deficit hyperactivity disorder (ADHD). In the past, amphetamines have also been used as appetite suppressants. The substances stimulate the CNS by increasing norepinephrine (NE) and dopamine (D) activity in the brain. This is accomplished through several mechanisms including

binding to NE and D receptors, stimulating the release of NE and D, and preventing the reuptake of NE and D. Examples include Adderall and Ritalin, used in the management of ADHD, and Dexedrine, used in the management of weight gain through appetite suppression. There is the risk of drug dependency with these medications. Some side effects include dry mouth, rapid heartbeat, hypertension, tremor, insomnia, and paranoia. It is recommended to avoid high-dose vitamin C and alcohol and to limit caffeine, high-acid foods (fruit juice), and antacids.

## Anti-Infection Medications

Antibiotics are some of the most commonly prescribed medications. In addition, because they are introduced into the production of our food supply, they are ubiquitous. This allows organisms to develop resistance, which creates a never-ending battle to find the next generation of antibiotic. This has been a concern of the medical community and as a result, restrictions on the addition of antibiotics to the food supply of farm animals and the recommendations to avoid antibiotics as the first response to ear infections or persistent coughs are attempts at slowing down the ability of organisms to develop resistance. That being said, there are critical clinical scenarios where antibiotics and anti-infective agents are life-saving and necessary. A brief overview of organisms and their classifications is given in **Figures B-12** through **B-14**.

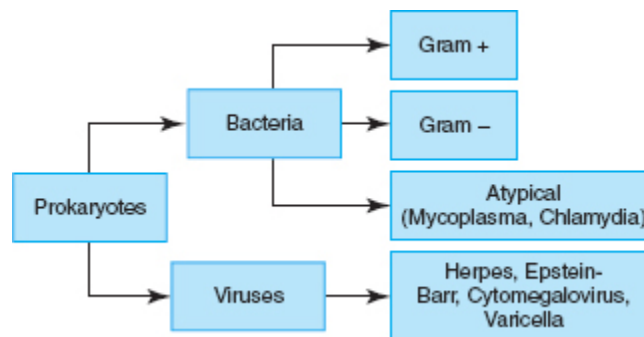

Bacteria are often categorized by their cell wall staining:

- Gram-positive organisms stain blue during gram staining because the cell wall is impenetrable, retaining the color of the dye. These are further divided into cocci and bacilli, and then further divided into aerobic and anaerobic. The most common aerobic bacteria are strep and staph. Mycobacteria such as

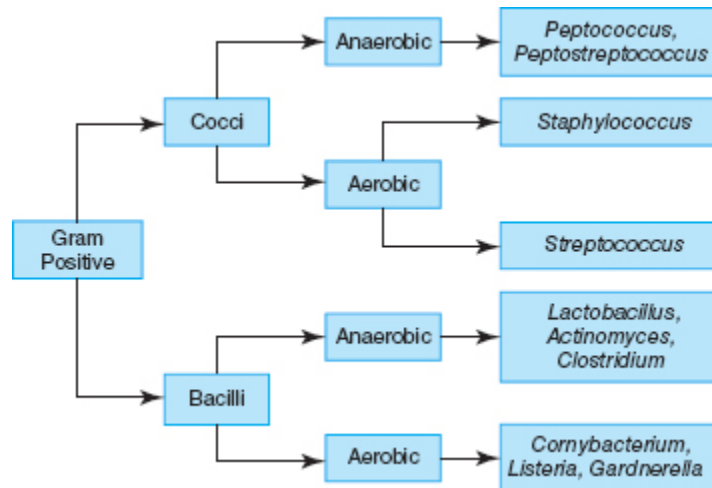

tuberculosis (TB) and leprosy are unique in that they stain gram-positive weakly. They are often called “acid fast” because the stain remains even when washed with acid alcohol. These organisms are unique in their approach because they live inside mononuclear phagocytes, often for years, and are therefore intracellular parasites.

- Gram-negative organisms are negative to staining. They are unique in that they have an additional protection for their plasma membranes in the form of a rigid peptidoglycan wall covered by an outer membrane. Gram-negatives protect themselves against penicillin through the production of betalactamases, enzymes that destroy penicillin. Gram-negatives are also categorized as cocci and bacilli, aerobic and anaerobic. Functionally, they are also categorized as:

**Figure B-12** Organism classification.

**Figure B-13**

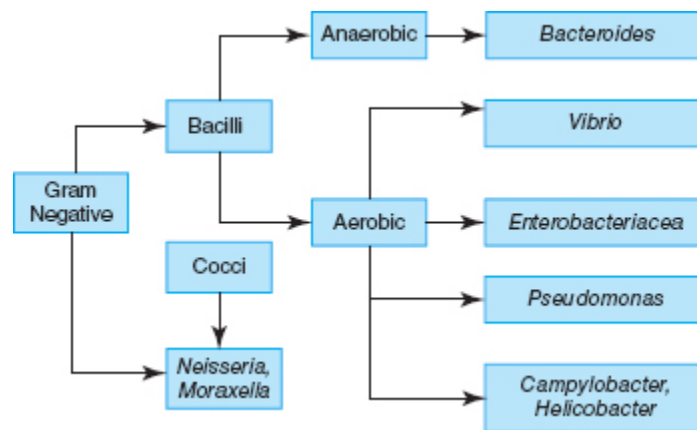

1. Enterics (organisms infecting the GI tract)—*Escherichia, Shigella, Salmonella, Klebsiella, Enterobacter*, and others.
2. *Haemophilus influenza*
3. *Neisseria*
4. *Pseudomonas*

The following will give a cursory overview of the topic of how medications are designed to fight infection. **Table B-7** lists some commonly prescribed antibiotics, antiviral, and antifungal medications for quick reference. So how do anti-infection drugs work? There are several targets of effect.

## The Cell Wall

The cell wall is one key feature for the categorization of organisms. If an organism does have a cell wall and is therefore less like human cells that, in fact, do not have cell walls, it is a prokaryote. These prokaryotes do not have a nucleus where DNA is housed. Prokaryotes include viruses and bacteria. These key differences allow for targeting of the organisms with agents that will in most cases do no harm to human cells, which are eukaryotes (i.e., have a

nucleus with DNA but no cell wall). Eukaryotes include animals, plants, fungi, and parasites. Using the cell wall as the target, some antibiotics are designed to kill bacteria by inhibiting cell wall synthesis; these are termed bactericidal. Other agents are bacteriostatic, meaning that they inhibit bacterial proliferation and allow the host defense system to kill the organism. Common infections such as staph and strep rely on protection through glycoprotein cross-linking in their cell walls. Bactericidal agents affect the cross-linking necessary for the cell wall's integrity and include the penicillins and cephalosporins.

**Figure B-14**

**Table B-7** Some Commonly Prescribed Antibiotic, Antiviral, and Antifungal Medications

Drug Class	Examples	General Mechanism/Used For	Interactions/Side Effects
<b>Antibiotic</b>			
<b>Aminoglycosides</b>		Passively diffuse through cell wall, enter cytoplasm and irreversibly bind to ribosomes, inhibiting protein synthesis requiring oxygen	Usually administered parenterally due to poor GI absorption Side effects include damage to kidneys and auditory nerve (tinnitus) and hearing loss)
Gentamycin	Garamycin Genoptic	A broad-spectrum usually bacteriocidal antibiotic effective against primarily Gram-negative and some Gram-positive organisms. Some include <i>Klebsiella</i> , <i>Proteus</i> , <i>E. Coli</i> , <i>Enterobacter</i> , <i>Pseudomonas</i> , among others. Usually reserved for serious infections when other less toxic antibiotics are ineffective.	Is ototoxic, hepatotoxic, and nephrotoxic with associated indications on lab testing. May cause a variety of hypersensitivity reactions, neuromuscular blockade, hypokalemia, and hypomagnesia with muscle cramps/weakness.
Streptomycin	Trobicin	A bacteriostatic antibiotic effective against numerous bacteria. Primarily used for <i>N. gonorrhoeae</i> .	Pain, swelling, tenderness at injection site. May cause dizziness, headache, and nausea. May elevate some liver enzymes or cause decrease in hematocrit or hemoglobin.
<b>Penicillins</b>		Cross-linking of peptidoglycan strands by inhibiting transpeptidase enzymes	Most common type of drug allergy Nutrient interactions: avoid K supplements
Penicillin (including G benzathine, G potassium, G sodium, G procaine, and V/V potassium)	Bicillin Permapen Megacillin Pentids Pfizerpen Cryptocillin Benzylpenicillin Wycillin	An antibiotic in many different forms used for different infections. Penicillin G benzathine – mild to moderate infections, syphilis, and prophylaxis for rheumatic fever. Penicillin G potassium or sodium – moderate to severe infections, meningococcal meningitis. Penicillin G procaine – moderate to severe infections, pneumococcal pneumonia, uncomplicated gonorrhea, and syphilis. Penicillin V & V potassium – mild to moderate infections and endocarditis prophylaxis.	Anaphylaxis is common, hypersensitivity symptoms, common GI disturbances, SLE-like syndrome, hypotension, rarely circulatory collapse, Loeffler's syndrome, thrombocytopenia, hemolytic anemia, and delayed skin rashes.
Ampicillin	Amcil Penbritin Omnipen Totacillin	Broad-spectrum antibiotic. Effective against Gram positives such as alpha- and beta-hemolytic streptococci, diplococci, pneumoniae, staphylococci, and <i>Listeria</i> . Also against some Gram-negatives such as <i>E. coli</i> , <i>N. Gonorrhoeae</i> , <i>Proteus</i> , <i>shigella</i> , <i>Salmonella</i> , mycoplasma, some viruses and fungi.	Possible anaphylaxis, diarrhea, pseudomembranous colitis, and rash.
Amoxicillin	Amoxil Polymox Larotid Trimox	Penicillin-type antibiotic (bacterial cell-wall inhibitor). Inhibits mucoprotein synthesis of cell wall in rapidly reproducing cells. Used for infections of the middle ear, throat, bronchi, and lungs. Also for UTI, skin infections, and gonorrhea. Specific susceptible organisms include <i>H. influenzae</i> , <i>N. gonorrhoea</i> , <i>E. coli</i> , <i>pneumococci</i> , <i>streptococci</i> , some forms of <i>staphylococci</i> .	Similar to other penicillin medications; possibility of hypersensitivity with rash, anaphylaxis. Also possible are hemolytic anemia, eosinophilia, pseudomembranous colitis, pruritus, and urticaria.

Cephalosporins		Same as penicillins: bind to and inhibit bacterial enzymes, causing defective cell wall formation and eventually bacterial death	Nutrient interactions: depletes vitamin K; avoid alcohol, decrease sodium in diet while taking cephalosporins
Cephalexin	Keflex Keftabs	A semi-synthetic cephalosporin antibiotic (similar to penicillin; $\beta$ -lactam binds penicillin binding proteins inhibiting crosslinking of bacterial cell wall). Susceptible bacteria are Gram-positive except for enterococci and methicillin resistant <i>Staph aureus</i> (MRSA), some Gram-negative; not anaerobes.	Hypersensitivity reactions (anaphylaxis, serum sickness), GI disturbances, rare neurologic problems (seizures), and hematologic abnormalities (cytopenias), and nephrotoxicity and hepatic enzyme increases.
Fluoroquinolones		Same as penicillins: bind to and inhibit bacterial enzymes, causing defective cell wall formation and eventually bacterial death	Nutrient interactions: divalent and trivalent minerals impair absorption (Zn, Mg, Ca, Fe, Al) – take 2 h prior or 6 h after drug; limit caffeine Inhibits CYP1A2 Contraindicated supplements: melatonin, chaparral, tobacco, herbal tea, broccoli, cabbage, charbroiled meats, shiitake mushrooms, turmeric
Ciprofloxacin	Cipro	A synthetic quinolone that is bactericidal by inhibiting DNA-gyrase an enzyme required for bacterial DNA replication. Often used for urinary tract infections caused by <i>E. coli</i> . Also for <i>C. jejuni</i> and <i>Shigella</i> . Also used for bacterial conjunctivitis.	May cause nausea, vomiting, abdominal pain, cramps, and gas. May elevate liver enzymes and eosinophils. May cause tendon rupture, headache, vertigo, seizures, or rash. If used for conjunctivitis may precipitate buildup on cornea or crusting scales.
Macrolides and Ketolides		Inhibit bacterial protein synthesis	Nutrient interactions: avoid St. John's Wort and grapefruit, limit alcohol Inhibits CYP3A4, CYP3A5 & CYP3A7 Supplements affected: DHEA, eucalyptus oil, tea tree oil, yohimbine
Erythromycin	Akne-Mycin Ery-Tab ApoErythroBase A/T/S/E-Mycin EryDerm Erythrocin Erythromid Illocycin Norvo-Rythro Robomycin Staticin T-Stat	A macrolide antibiotic effective primarily against Gram-positive. Effective against <i>Chlamydia trachomatis</i> . Also used for Pneumococcal and Mycoplasma pneumonia, <i>N. gonorrhea</i> , and <i>H. influenzae</i> . Main use is for ear, nose, and throat infections in those allergic to penicillin and cephalosporin.	Usual GI complaints, plus superinfection with yeast, nonsusceptible bacteria, and fungi. Also causes ototoxicity (reversible vertigo, hearing loss, and tinnitus), hypersensitivity reactions, and cholestatic hepatitis syndrome.

Azithromycin	Zithromax	A macrolide antibiotic effective primarily against pyogenic streptococci, <i>S. pneumoniae</i> , <i>H. influenzae</i> , and <i>S. aureus</i> . Interferes with protein synthesis by binding to 50S ribosome of bacteria.	May cause headaches, dizziness, hepatotoxic effects such as mild elevation of liver enzymes, and usual GI complaints.
<b>Nitromidazoles</b>			
Metronidazole	Flagyl Metizol Metro-Gel Protostat Noritate	A synthetic agent that is effective against a wide variety of organisms including <i>Trichomonas vaginalis</i> , <i>Entamoeba histolytica</i> , and <i>Giardia lamblia</i> . Also anti-bacterial anaerobic bacteria and some Gram-negatives. Used with other antibiotics (triple antibiotic regimen) for duodenal ulcers. Topical may be used for rosacea.	May cause a Candida infection (overgrowth), hypersensitivity, nausea and other GI symptoms, polyuria, dysuria, vertigo, headache, and a metallic or bitter taste. May decrease AST levels (interferes with chemical reaction).
<b>Tetracyclines and Glycylcyclines</b>		<b>Reversibly bind to ribosomes, inhibiting protein synthesis</b>	<b>Nutrient interactions: avoid St. John's wort; take Ca, Zn, Mg, Fe, or multivitamin at least 3 h before or 1 h after drug</b>
Tetracycline	Achromycin	A synthetic broad-spectrum antibiotic that is bacteriostatic (inhibits protein synthesis by binding to 30s subunit blocking amino acid linked tRNA from binding to the A site of the ribosome). Susceptible bacteria include <i>M. pneumoniae</i> , <i>C. psittaci</i> , <i>C. trachomatis</i> , and <i>N. gonorrhea</i> . Used for respiratory infections, nongonococcal urethritis (ureaplasma), Rocky Mountain spotted fever, typhus, chancroid, anthrax, syphilis, cholera, brucellosis, chlamydia, acne, and Lyme disease. Doxycycline approved for malaria prophylaxis.	GI distress, reversible nephro- and hepatotoxicity, photosensitivity, and dental staining (not used in prepubertal children).
Doxycycline	Vibromycin	A synthetic broad-spectrum antibiotic that is bacteriostatic (inhibits protein synthesis by binding to 30s subunit blocking amino acid linked tRNA from binding to the A site of the ribosome). Susceptible bacteria include <i>M. pneumoniae</i> , <i>C. psittaci</i> , <i>C. trachomatis</i> , and <i>N. gonorrhea</i> . Used for respiratory infections, nongonococcal urethritis (ureaplasma), Rocky Mountain spotted fever, typhus, chancroid, anthrax, syphilis, cholera, brucellosis, and acne.	May cause GI distress, reversible nephro- and hepatotoxicity, photosensitivity, and dental staining (not used in prepubertal children).
<b>Folate Antagonists</b>			
Trimethoprim-Sulfamethoxazole	Bactrim Septra Co-Trimoxazole	A combination drug that acts as a synthetic folate antagonist acting as an enzyme inhibitor preventing bacterial synthesis. Used with <i>Pneumocystis carinii</i> pneumonitis, <i>Shigella</i> enteritis, and UTI caused by <i>Enterobacteriaceae</i> .	Possible toxic epidermal necrosis syndrome, pseudomembranous colitis, agranulocytosis, aplastic anemia (rare), and anorexia, nausea, and skin rash. May elevate liver enzymes and bilirubin.

### Glycopeptides

Vancomycin	Vancocin Vancoled	An antibiotic that interferes with cell membrane synthesis. Primarily for Gram-positive. Organisms include beta-hemolytic streptococci, staphylococci, pneumococci, enterococci, clostridia, and corneobacteria.	Is ototoxic, and nephrotoxic. May cause anaphylaxis, and hypersensitivity reactions, "red neck" syndrome with IV administration, thrombophlebitis, super-infections, and transient leucopenia and eosinophilia.
------------	----------------------	--	---

### Antimycobacterials

Isoniazid	INH Isotamine Laniazid Nydrazid Teebaconin	An anti-TB medication that interferes with the synthesis of bacterial proteins, lipids, and nucleic acids. Used also for high-risk individuals as a preventive. Additional use for tremors with multiple sclerosis.	May cause paresthesias, peripheral neuropathies, tinnitus, dizziness, hallucinations, increased liver enzymes, decrease in vitamin B absorption, RA and SLE-like syndromes, or possible agranulocytosis and aplastic anemia (rare).
-----------	--	---	---

### Others

Chloramphenicol	Chloromycetin Chlorofair Fenicol Novochloroscap	A broad-spectrum antibiotic that is primarily bacteriostatic (bacteriocidal to <i>H. influenzae</i> ). Interferes with protein synthesis by binding to 50S ribosome of bacteria. Used when infection is serious and unaffected by other antibiotics. Examples include <i>Salmonella</i> , <i>Rickettsia</i> , <i>Chlamydia</i> , <i>Mycoplasma</i> , <i>Streptococcus pneumoniae</i> and <i>Neisseria</i> among others.	May cause hypersensitivity reactions, bone marrow suppression, neurotoxicity, angioedema, pancytopenia, headache, confusion, stomatitis, glossitis, and the usual GI complaints.
Norfloxacin	Chibroxin Noroxin	A strong broad-spectrum antibiotic that alters DNA-gyrase inhibiting protein synthesis. Used primarily for UTIs and conjunctivitis. Effective against many organisms including <i>Klebsiella</i> and other pneumonias, <i>Salmonella</i> , <i>Shigella</i> , <i>Pseudomonas</i> , <i>S. aureus</i> , among others.	May cause joint pain, swelling, and erosions in weight-bearing joints. Usual GI complaints, headaches, dizziness, pruritus, elevated liver enzymes, and immunosuppressed swelling of ankle and hip with tendon tenderness and swelling of 3rd finger bilaterally after one month of continuous therapy.

### Antiviral

Valacyclovir	Valtrex	An antiviral medication that interferes with viral DNA synthesis. Due to increased GI absorption, plasma levels are higher than acyclovir. Used for the treatment of herpes zoster (shingles) and recurrent genital herpes.	Headache, weakness, fatigue, nausea, vomiting, dyspepsia, abdominal pain, renal damage, allergic reactions.
Acyclovir	Zovirax Acycloguanosine	Interferes with DNA synthesis for specific viruses including herpes simplex 1 and 2, varicella-zoster, and cytomegalovirus. It does not eliminate the latent herpes virus.	May cause headache, nausea, vomiting, diarrhea, and rarely acute renal failure or thrombocytopenia purpura or hemolytic uremic syndrome.

Amantadine	Symmetrel	A medication that is effective as an antiviral against influenza A (not B) and also an initial or adjunct therapy with anticholinergic drugs for Parkinson's. Antiparkinsonian effects may be due to effect of release of dopamine and other catecholamines.	May cause dizziness, lightheadedness, difficulty with memory, hallucinations, confusion, mood or other mental effects, nausea, vomiting, or dry mouth.
Hepatitis B Immune Globulin	H-BIG Hep-B-Gamma- gee HyperHep	Sterile human-based solution of IgG used to provide passive immunity for hepatitis B or post-exposure prophylaxis.	May cause a hypersensitivity reaction, muscle stiffness and aching, fever, dizziness, malaise, rash, or leg cramps.
Immunoglobulin	BayGam Gamimune Gammagard Gammar P Iveegam Sandoglobulin Venoglobulin	A sterile concentrated human globulin solution used both as prophylaxis or to modify the severity of a number of diseases including rubella, rubeola, varicella zoster, type A hepatitis, idiopathic thrombocytopenia purpura, among others.	Side effects related to site of injection. Also may cause hypersensitivity reactions, headache, GI symptoms, chest tightness, or wheezing.
Interferon Alfa n-1, Alfacon-1, Alfa 2a, and Alfa 2b	Wellferon Infergen	A variety of medications used in the management of hepatitis C. Actions include suppression of cell proliferation and augmentation of lymphocyte natural killer cells.	Common to have side effects including headache, fever, chills, anxiety, nervousness, GI disturbances, alopecia, abnormal mood, emotional lability, and confusion. Possible lab effects on thrombocytes and granulocytes.

### Antifungal

Amphotericin B Amphotericin B Lipid Based	Amphocin Fungizone Amphotec Abelcet	An antifungal that binds to sterols in the fungus cell membrane. Produced from <i>Streptomyces nodosus</i> . Used intravenously to treat serious, life-threatening fungal infections such as aspergillosis, blastomycosis, coccidiomycosis, cryptococcosis, histoplasmosis, and others.	May cause fever, chills, anaphylaxis, cardiac arrest, nephrotoxicity, hypokalemia, hypomagnesemia, and super-infections.
Clotrimazole	Lotrimin Gyne-Lotrimin Canasten Mycelex	A broad-spectrum antifungal agent that alters the fungal wall permeability allowing loss of potassium and other important elements necessary for replication. Used for both dermal fungal infections and vaginal yeast infections.	May alter liver function tests and cause the usual GI disturbances, UTI symptoms, and pruritus.
Ketoconazole	Nizoral	Cell membrane function is disrupted by inhibiting sterol (ergosterol) synthesis in fungi. Used for serious systemic fungal infections such as Candida, coccidiomycoses, histoplasmosis, blastomycosis, and similar infections. Also used for superficial treatment of mycosis such as the "tineas."	May cause usual GI disturbances, anaphylaxis, gynecomastia, decreased libido, hair loss, acute hypoadrenalism, rarely hepatic necrosis, and may change multiple lab values such as decreases in cholesterol and triglycerides, and low serum testosterone.

Miconazole	Monostat (Derm, 3, 7) Femizole M-Zole Micatin Tetterine Fungoid Lotrimin Desenex	A broad-spectrum antifungal that inhibits absorption of essential material for cell reproduction, growth, and cell wall integrity. Used primarily for Candida, common dermatophytes, and tinea vesicolor. Used for a variety of body sites: vaginal Candida infection, athlete's foot (tinea pedis), and similar "tineas" caused by dermatophytes.	May cause burning at the site of application, skin reactions, or ulcerations.
Nystatin	Mycostatin Nadostine Nilstat Nyaderm Nystex	An antifungal antibiotic that binds to cell membrane and causes leakage of intracellular components. Used primarily for Candida infections.	May cause nausea, vomiting, epigastric pain, or diarrhea.
Terbinafine	Lamasil Lamasil Derma-Gel	Cell membrane function is disrupted by inhibiting sterol (ergosterol) synthesis in fungi. Used for superficial treatment of mycosis such as the "tineas."	May cause burning at the site of application, skin reactions, or ulcerations. Also, may cause headache, GI disturbance, liver function test abnormalities, taste abnormalities, and rarely liver failure or neutropenia.

## Protein and DNA Synthesis

What if the organism does not have a cell wall such as some bacteria, fungi, and parasites? Then the approach is to affect DNA synthesis by disruption of the code or interference in protein synthesis. The DNA in a prokaryotic cell is coiled up in a region called the nucleoid not separated in a cell nucleus like animals, and consists of one long strand. Following are some examples: • Fluoroquinolones, such as Cipro and Noroxin, introduce defective building blocks into DNA creation.

- Sulfonamides and acyclovir (used for many viral infections) inhibit enzymes or cofactors necessary for DNA synthesis. Sulfonamides are similar to para-aminobenzoic acid (PABA) and prevent the incorporation of PABA into folate necessary for its function. A commonly used sulfonamide combination is Septra (trimethoprim sulfamethoxazole), which is utilized against enteric Gram-negative infections such as *Shigella*, *Salmonella*, and *E. coli*, and for urinary tract infections.

- The antimetabolites disarm the synthesis of DNA, RNA, or proteins. Examples include tetrahydrofolate, which is able to donate a single carbon molecule affecting the synthesis of purines, pyrimidines, and some amino acids.
- Destroying the RNA code through the inhibition of RNA polymerase is another strategy used in the treatment of tuberculosis (TB). This is the mechanism of rifampin, one of two common drugs utilized in the treatment of TB.
- Drugs such as erythromycin, tetracycline, chloramphenicol, and the aminoglycosides all attack at the level of the ribosome (70s ribosome) preventing assembly of proteins from the mRNA.

The prescription of antibiotics is complex, involving the decision as to whether it is appropriate given the development of resistant organisms, the need to identify the organism and prescribe the appropriate medication, and the consideration of harm when the medication affects human cells. The patient must be reminded to adhere to the prescription regimen for antibiotics or risk failure and potential additional infection.

To understand the strategies utilized by prescribing physicians, it might be worth summarizing. Some general rules-of-thumb that prescribing physicians use in their decision making include:

- For Gram-positive organisms, most physicians rely on Nafcillin (IV) and dicloxacillin (PO) because they are not susceptible to penicillinases.

- For Gram-negative organisms, third-generation cephalosporins are effective. They can access the brain as well. Another approach is the combination of cephalosporins combined with penicillins, which augments the effectiveness of aminoglycosides.
- The combination of ampicillin and gentamycin ("amp and gent") is effective against the combination of

Gram-positive and Gram-negative organisms.

- Amoxicillin is commonly prescribed for otitis media and many upper respiratory infections.
- Septra (trimethoprim-sulfamethoxazole [Bactrim/Septra]) is commonly prescribed for urinary tract infections.
- For anaerobic bacteria, metronidazole (Flagyl) and clindamycin are commonly employed.
- For infections of the brain, testes, joints, and eye, targeted therapy is necessary due to the inherent protection for these sites.
- Abscesses form a protective wall in many anaerobic infections and therefore must be drained and then treated.

## **Antiviral Medications**

Antibiotics are for bacterial infections. Different agents are used for viruses because their structure and strategy of infection are different. Viruses are obligate intracellular parasites inserting themselves into cells and utilizing those cells to produce new viruses with the inserted viral DNA and RNA. There are commonly several viruses that are seen by medical physicians including:

- Herpes—including herpes simplex causing genital and oral involvement, and the varicella virus (chicken pox) leading to herpes zoster and latent infection of the dorsal root ganglion leading to skin lesions. These are often treated with acyclovir (Zovirax), which inhibits viral DNA polymerase.

- Influenza is of particular concern for the immunocompromised, the elderly, and some infants. Medications are either prophylactic or targeted to infection. Amantadine (Symmetrel) is an example of a medication utilized to prevent the virus from infecting cells; prophylactic.

- Cytomegalovirus (CMV) is of particular concern in transplant patients, those with AIDS, and others who are immunocompromised. Ganciclovir (Cytovene) is used to prevent DNA synthesis through inhibition of DNA polymerase.
- HIV is a retrovirus. Its ability to mutate through substitutions of base-pair substitutions requires a different approach to treatment. Multiple medications are utilized. The drugs include nucleoside analogs, non-nucleoside reverse transcriptase inhibitors, and protease inhibitors given more as a “cocktail” of medications. Commonly used drugs are Retrovir, Videx, Viracept, and Norvir, among others.

## **Antifungal Medications**

Fungi are either yeast or mold. Reproduction strategies and mechanisms are different for each. Yeast spreads through budding or spore formation, whereas mold spreads through extending hyphae; branching out. The most common yeast infection is Candida. Infection of the mouth is often referred to as thrush. This may be secondary to treatment of asthma with aerosol corticosteroids. Candida infections in women are common vaginally and are more common with the use of corticosteroids, antibiotic treatment, and diabetes.

Treatment for oral Candida is usually with nystatin (Mycostatin), whereas vaginal infection is treated first with miconazole (Monistat). If the Candida infection is systemic, amphotericin B is incorporated; this is a very toxic medication.

Fungal infections are difficult to treat, with medications often being toxic. All may find their way to the lungs where granulomas develop. Although there are many different forms of fungal infection, following are some examples of common types: • Histoplasmosis, blastomycosis,

aspergillus, and San Joaquin Valley fever (coccidioidomycosis) are the most common fungal infections and usually present as pneumonia. Treatment is either with the older amphotericin B, or the newer fluconazole or itraconazole, both of which have the advantage of being taken orally versus the IV administration for amphotericin B.

- Cryptococcus is another fungal infection that may present as pneumonia, but more commonly presents as meningitis. This requires medications that can cross the blood-brain barrier. Fluconazole is the most effective, followed by flucytosine. Fluconazole inhibits fungal cytochrome P-450 enzymes.

## **Antiparasitic Medications**

Parasitic infections are more common in those who travel to foreign countries or, in some cases, are exposed to a crowded environment such as daycare centers. Parasites use the human as host and are difficult to treat. The standard treatment is with metronidazole (Flagyl), commonly used for the treatment of Giardia. Lindane is a medication used for the treatment of head lice. Malaria is even more complicated due to variations in regions and the growing resistance to antimalarial medications. Prophylactic treatment seems appropriate when traveling to endemic areas.

## **Cardiovascular Medications**

Cardiovascular effects are needed to modulate a number of pathological processes or conditions including:

- Arrhythmias
- Cardiac ischemia

- Congestive and chronic heart failure
- Hypertension
- Atherosclerosis
- Anticoagulants

Some of the drugs overlap in their application such that management of hypertension, cardiac ischemia, and sometimes arrhythmias may be similar.

## Antiarrhythmics

The mechanism of action is generally to block transmission through sodium and potassium blockade or through smooth muscle relaxation through calcium channel blockers or sympathetic blockers (i.e., beta blockers). Examples include:

- Sodium channel blockers—including Quinidine, Procainamide, and Lidocaine. Avoid Ca and K supplements and grapefruit, and maintain sodium. Metabolized by CYP2D6; therefore avoid substances as listed above.

- Beta blockers (B1)—Commonly used is Propranolol. Avoid alcohol, calcium, sodium, and licorice supplements. Also metabolized by CYP2D6.
- Potassium channel blockers—Example is Cordarone. Taken with food due to increased absorption with fat. Avoid St. John's wort and grapefruit. Metabolized by CYP3A4.
- Calcium channel blockers—Example is Cardizem. Avoid Ca supplements; decrease salt intake; limit caffeine; and high dose vitamin D (>2000 IU). Also metabolized by CYP3A4.

Some supplements with purported anti-arrhythmic activity include alpha-linolenic acid, cat's claw, coenzyme Q10, *Cordyceps*, fish oil, Indian snakeroot, lotus, and omega-3 fatty acids.

## **Anti-Anginal**

The most common drugs used to manage an acute angina attack are vasodilators. Nitrates are the most common example, affecting both arteries and veins through conversion into nitric oxide (NO), a potent vasodilator due to smooth muscle relaxation. This is given sublingually during an attack or prophylactically using a dermal patch. A common side effect with sublingual administration is headache. Some herbals that may have anti-anginal properties include bilberry, feverfew, sweet Annie, horse chestnut, shark cartilage, and noni.

## **Antihypertensives**

Medications reduce the pressure in the cardiovascular system by reducing the force of contraction of the heart, reducing the amount of fluid in the system, or reducing the tension in the arteries/veins. The following general classes of medications accomplish these actions: • Diuretics (decrease fluid in system)

- Drugs that affect the sympathetic nervous system such as beta blockers and alpha adrenergic blockers (reduce force of contraction of the heart and/or tension in the vascular system)
- General vasodilators (often based on activation of nitric oxide)
- Calcium channel blockers (similar effect on heart and vasculature as sympathetic blockers)
- Angiotensin-converting enzyme (ACE) inhibitors (inhibit the renin-angiotensin-aldosterone cycle)
- Angiotensin receptor blockers

Each drug has its potential side effects. The most characteristic side effects are as follows:

- Diuretics—Thiazide diuretics include Diuril, Thalitone, and Lozol. Some diuretics will cause loss of potassium or magnesium and lead to some increase in low-density lipoprotein cholesterol.
- Beta blockers—These often have an effect of causing a decrease in energy or inducing general malaise.
- Calcium channel blockers—Some of the older types of calcium channel blockers have been associated with an increased risk for certain cancers.
- ACE inhibitors—Examples include Monopril, Lotensin, Capoten, and Captopril. Side effects include headache, dizziness, GI distress, and a chronic nonproductive cough. Other concerns are that ACE inhibitors may deplete iron and magnesium. Also patients should avoid potassium supplements and limit Na, Ca, and alcohol.

Some herbs that have purported antihypertensive effects include blue cohosh, cayenne, cola nut, ephedra, ginger, ginseng, grape seed, green tea, hawthorn, kola nut, *Verbena*, vervain, yerba mate, lavender, licorice, maté, and yohimbe.

It is important that the patient consult his or her physician prior to decreasing or increasing the dose of medication. Older patients may forget to take their medication (or with diuretics, potassium supplementation) or decide to stop taking medication because of the cost. It is important to ask questions regarding any change in medication, in particular with those patients who appeared to be under control, yet now have a high BP. For these patients, consider in the older patient renal stenosis as the cause.

## **Lipid-Lowering Drugs**

There are several classifications of drugs used to lower lipids. The two major mechanisms are to block absorption and/or to block intrinsic production in the liver.

- 3-hydroxy-3-methylglutaryl coenzyme A (HMGCoA) reductase inhibitors (“statins” such as Lipitor, Crestor, Zocor, Mevacor, Pravachol)—Inhibit the conversion of HMG-CoA to mevalonic acid, which is needed for cholesterol production. Also, statin use may lead to an increase in LDLc receptors, lowering LDLc levels. Avoid alcohol, red yeast rice, grapefruit, and St. John’s wort. It is also important to limit soluble fiber at the time of ingestion of these drugs. They are metabolized by CYP3A4. Due to hepatotoxicity, statins require liver function testing every 6 to 12 weeks. A common complaint seen in the chiropractor’s office is muscle achiness and sometimes weakness.
- Cholesterol absorption blockers—Ezetimibe (Zetia) is used alone or with statins (e.g., with Zocor it is marketed as Vytorin). It decreases cholesterol levels but has not been shown to improve cardiovascular risk compared to placebo. It prevents cholesterol absorption from the small intestine at the brush border. Another drug, probucol (Lorelco) may inhibit the absorption of cholesterol and decrease LDLc levels.
- Bile acid-binding resins (cholestyramine [Questran] and colestipol [Colestid])—These combine with bile acids and salts and then are excreted in feces; removal of bile acids causes conversion of cholesterol to bile acids, which reduces blood levels of cholesterol.
- Nicotinic acid (niacin)—Examples include Niaspan and Niacor. It is often combined with Lipitor. Nicotinic acid decreases hepatic production of LDLc and increases levels of HDLc (significantly lower doses are needed to increase HDLc) through inhibition of triglyceride lipase and induction of lipoprotein lipase. Common side

effects are nausea, flushing (which can be avoided or decreased by taking aspirin 30 minutes prior to administration for first week), gout, jaundice, and liver damage (liver enzymes should be checked every three months). Nutrient interactions require a recommendation to avoid alcohol, hot liquids, and spicy foods.

- Fibric acid derivatives (gemfibrozil [Lopid])—Decrease triglycerides, raise HDLc, do not have much effect on LDLc.
- Estrogen replacement therapy—Estrogen raises HDLc levels, lowers LDLc; however, may increase triglyceride levels; progestogens typically lower HDLc levels.

The use of these drugs is somewhat controversial given that there are, as with most drugs, contraindications to their use, side effects, and cost considerations. In general, in patients with isolated LDLc elevations, bile acid-binding resins or statins are used first. For those with mixed hyperlipidemia, nicotinic acid (if tolerated) is the first drug used; if not effective, gemfibrozil or one of the statins is used. For isolated triglyceride elevation, niacin is used. However, niacin can unmask or increase the risk of developing diabetes.

## **Anticoagulants**

For patients who have stroke or other thromboembolic events such as deep vein thrombosis, anticoagulants are often prescribed on a limited basis. As a prophylactic for patients at high risk, daily aspirin is recommended, although the value is less for those not at high risk. The most common prescribed drug is warfarin (Coumadin). Coumadin interferes with several clotting factors (II, VII, IX, X). Side

effects may include nausea, diarrhea, hypotension, fatigue, headache, and alopecia. Patients should be constantly monitored for prothrombin time. Metabolized by CYP2C9, patients should avoid supplements containing vitamin K, vitamin E, vitamin A, CoQ<sub>10</sub>, St. John's wort, turmeric, milk thistle, tea, anticoagulants (garlic, ginger, ginkgo, ginseng, saw palmetto, fish oils and avocado). More recently clopidogrel (Plavix) has begun to be used commonly as an anticoagulant.

## **Respiratory Drugs**

Drugs used for management of the respiratory tract include the following categories:

- Infection (see below under anti-infection section)
- Allergic reactions
- Chronic obstructive pulmonary diseases (COPDs) including asthma, chronic bronchitis, and emphysema

## **Antihistamines**

Antihistamines (H<sub>1</sub> blockers) such as Zyrtec, Dramamine, Benadryl, Claritin, and Sudafed all block the release of histamine from mast cells in response to IgE-mediated allergies. They bind to H<sub>1</sub> receptors on blood vessels, bronchiolar smooth muscle, and intestinal smooth muscle in an attempt to avoid itching, redness, and swelling, and inflammatory reactions in the bronchial tree (e.g., cromolyn sodium [Intal]). Benadryl inhibits CYP2D6.

<b>Bronchodilators</b>
------------------------

For COPDs, beta-2 receptor stimulation or anticholinergic drugs that decrease parasympathetic activity both result in bronchodilation. Beta-2s such as Albuterol (Ventolin), Formoterol, and Terbutaline increase the synthesis of cAMP, which causes bronchodilation and prevents synthesis and secretion of inflammatory compounds from mast cells. Bronchodilators such as methylxanthines (a caffeine derivative) inhibit the enzyme that degrades cAMP. One example, theophylline (Theodur) is metabolized by CYP1A2 and may deplete B<sub>6</sub> and thiamine. Anticholinergics such as Spiriva are inhaled. These are not as effective as beta-2s. Combination drugs include Symbicort and Advair, which are a combination of a beta-2 agonist and anti-inflammatory.

Some substances with purported bronchodilator effects are alpha-linolenic acid, coffee, black tea, *Boswellia* (genus), *Tylophora* (genus), butterbur, choline, coleus, ephedra, fish oil, green tea, hawthorn, *Lactobacillus acidophilus*, lycopene, melatonin, omega-3 fatty acids, perilla, Pycnogenol, selenium, vitamin B<sub>6</sub>, and vitamin C.

### **Anti-Inflammatory Drugs for COPD**

Corticosteroids are utilized for those with severe COPDs. They inhibit activity of inflammatory cells, prevent the release of inflammatory compounds from mast cells, decrease the production of IgE, and reduce edema. They may be administered orally or through an inhaler (i.e., aerosol). Oral corticosteroids used for over seven weeks may result in severe adverse effects including osteoporosis, soft tissue damage, anemia, Cushing's disease, and so on. Aerosol corticosteroids are cleared on their first pass through the liver so do not carry as severe a restriction. However, used as an inhaler, they do carry the risk of causing oral candidiasis. This is decreased through the use of what is called a spacer added to the inhaler.

Corticosteroids such as prednisone and hydrocortisone are metabolized by CYP3A4.

Lipoxygenase (LOX) inhibitors such as Zylflo prevent leukotriene formation, thus preventing bronchoconstriction and inflammation. It is metabolized by CYP1A2. Singulair is similar. Its main mechanism is to block leukotriene receptors, which then prevents the production of inflammatory cytokines. Singulair inhibits CYP2C8.

## **Gastrointestinal Drugs**

### **Gastroesophageal Reflux Disease (GERD) and Peptic Ulcers**

One concern in the upper GI is hyperchlorhydria. The result may be peptic ulcers that include the esophagus, stomach, or duodenum. The approach is either to decrease the production of hydrochloric acid, buffer its effects, or eradicate *H. pylori* as a source of hyperchlorhydria. As a normal process, acetylcholine (ACH) causes the release of enzymes, gastrin, histamine, and HCl. Specifically, gastrin releases histamine. Histamine then binds to H<sub>2</sub>-receptors on parietal cells, releasing HCl. Antacids or the newer OTC H<sub>2</sub> antagonists usually help for short-term relief. Alcohol and smoking also increase HCl production and limitation or cessation will help. Antacids such as Tums, Rolaids, Maalox, and Mylanta neutralize acid already released but may cause nutrient depletions for calcium, phosphorus, copper, iron, magnesium, potassium, and zinc. H<sub>2</sub>-receptor antagonists (antihistamines) such as Tagamet, Pepcid, Axid, and Zantac are now sold OTC and competitively inhibit histamine from binding to receptors, preventing acid secretion. They too should be used only for short-term relief. It should be noted that Tagamet inhibits CYP2C9, CYP2D6, and CYP3A4, thus impairing the metabolism of many drugs. Also, Zantac

prevents warfarin (Coumadin) clearance and inhibits CYP2D6. An older less commonly used drug is Carafate (Sucralfate), which binds proteins building up a protective mucosal barrier.

The next step is to provide a neutralizing effect and also provide for ulcer healing. Proton pump inhibitors (PPIs) such as Nexium, Prevacid, and Prilosec inhibit the exchange of  $H^+$  and  $K^+$  ions in parietal cells, thus decreasing HCl secretion. Omeprazole (Prilosec) is the standard for treatment of GI reflux. However, long-term use may lead to problems with absorption of calcium and other important nutrients. The most serious side effect is osteoporosis and an increased risk of fracture.<sup>10</sup> Unfortunately, pediatricians are prescribing this medication for infants with colic, increasing the risk of decreased absorption and possible increased risk of infection.<sup>11, 12</sup> Prilosec prevents excretion of warfarin and diazepam, and inhibits the absorption of Plavix (an anticoagulant). Also, Prilosec induces CYP1A2 and inhibits CYP2C19.

Most importantly, gastroesophageal reflux should not be confused with the temporary reflux of infants. A concern that has warranted strong editorial warnings is that medical doctors are prescribing proton-pump inhibitors for infants with reflux. The critics of this approach feel that this practice is more for the parents than the infant and may harm the infant with regard to important nutritional absorption and potentially increase risk for infection.

For duodenal ulcers, the mainstay is not an attempt to irradiate an underlying *H. pylori* overgrowth infection. This “triple therapy” is a combination of omeprazole or lansoprazole (proton-pump inhibitor) with metronidazole (Flagyl) and amoxicillin (antibiotics). For gastric ulcers, discontinuing NSAIDs combined with a two- to three-month course of  $H_2$  antagonists or sucralfate (a drug that acts locally as a mucous bandage) is usually effective.

## **Irritable Bowel Syndrome (IBS) Drugs**

Generally, the two main problems with IBS are distention and pain, coupled with either or both diarrhea and constipation. The prescribing physician attempts to match the drug based on the predominance of either diarrhea or constipation related to specific serotonin receptors. For pain and diarrhea, selective serotonin (5-HT<sub>3</sub>) receptor antagonists (Alosetron) are utilized. These receptors are located throughout the myenteric plexus and have an effect on distention perception, GI motility, and secretions. For patients with primarily constipation and pain, a serotonin 5-HT<sub>4</sub> receptor agonist is used (Tegaserod). The 5-HT<sub>4</sub> receptor, a serotonin receptor, normalizes intestinal contractions. In addition, this medication acts to raise the pain threshold for distention of the colon. Other medications specific to diarrhea or constipation may also be used.

## **Antidiarrhea Drugs**

There are generally three types of medications available:

- 1. Antimotility drugs**—Loperamide (Imodium) is the most common type and quite effective (codeine is an effective prescription drug).
- 2. Antisecretory drugs**—Bismuth subsalicylate (Pepto-Bismol) reduces diarrhea through prostaglandin inhibition (aspirin has some effect).
- 3. Absorbents**—Kaopectate (mainly clay and pectin from apples/citrus fruits) bulks up the stool.

The primary goal of management of the immunosuppressed or infants is to maintain proper glucose and electrolytes. Sports drinks are not appropriate because the fluid must be hypoosmolar. For infants, several OTC

drinks are available, such as Pedialyte. A simple home concoction is a mixture of ½ tsp salt, 1 tsp baking soda, 8 tsp sugar, and 8 oz of orange juice diluted in water to produce 1 L of liquid.

### **Anticonstipation (Laxative) Drugs**

Bulk-forming agents act similarly to fiber. When ingested these agents form emollients and gels when they mix with intestinal water, expanding their size. This distention increases peristaltic activity. One side effect with these agents is that they may contribute to gas production, causing distention and discomfort. Lubricants (i.e., mineral oils) are of limited value. Chronic use may impair fat-soluble vitamin absorption and lead also to a chronic perianal inflammatory response. Salts are used for their osmotic effects of drawing in fluid and increasing reflex colon contractions. They are usually the sulfate or phosphate salts of sodium and magnesium ions (saline cathartics). A similar action occurs with lactulose; however, lactulose has no effect on the small bowel. Another group of agents is referred to as surface-active agents. They act to decrease colonic absorption and increase secretion. Stimulation of adenylate cyclase and prostaglandin E, inhibition of sodium absorption, and alteration in mucosal permeability are all possible mechanisms of these agents. Castor oil is an example of a surface-acting agent.

Rectal enemas or suppositories are usually in the form of glycerin, bisacodyl, water (tap and saline), and soaps (usually castile). These should be reserved for the patient with impaction. Chronic use may lead to colitis.

## **Medications Used in the Management of the Female Patient**

# Contraceptives

Contraceptives are used to prevent pregnancy by inhibiting the release of follicle stimulating hormone (FSH) and luteinizing hormone (LH) necessary for ovulation. They are also used to regulate menstruation, especially for those with physiological vaginal bleeding. Either alone or in combination, estrogen and progesterone are the primary hormones utilized. Examples include some monophasics: Loestrin, Ortho-Novum, Yasmin, Yaz; and triphasics such as Ortho Tri-Cyclen. Other options include an injection (Depo-Provera) or an intrauterine device (Mirena). Side effects are largely related to the sodium retention caused by estrogen, including edema, hypertension, weight gain, and depression. Diabetics may have restrictions due to an increase in insulin secretion that may occur with some of the drugs. Some nutritional concerns are depletion of many B vitamins including folate, vitamins B<sub>6</sub> and B<sub>12</sub>, riboflavin, magnesium, and zinc.

# Fertility Drugs

The opposite of contraceptives, fertility drugs are used to stimulate ovulation by effecting LH and FSH. The effect does not focus on the Graafian follicle but includes multiple follicles, which leads to a risk of multiple fetuses. Examples include Clomid, Follistim (peptide), and human chorionic gonadotropin (hCG). Side effects include those similar to dysmenorrhea including bloating, hot flashes, headache, pelvic pain, and breast pain. There may be an increase in ovarian cysts.

# Medications for Osteoporosis

Although in the past, estrogen replacement therapy and calcitonin have been the mainstay for the prevention of further bone loss in postmenopausal females, three new therapies are now becoming first-line therapy:

- Selective estrogen receptor modulators (raloxifene)

- Bisphosphonates (alendronate and risedronate)
- Parathyroid hormone

Both raloxifene and the bisphosphonates comprise a group of medications classified as antiresorptive. These medications inhibit bone resorption but eventually reduce bone formation due to a decrease in overall bone turnover. A standard intermittent treatment program with parathyroid hormone is intended to increase bone formation; however, it also increases bone resorption. The net effect, however, is bone formation. It is clear that prolonged exposure to parathyroid hormone such as in hyperparathyroidism causes osteoporosis. Intermittent use through daily subcutaneous injections has an anabolic effect, particularly with trabecular bone. The effect on cortical bone may be an increase in cortical porosity, yet most of this occurs at the endocortical surface (partially at the Haversian canals), having little mechanical effect (i.e., no increased risk of fracture). A recent study confirmed the effect of increased trabecular bone content in parathyroid treated patients versus combination treatment with alendronate and parathyroid.<sup>13</sup> A separate study in men confirmed the same effect. Additional findings indicate that any initial benefit of combined therapy changes over time, so that those treated with parathyroid hormone had higher bone mineral density than with combination therapy.<sup>14</sup> In fact, it appears that alendronate may reduce the beneficial effects of parathyroid treatment. The positive effect of parathyroid hormone therapy on reducing the risk of fracture has been demonstrated in one study.<sup>15</sup> Although it appears that 5-reductase inhibitors (statins) have been demonstrated to

increase bone formation in vitro and in vivo in some studies, a recent study indicated that this had no effect on fracture risk for postmenopausal females.<sup>16</sup>

Calcitonin appears to have two effects. In addition to increasing bone density, it may reduce pain significantly in some patients. The infrequent complaints of nausea and flushing are usually managed by beginning with a low dose given at bedtime. Newer approaches that are being investigated are fluoride and parathyroid hormone use.

## **Incontinence Medications**

Parasympathetic activation is necessary for micturition. Medications for inhibiting this stimulation are directed mainly at the receptors, including muscarinic receptors, anticholinergics, or smooth muscle relaxants (antispasmodic). This is particularly true of drugs used in the management of detrusor instability or unstable bladder.

- Muscarinic receptor (antagonist) blockers—VESicare, Ditropan, Detrol
- Anticholinergic, antispasmodic—Oxytrol

## **Medications Used in the Management of the Male Patient**

### **Erectile Dysfunction**

Frequently marketed in television advertising are medications to address erectile dysfunction (ED). However, prior to being prescribed these medications, it is important to understand that there are underlying treatable disorders that may lead to ED. The most common disorders are

diabetes, atherosclerosis, surgery for prostate cancer, and a multitude of medications. When age is the primary factor, these medications may be of benefit. The primary mechanism of these medications is stimulation of central release of nitric oxide and selective inhibition of phosphodiesterase type 5, preventing metabolism of cGMP. Common examples include Viagra, Cialis, and Levitra. Side effects include hypotension and resulting orthostatic hypotension leading to a complaint of dizziness upon rising, headache, flushing, nasal congestion, rash, diarrhea, and photophobia. It is important to avoid grapefruit and limit alcohol intake.

### **Benign Prostatic Hypertrophy (BPH)**

BPH is one of the most common disorders of older males. Compression of the urethra by the surrounding prostate results in symptoms related to difficulty starting a stream, frequent urination, and sometimes dysuria. Risk factors include the use of beta-blockers often used for hypertension. Higher physical activity seems to decrease risk. Lower androgen levels may also decrease risk as is seen in cirrhosis of the liver with chronic alcoholism. The most effective medications are alpha-adrenergic antagonists such as Flomax and Hytrin, which in part reduce smooth muscle tone in the prostate. Other commonly used drugs are 5-alpha reductase inhibitors, which block the conversion of testosterone to 5 alpha DHT (responsible for prostate hypertrophy). Examples are Proscar and Avodart.

### **Low Testosterone (Testosterone Deficiency)**

Low testosterone is defined as levels  $< 300$  ng/dL. Symptoms in addition to low sexual drive include decrease in muscle mass and strength, and fatigue. Clearly, these may also be related in part to aging, and certainly are

related to other disorders that may be risk factors such as obesity, diabetes, and COPD. Causes may include undescended testicles, mumps infection (orchitis), Cushing syndrome, hemochromatosis, TB, HIV/AIDS, and testicular trauma. Luteinizing hormone released from the pituitary stimulates the release of testosterone from the testes. Treatment is with testosterone gels such as AndroGel and Testim. Patients who use these medications are cautioned not to transfer the gel to females or children, which may result in increased testosterone and its effects. Other approaches include a patch (Androderm and Testoderm) and injection with Delatestryl or Depo-Testosterone.

## **Hormonal Imbalance**

### **Thyroid**

There are primarily two main causes of thyroid dysfunction. For hyperthyroidism it is usually the auto-immune disorder Graves' disease and for hypothyroidism, the auto-immune disorder Hashimoto's disease. For hypothyroidism, Synthroid and Armour Thyroid are the primary synthetics utilized. When taking Synthroid separate by 4 hours from the ingestion of Ca, Fe, or Mg supplements, soy, walnuts, or high-fiber meals. For hyperthyroidism, primarily Graves' disease, treatment may be surgical, with radiation, or through medication. The primary drug used is Propylthiouracil. The intention is to destroy the function of the thyroid, leading to the eventual need of Synthroid or Armour Thyroid.

### **Diabetes**

Diabetes is categorized as type-1 diabetes mellitus (DM) associated with pancreatic failure to produce insulin and the acquired, type-2 DM which starts as decreased insulin production and decreased sensitivity of insulin receptors. For type-1 DM, insulin is given by subcutaneous injection in the arms, abdomen, thighs, or buttocks using pen injections or pump delivery systems. There are many factors affecting insulin requirements and absorption when injected including colds, fever, infections, illness, surgery, stress, and exercise. Side effects are related mainly to hypoglycemia, but also include allergic reactions, and lipodystrophy at the injection site. Some contraindicated supplements include melatonin, chaparral, tobacco, herbal tea, broccoli, cabbage, charbroiled meats, shiitake mushrooms, and turmeric.

Medical management of type-2 diabetes includes the use of the following drugs prior to resorting to insulin:

- Sulfonylureas (e.g., glipizide [Glucotrol], glyburide [Glynase, Micronase, DiaBeta], glimepiride [Amaryl], chlorpropamide [Diabinese])—close energy-sensitive potassium channels on beta cells causing influx of calcium and subsequent release of insulin • Biguanides (e.g., Glucophage [metformin])—hypoglycemic action is based on its effect of decreasing glucose production from the liver • Thiazolidinones (e.g., Actos [pioglitazone], Avandia [rosiglitazone])—attach to nuclear receptors in cells to cause an increase in production of cellular proteins that facilitate glucose transport. Note Avandia has been taken off the market in Europe since fall of 2010 and restricted in the United States to patients who do not respond to other medications due to its associated increase in cardiovascular risk. Inhibits CYP2C8.
- Alphaglucosidase inhibitors (e.g., Acarbose [Precose], Miglitol [Glyset])—reduces the rate of digestion of carbohydrates by competitive inhibition of enzymes

needed to digest carbohydrates • Dipeptidyl peptidase 4 inhibitor (e.g., sitagliptin [Januvia])—increases incretin levels, which inhibit glucagon which allows increase in insulin secretion. Incretins are a group of proteins secreted by the GI tract along with glucose that enhance insulin secretion in the pancreas. These include glucagon-like peptide-1 (GLP-1) and gastric inhibitory peptide (GIP). GLP-1 also inhibits glucagon secretion and delays gastric emptying.

- GLP-1 receptor agonist injectables—Exenatide (Byetta) and Liraglutide (Victoza).
- SGLT2 inhibitors (e.g., canagliflozin [Invokana ® ], dapagliflozin [Farxiga ® ])—act by blocking the kidneys' reabsorption of glucose. The result is decreased plasma glucose due to loss in the urine. Soon to be released is a GLP-1 receptor agonist that is delivered intranasally not requiring injection.

**Tables B-8** and **B-9** list common examples of medications based on generic and product name, and list common side effects. There are many handbooks with far more extensive information on these and other medications. This table is intended to serve as a quick reference guide. Further information should be sought from more comprehensive sources available.

**Table B-8** Some Common Medications (Listed by Generic Name)

Name	Examples	Mechanism/Use	Some Side Effects/Concerns
Abatacept	Orencia	A disease-modifying antirheumatic drug (DMARD) which inhibits T-cell proliferation and tumor necrosis factor alpha, gamma-interferon and interleukin-2, and decreases anticollagen antibody production. Used in the management of rheumatoid arthritis in patients who have an inadequate response to other MARDs. Used as monotherapy or in combination. Given as IV infusion.	May cause hypersensitivity reactions, headache, dizziness, hypertension, upper respiratory infection, malignancies, or urinary tract infections.

Acyclovir	Zovirax Acycloguanosine	Interferes with DNA synthesis for specific viruses including herpes simplex 1 and 2, varicella-zoster, and cytomegalovirus. It does not eliminate the latent herpes virus.	May cause headache, nausea, vomiting, diarrhea, and, rarely, acute renal failure, thrombocytopenia purpura, or hemolytic uremic syndrome.
Adalimumab	Humira	A disease-modifying antirheumatic drug (DMARD) used alone or with methotrexate for the treatment of rheumatoid arthritis and similar disorders. A human monoclonal antibody, it works by blocking tumor necrosis factor (TNF) alpha, a major protein involved in inflammation.	May cause a local injection response, rash, or increase the risk of serious infection such as tuberculosis, neurologic events, or malignancies. Very expensive.
Albuterol	Ventolin Proventil	Beta-2 agonist used in the treatment of asthma. Causes bronchodilation without secondary vascular and cardiac effects.	May cause anorexia, tachycardia, nausea, arrhythmias, tremor, hypertension, muscle cramps, convulsions, weakness, hallucinations, or postural hypotension.
Alendronate	Fosamax	Bisphosphonate; antiresorptive used in the treatment of osteoporosis and Paget's disease. These medications inhibit bone resorption but eventually reduce bone formation due to a decrease in overall bone turnover.  A standard intermittent treatment program with parathyroid hormone is intended to increase bone formation; however, it also increases bone resorption.  The net effect though is bone formation. It is clear that prolonged exposure to parathyroid hormone such as in hyperparathyroidism causes osteoporosis.	Hypocalcemia. GI effects include esophageal irritation/ulceration with abdominal pain, nausea, vomiting, diarrhea/constipation, arthralgias, myalgias, headache, and rash. Dairy products decrease absorption.
Allopurinol	Alloprin Lopurin Novopurinol Zyloprim	A xanthine oxidase inhibitor used in the treatment of gout. It decreases endogenous uric acid. Inhibiting xanthine oxidase prevents conversion of hypoxanthine to xanthine and then xanthine to uric acid.  Not used for anti-inflammatory effect.	May cause nausea, vomiting, diarrhea, and abdominal pain. Concerns over possible hepatotoxicity, renal insufficiency, aplastic anemia, and thrombocytopenia.  Check CBC and liver function tests.
Alosetron	Lotronex	Selective serotonin (5-HT <sub>3</sub> ) receptor antagonist. These receptors are located throughout the myenteric plexus and affect distention perception, GI motility, and secretions. Used in the control of abdominal pain and diarrhea with irritable bowel syndrome in women.	May cause constipation, ischemic colitis, urinary frequency, muscle cramps, weakness, and anxiety.
Alprazolam	Xanax	A benzodiazepine sedative causing CNS depression. Suggested sites of action are the limbic, thalamus, and hypothalamus. Used in the treatment of anxiety, panic attacks, insomnia, and muscle spasms. Also used as adjunctive therapy with depression (associated anxiety).	May cause lethargy. Some concern over dependency/abuse and withdrawal problems.

Amantadine	Symmetrel	A medication that is effective as an antiviral against influenza A (not B) and also as an initial or adjunct therapy with anticholinergic drugs for Parkinson's. Anti-parkinsonian effects may be due to effect of release of dopamine and other catecholamines.	May cause dizziness, lightheadedness, difficulty with memory, hallucinations, confusion, mood or other mental effects, nausea, vomiting, or dry mouth.
Amiloride	Midamor	A potassium-sparing diuretic without direct effects on aldosterone used in the management of CHF, hypertension, or hepatic cirrhosis. Usually combined with a thiazide or loop diuretic.	May cause headache, diarrhea, nausea, aplastic anemia, rash, weakness, cramps, hyperkalemia, or hyponatremia.
Amitriptyline	Elavil Endep	Increases levels of serotonin and to a lesser degree norepinephrine through inhibition of reuptake at the pre-synaptic neuron in the brain. It is used for depression and associated insomnia, restlessness, and nervousness. Also used for fibromyalgia and chronic pain.	May cause drowsiness, sedation, dizziness, orthostatic hypotension, tachycardia, increased appetite, weight gain, urinary retention, or constipation.
Amlodipine/ Atorvastatin	Caduet	A combination antihypertensive (selective calcium channel blocker) medication with a statin (5 reductase inhibitor) used as an adjunct to diet in the treatment of primary hypertension.	May cause back pain, myalgia, constipation, diarrhea, flatulence, palpitations, tachycardia, facial edema, postural hypotension, headache, sexual dysfunction.
Amoxicillin	Amoxil Polymox Larotid Trimox	Penicillin-type antibiotic (bacterial cell-wall inhibitor). Inhibits mucoprotein synthesis of cell wall in rapidly reproducing cells. Used for infections of the middle ear, throat, bronchi, and lungs. Also for UTI, skin infections, and gonorrhea. Specific susceptible organisms include <i>H. influenzae</i> , <i>N. gonorrhea</i> , <i>E. coli</i> , pneumococci, streptococci, and some forms of staphylococci.	Similar to other penicillin medications, possibility of hypersensitivity with rash, anaphylaxis. Also possible are hemolytic anemia, eosinophilia, pseudomembranous colitis, pruritus, and urticaria.
Amphotericin B Amphotericin B Lipid Based	Amphocin Fungizone Amphotec Abelcet	An antifungal that binds to sterols in the fungus cell membrane.  Produced from <i>Streptomyces nodosus</i> . Used intravenously to treat serious, life-threatening fungal infections such as aspergillosis, blastomycosis, coccidioidomycosis, cryptococcosis, histoplasmosis, and others.	May cause fever, chills, anaphylaxis, cardiac arrest, nephrotoxicity, hypokalemia, hypomagnesemia, and super-infections.
Ampicillin	Amcil Penbritin Omnipen Totacillin	Broad-spectrum antibiotic. Effective against Gram-positives such as alpha- and beta-hemolytic streptococci, diplococci, pneumoniae, staphylococci, and <i>Listeria</i> . Also against some Gram-negatives such as <i>E. coli</i> , <i>N. gonorrhea</i> , <i>Proteus</i> , shigella, <i>Salmonella</i> , mycoplasma, some viruses, and fungi.	Possible anaphylaxis, diarrhea, pseudomembranous colitis, and rash.
Aripiprazole	Abilify	A psychotropic drug used in the management of schizophrenia, bipolar disorder, and adjunctive therapy for major depressive disorder.	Not recommended for the elderly with dementia-related psychosis. May cause tardive dyskinesias, orthostatic hypotension, seizures, worsening of suicidal risk, neuroleptic malignant syndrome, hyperglycemia, diabetes, cognitive impairment, body temperature regulation interference, nausea, vomiting, constipation, headache, dizziness, anxiety, or insomnia.

Aspirin (acetylsalicylic acid)	Alka-Seltzer A.S.A. Aspergum Bayer Cosprin Easprin Ecotrin Empirin Entrophen Novasen St. Joseph's Triaphen-10 ZORprin	Inhibits the formation of proinflammatory prostaglandins. Acts as an anti-inflammatory, antipyretic, and analgesic. Also has an antiplatelet effect. Used in the management of pain, fever, and prophylactically for its ant clotting action to prevent stroke (transient ischemic attack), recurrence of MI, and thrombus formation (such as deep vein thrombosis).	Some individuals are allergic to aspirin and may have a hypersensitivity reaction including an asthma-like response. Heartburn and stomach upset may be due to irritation leading to peptic ulcer formation. Anemia may be due to blood loss or hemolytic anemia. Ototoxic effects include tinnitus and hearing loss. High doses may impair renal function.
Atenolol	Tenormin	Beta-blocker: A $\beta$ -adrenergic antagonist blocking primarily $\beta_1$ receptors (less bronchoconstriction effect than $\beta_2$ blockers), decreases heart rate and rennin release used in the treatment of hypertension.	CNS depressive effects with concerns for those with diabetes, heart block and heart failure, asthma, and emphysema.
Atomoxetine	Strattera	Strattera is a selective norepinephrine reuptake inhibitor used for the treatment of Attention Deficit Hyperactivity Disorder (ADHD).	Decreased appetite, sleeping problems, constipation, dry mouth, nausea, allergic reactions, dizziness, lethargy, mood swings.
Atorvastatin	Lipitor	A statin: An HMGCoA reductase inhibitor. This blocks the enzyme that controls production of cholesterol in the liver. Therefore used in the treatment of hyperlipidemia. Lowers both total cholesterol and LDL cholesterol while increasing HDL cholesterol. Atorvastatin is different from other statins in that it reduces triglycerides. These effects may retard or reverse coronary artery disease.	GI upset, headache, myalgia, weakness, rhabdomyolysis, ocular and liver toxicity. Should have liver enzymes monitored.
Azithromycin	Zithromax	A macrolide antibiotic primarily effective against pyogenic streptococci, <i>S. pneumoniae</i> , <i>H. influenzae</i> , and <i>S. aureus</i> . Interferes with protein synthesis by binding to 50S ribosome of bacteria.	May cause headache, dizziness, hepatotoxic effects such as mild elevation of liver enzymes, and usual GI complaints.
Bevacizumab	Avastin	A recombinant humanized monoclonal IgG1 antibody that binds to and inhibits vascular endothelial growth factor. In combination with other chemotherapy used in the treatment of non-small cell lung cancer and metastatic colorectal cancer. As an injectable into the eye, used for the treatment of the wet variety of age-related macular degeneration.	Intravenous use may cause GI perforation. May also cause delayed wound healing, hemoptysis, hypertensive crisis, nervous system and visual disturbances, neutropenia, nephrotic syndrome, or congestive heart failure.
Bisacodyl	Apo-Bisacodyl Bisacolax Deficol Dulcolax Fleet Laxit Theralax	Used in the management of constipation. It increases intestinal fluid volume through increasing epithelial permeability.	May cause mild cramping or nausea. May have mild electrolyte disturbances.

Bismuth	Pepto-Bismol	Hydrolyzed to salicylate that inhibits inflammatory prostaglandins. Used as an antidiarrheal both prophylactic and treatment. Also for temporary relief of indigestion.	May cause temporary darkening of stool, a metallic taste in the mouth, a bluish gum line, and possible bleeding tendencies.
Botulinum Toxin Type A	Botox	In addition to standard cosmetic uses, injectable Botox is used for patients with cervical dystonia, primary axillary hyperhidrosis, strabismus, or blepharospasm.	May cause anaphylaxis, dysphagia, cardiovascular adverse events such as arrhythmias, MI (some fatal), skin rash, or pruritus.
Bretylium tosylate	Bretylol Bretylate	An adrenergic blocker having an effect on ventricular fibrillation and also a peripheral vascular effect that initially leads to postural hypotension. Used specifically for re-entry arrhythmias.	May cause dizziness, headache, syncope, bradycardia, nausea, vomiting, and postural hypotension.
Bromocriptine	Parlodel	Reduces prolactin levels through a series of events, activation of dopaminergic receptors in the hypothalamus, which then releases prolactin inhibiting factor. Used for amenorrhea/galactorrhea or female infertility, but also used as adjunctive therapy to levodopa for Parkinson's.	May cause headache, agitation, nervousness, mania, orthostatic hypotension, Raynaud's, depression, acute MI, or shock.
Bupivacaine	Marcaine Sensorcaine	An anesthetic that acts as a sodium channel blocker resulting in effects primarily in the medulla and higher centers. Effects patient's reaction to pain, temperature, proprioception, and muscle tone. Used as a sympathetic and peripheral nerve block agent.  Used for postoperative pain, trigeminal neuralgia, kidney (ureteral) stones, and accidental trauma pain.	May cause sedation, drowsiness, dizziness, headache, amnesia, insomnia, withdrawal symptoms, nausea, vomiting, or constipation.
Bupropion	Wellbutrin Zyban Wellbutrin SR	Inhibits the reuptake of dopamine, serotonin, and norepinephrine with the major effect on dopamine. Wellbutrin is used in the treatment of depression; Zyban has been approved as an aid for smoking cessation.	Possible problems with seizures, hepatotoxicity, nausea, vomiting, headache, agitation, tremor, and anticholinergic effects.
Captopril	Capoten	Angiotensin-converting enzyme (ACE) inhibitor used in the management of hypertension, congestive heart failure, diabetic nephropathy, left ventricular dysfunction, and post MI.	May cause hypersensitivity reactions, angioedema, persistent cough, orthostatic hypotension, altered taste sensation, or positive ANA titers.
Carbamazepine	Carbatrol Tegretol Tegretol-XR	Sodium potassium and calcium currents are reduced across neuronal membranes decreasing neuronal transmission. Has an antidiuretic effect. Used in the treatment of seizures and facial neuralgias, also sometimes schizophrenia.	CNS toxicity including sedation, dizziness, imbalance, and nausea/vomiting. Agranulocytosis or aplastic anemia.  Also possible cause of birth defects.
Carbidopa	Sinemet Lodosyn	Prevents peripheral metabolism of levodopa, in effect making more available to the brain. Also prevents the inhibitory effects of pyridoxine ( $B_6$ ) on levodopa. Used in the management of Parkinson's.	May cause visual disturbances, GI problems, confusion, involuntary movements, hallucinations, dyskinesia, hypotension, and depression with suicidal tendencies.

Celecoxib	Celebrex	NSAID: Cyclooxygenase (COX) 2 inhibitor (does not inhibit COX-1) used primarily for arthritis (osteo and rheumatoid, and rheumatoid variants), acute pain, and menstrual cramps. Reduces fever. Also approved to prevent and reduce the size of polyps in patients with genetic disease.	May cause back pain, peripheral edema, GI problems, dizziness, headache, pharyngitis, and rash.
Cephalexin	Keflex Keftabs	A semi-synthetic cephalosporin antibiotic (similar to penicillin; $\beta$ -lactam binds penicillin-binding proteins inhibiting crosslinking of bacterial cell wall).  Susceptible bacteria are Gram-positive except for enterococci and methicillin-resistant <i>Staph aureus</i> (MRSA), some Gram-negative; not anaerobes.	Hypersensitivity reactions (anaphylaxis, serum sickness), GI disturbances, rare neurologic problems (seizures), hematologic abnormalities (cytopenias), and nephrotoxicity and hepatic enzyme increases.
Chloramphenicol	Chloromycetin Chlorofair Fenicol Novochloroscap	A broad-spectrum antibiotic that is primarily bacteriostatic (bactericidal to <i>H. influenzae</i> ).  Interferes with protein synthesis by binding to 50S ribosome of bacteria. Used when infection is serious and unaffected by other antibiotics. Examples include <i>Salmonella</i> , <i>Rickettsia</i> , <i>Chlamydia</i> , <i>Mycoplasma</i> , <i>Streptococcus pneumoniae</i> , and <i>Neisseria</i> , among others.	May cause hypersensitivity reactions, bone marrow suppression, neurotoxicity, angioedema, pancytopenia, headache, confusion, stomatitis, glossitis, and the usual GI complaints.
Chlordiazepoxide	Libritabs Librium Epoxide Medilium Novo Epoxide Seren	A benzodiazepine that affects sleep by suppression of REM and increasing stage 4 NREM with an increase in total sleep time. Has a mild anxiolytic effect. Used primarily for anxiety and tension and assisting sleep in these individuals.	May cause drowsiness, lethargy, depression, orthostatic hypotension, dry mouth, vertigo, syncope, photosensitivity, or urinary frequency.
Chlorothiazide	Diuril Diachlor SK-Chlorothiazide	A diuretic that acts at the distal convoluted tubules, inhibiting absorption of sodium, potassium, and chloride. Increases excretion of sodium, bicarbonate, and potassium. Used in the management of CHF, hepatic cirrhosis, and fluid retention from corticosteroid and estrogen therapy.	May cause hypokalemia (should supplement with potassium) with associated problems such as muscle cramps and cardiac arrhythmias, anaphylaxis, agranulocytosis (rare), hyperglycemia, or hyperuricemia.
Chlorpromazine	Chlorpromazine Largactil Ormazine Promapar Promaz Somazina Thorazine Thor-Prom	A phenothiazine derivative that has alpha-adrenergic blocking effects, an antiemetic effect through depression on chemoreceptor trigger zone, and antipsychotic effects through actions (blocks post-synaptic dopamine receptors) in the hypothalamus and reticular formation. Used in the management of manic phase of manic depression, for psychotic disorders such as schizophrenia, and for severe nausea and vomiting. Also, sometimes used for behavioral disorders in attention deficit disorder in children.	A phenothiazine derivative that has alpha-adrenergic blocking effects, an antiemetic effect through depression on chemoreceptor trigger zone, and antipsychotic effects through actions (blocks post-synaptic dopamine receptors) in the hypothalamus and reticular formation. Used in the management of manic phase of manic depression, for psychotic disorders such as schizophrenia, and for severe nausea and vomiting. Also, sometimes used for behavioral disorders in attention deficit disorder in children.

Chlorzoxazone	Paraflex Parafon-Forte	Used as a muscle relaxant due to action of depression of nerve transmission. Has slight sedative action. Used in combination with other medications in the treatment of low back and neck pain associated with muscle spasm.	May cause drowsiness, dizziness, nausea, vomiting, constipation, rash, or jaundice.
Cholestyramine	Questran Lo-CHOLEST Prevalite	By combining with bile acids in exchange for chloride ions, an insoluble complex is formed that is excreted in the feces. Used in the management of hypercholesterolemia with reductions in both total cholesterol and LDL cholesterol.	May cause constipation; weight loss or gain; deficiencies in vitamins A, D, and K, and decreased erythrocyte folate levels; nausea; vomiting; and other GI disturbances.
Cimetidine	Novo-Cimetidine Peptol Tagamet	An H <sub>2</sub> (histamine) inhibitor blocking gastric acid secretion and raising pH of the stomach, decreasing pepsin secretion. Used as an OTC medication in the management of ulcers, GERD, and Zollinger-Ellison syndrome.	May cause the usual GI symptoms; increase pain in joints for patients with preexisting arthritis; rash; Stevens-Johnson syndrome; neutropenia; increase in uric acid, BUN, and creatinine; feminizing effects; and rarely, aplastic anemia or cardiac arrest.
Ciprofloxacin	Cipro	A synthetic quinolone that is bactericidal by inhibiting DNA-gyrase, an enzyme required for bacterial DNA replication. Often used for urinary tract infections caused by <i>E. coli</i> . Also for <i>C. jejuni</i> and shigella. Also used for bacterial conjunctivitis.	May cause nausea, vomiting, abdominal pain, cramps, and gas. May elevate liver enzymes and eosinophils. May cause tendon rupture, headache, vertigo, seizures, and rash. If used for conjunctivitis may cause precipitate buildup on cornea or crusting scales.
Cisplatin (cis-DDP or cis-PLATINUM II)	Carboplatin Oxaliplatin Platinol	A heavy metal medication (platinum) that cross-links in DNA or rapidly reproducing cells preventing DNA, RNA, and protein synthesis. Used as part of combination therapy (vinblastine and bleomycin) for patients with testicular cancer or ovarian cancer.	Anaphylactic reaction, nausea and vomiting, myelosuppression (25% to 30% of patients), hypomagnesemia, hepatic- and nephrotoxicity.
Citalopram	Celexa	A selective serotonin reuptake inhibitor (SSRI) (prevents reuptake at presynaptic neuron) making more serotonin available in the CNS. Used in the treatment of depression.	May cause fatigue, fever, arthralgia, myalgia, postural hypotension, anorexia, paresthesia, tremor, agitation, anxiety, migraine.
Clonazepam	Klonopin Rivotril	A benzodiazepine derivative that potentiates GABA and acts to inhibit seizure activity. Used alone or in combination with other medications for absence seizures, myoclonic seizures, Lennox-Gastaut, akinetic seizures, and restless leg syndrome.	May cause palpitations, dry mouth, anorexia, drowsiness, ataxia, sedation, respiratory distress, GI symptoms, diplopia, facial edema, hallucinations and other psychogenic problems.
Clonidine	Catapres	An $\alpha_2$ adrenergic agonist used as an anti-hypertensive. It decreases cardiac output, heart rate, and blood pressure.	Rash, drowsiness, headache, impaired ejaculation, dry mouth, and if stopped suddenly, rebound hypertension.

Clopidogrel bisulfate	Plavix	Inhibits platelet aggregation by preventing ADP from binding to its platelet receptor. Used in combination with aspirin/NSAIDs to prevent stroke, MI, and vascular disease in patients who have had recent types of health events.	Should not be given to patients at risk for bleeding due to the increased bleeding time. Usual possible complaints of dizziness, headache, abdominal pain, chest pain/dyspnea, thrombocytopenia purpura, epistaxis, etc.
Clotrimazole	Lotrimin Gyne-Lotrimin Canesten Mycelex	A broad-spectrum antifungal agent that alters the fungal wall permeability allowing loss of potassium and other important elements necessary for replication. Used both for dermal fungal infections and vaginal yeast infections.	May alter liver function tests and cause the usual GI disturbances, UTI symptoms, and pruritus.
Codeine	Methylmorphine Paveral	An opiate derivative from morphine. Antihistamine effect stronger than morphine. Effective for pain relief and cough suppression.	May cause constipation, dizziness, urticaria, anaphylactic reaction, or urinary retention.
Colchicine	Novocolchine	Used as an anti-inflammatory agent in the treatment of gout. Sometimes used for sarcoid arthritis and pseudogout.	May cause nausea, vomiting, diarrhea, abdominal pain, steatorrhea, and pancreatitis. Also, a syndrome of muscle weakness may occur with accompanying elevation of serum creatine kinase.
Colestipol	Colestid Lestid Cholestabyl	By combining with bile acids in exchange for chloride ions, an insoluble complex is formed that is excreted in the feces. Used in the management of hypercholesterolemia with reductions in both total cholesterol and LDL cholesterol.	May cause constipation; weight loss or gain; deficiencies in vitamins A, D, and K, and decreased erythrocyte folate levels; nausea; vomiting; and other GI disturbances.
Cromolyn	Intal Disodium cromoglycate Fivent NasalCrom Gastrocrom Rynacrom Vistacrom	A prophylactic medication used in the management of asthma; specifically extrinsic or allergic-related asthma. Stabilizes sensitized mast cells preventing the release of histamine and SRS-A (slow-reacting substance of anaphylaxis). May also be used ophthalmologically for allergic ocular disorders.	Side effects mainly due to method of administration. Includes nasal stinging and burning, irritation of throat, nausea, rarely angioedema and bronchospasm.
Cyclizine HCL	Marezine Marzine	A specific antihistamine that depresses the labyrinth and vestibular/cerebellar pathways. Used in the management of vertigo, motion sickness, and nausea.	May cause dizziness, dry mouth, blurred vision, or fatigue.
Cyclobenzaprine	Cycloflex Flexeril	Similar in structure to tricyclic antidepressants, these medications are used as muscle relaxants acting primarily on the CNS specifically at the brainstem. Increases circulating norepinephrine by blocking reuptake effects and anticholinergic effects. Also has sedative effects and anticholinergic effects.	Drowsiness, dizziness, dry mouth, edema of the tongue, palpitations, chest pain, pruritus, and similar side effects of tricyclic antidepressants. Contraindicated for patients with heart problems.
Cyclosporine	Gengraf Neoral Sandimmune Restasis	An immunosuppressant used for organ transplant, RA, severe psoriasis, Sjogren's, and ulcerative colitis. Inhibits helper T cells. Also used for keratoconjunctivitis sicca to produce tears.	May cause hypertension, vomiting, tremor, hypermagnesemia, hyperkalemia, hyperuricemia, hyperglycemia, decreased sodium bicarbonate, pancytopenia, and nephrotoxicity. May cause sinusitis, sore throat, or tinnitus.

d-Amphetamine	Dexedrine	Causes the release of norepinephrine, dopamine, and serotonin from storage vesicles resulting in CNS stimulation, causing an increase in performance, coordination, and energy. There is a decrease in appetite with an increase in blood pressure. Used for narcolepsy and attention deficit disorder.	May cause restlessness, insomnia, dizziness, anorexia, psychic disturbances, and arrhythmias.
Danazol	Cyclamen Danocrine	A synthetic androgen derivative from testosterone used in the management of endometriosis and fibrocystic breast disease. Causes a reduction in FSH and LH leading to anovulation and amenorrhea.	May cause hypersensitivity reaction, weight gain, hair loss, deepening of voice, breast reduction, hot flashes, hirsutism, hot flashes, irregular menstrual periods/amenorrhea, dizziness, tremor, and rarely hepatic damage. May increase LDL cholesterol.
Dexamethasone	Decadron Aeroseb-Dex Decaderm Decaspray Dexasone Dexone Hexadrol Mymethasone Deronil Dalalone Alba-Dex	A long-acting adrenocorticoid with anti-inflammatory and immunosuppressant effects used in the treatment of adrenal insufficiency, cerebral edema, Addisonian shock, and short-term therapy for rheumatic disorders. Used as a diagnostic test for Cushing's. May also be used for antiemetic with cancer therapy.	Dependent on type of administration of medication.  Can cause osteopenia, increased risk of compression fracture, posterior subcapsular cataract, hyperglycemia, impaired wound healing, ligament/tendon weakness, peptic ulcer, and skin changes.
Dextromethorphan	Balminil Benylin Delsym Mediquell Pertussin Romalar	Primarily a cough suppressant that acts on the cough center of the medulla.	May cause some drowsiness, constipation, or GI disturbances.
Diazepam	Apo-Diazepam Diastat Diazemuls Novo-Dipam Valium Vivol	Drug of choice for status epilepticus; also used as an anti-anxiety, sedative, or muscle relaxant. A long-acting benzodiazepine acting at the limbic, hypothalamic areas producing sedation.	May cause vertigo, dizziness, fatigue, laryngospasm, thorax or chest pain, incontinence or urinary retention, hiccups, hypotension, or cardiovascular collapse.
Digoxin	Lanoxin Lanoxicaps	A cardiac glycoside that increases the force and velocity of myocardial contraction. Also increases conduction velocity at AV node. Used in the management of congestive heart failure (CHF).	May cause fatigue, muscle weakness, facial neuralgia, visual disturbances, GI symptoms, paresthesias, hallucinations, arrhythmias, hypotension, and AV block.
Diphenoxylate and Atropine	Diphenatol Lofene Lomanate Lomotil Lomox Low-Quel Nor-Mil	A narcotic similar to meperidine is combined with atropine to possibly prevent deliberate overdose. Reduces GI motility by inhibiting receptors for peristalsis. Use in the management of diarrhea.	May cause hypersensitivity, swelling of gums, urinary retention, drowsiness, depression, lethargy, numbness, dry mouth, GI complaints, and palpitations or tachycardia.

Diphenhydramine HCL	Allerdryl Banophen Belix Ben-Allergin Benadryl Benahist Benylin Diahist Nordryl Nytol with DPM Valdrene Many others	An H1 receptor antagonist used in the treatment of many varied conditions. Has significant anticholinergic effects and seems to prevent reuptake of dopamine.  As a result, it is used for both allergic conditions, partial management of Parkinson's, as a non-narcotic cough suppressant, and as a sleep aid for those with intractable insomnia.	May cause dizziness, drowsiness, tachycardia, thickening of bronchial mucus with associated wheezing, anaphylaxis, dry mouth, and hypersensitivity.
Docusate	PMS Docusate Surfak Dialose Colace Regulax Therevac	Used as a stool softener. Through detergent action lowers surface tension allowing water and fats to penetrate stool.	May cause mild abdominal cramps, diarrhea, bitter taste, and throat irritation.
Donepezil HCL	Aricept	A cholinesterase inhibitor used in the management of mild to moderate Alzheimer's disease. Works in the cerebral cortex blocking degradation of acetylcholine.	May cause headache, fatigue, insomnia, nausea, diarrhea, vomiting, cramps, anorexia, or muscle cramps.
Doxepin	Adapin Sinequan Triadapin Zonalon	A tricyclic antidepressant that acts as a serotonin reuptake inhibitor and, to a lesser degree, norepinephrine. Used in the management of depression and anxiety.	May cause drowsiness, orthostatic hypotension, dry mouth, metallic taste, photophobia, urinary retention, or weight gain.
Doxycycline	Vibramycin	A synthetic broad-spectrum antibiotic that is bacteriostatic (inhibits protein synthesis by binding to 30s subunit blocking amino acid linked tRNA from binding to the A site of the ribosome). Susceptible bacteria include <i>M. pneumoniae</i> , <i>C. psittaci</i> , <i>C. trachomatis</i> , and <i>N. gonorrhea</i> . Used for respiratory infections, nongonococcal urethritis (ureaplasma), Rocky Mountain spotted fever, typhus, chancroid, anthrax, syphilis, cholera, brucellosis, and acne.	May cause GI distress, reversible nephro- and hepatotoxicity, photosensitivity, and dental staining (not used in prepubertal children).
Drospirenone and Estradiol	Yaz	A combination contraceptive pill that, in addition to preventing pregnancy, is used for the emotional symptoms manifested as premenstrual dysphoric disorder in a 24/4-day dosing.	May cause headache, nausea, breast pain, intermenstrual bleeding, decreased libido, upper respiratory infection, emotional lability, back pain, or urinary tract infection.
Duloxetine	Cymbalta	Used in the management of depression, it acts as a selective serotonin and norepinephrine reuptake inhibitor (SSNRI). Caution with narrow-angle glaucoma or patients taking MAOIs.	May cause fatigue, hot flashes, rashes, nausea, dry mouth, constipation, decreased appetite, decreased libido, insomnia, or tremors.

Dutasteride	Avodart	Blocks the conversion of testosterone to 5-alpha DHT (responsible for prostate hypertrophy). Inhibits both type 1 and 2 5-alpha reductase inhibitors.	May cause gynecomastia, ejaculation dysfunction, impotence, or decreased libido.
Edrophonium	Enlon Reversol Tensilon	An indirect cholinesterase inhibitor sometimes used as short-term management of myasthenia gravis and to reverse the effects of curariform muscle relaxants.	May cause muscle weakness, hypotension, convulsions, bronchospasm, or respiratory distress.
Enalapril	Vasotec	An ACE inhibitor. Blocks the conversion of rennin to angiotensin II thereby decreasing the release of aldosterone. This blocks the potent vasoconstriction effects of these substances resulting in a decrease in blood pressure without a compensation of increased heart rate or cardiac output.	May cause headache, dizziness, fatigue, postural hypotension, chronic cough, hoarseness, and rash. May increase potassium levels, BUN, or creatinine.
Epinephrine	Bronkaid Mist Epi E-Z Pen Epinephrine Primatene Mist Bromitin Mist Asthmahaler AsthmaNefrin Epitrate	Both synthetic and prepared from animal adrenal glands. Used in the treatment of asthma. Effects are to cause bronchial arterial constriction, bronchodilation (smooth muscle relaxation), and inhibit histamine release. Also used for anaphylactic shock, restoring sinus rhythm, open-angle glaucoma, and to reduce uterine contractions.	Causes sympathetic effects of nervousness, tremor, palpitations, tachycardia, anorexia, urinary retention, etc. Also may cause pulmonary edema, ventricular fibrillation, or MI.
Epoetin Alfa (Human Recombinant Erythropoietin)	Epogen Eprex Procrit	A glycoprotein that stimulates RBC production used to elevate the hematocrit for patients with anemia from secondary causes such as chronic kidney failure, AIDS, or malignancies.	May cause headache, nausea, diarrhea, iron deficiency, thrombocytosis, clotting of AV fistula, seizures, sweating, arthralgias, and bone pain.
Erythromycin	Akne-Mycin Ery-Tab Apo-Erythro Base A/T/S/E-Mycin Eryderm Erythromid Erythrosine Novo-Rythro Robimycin Staticin T-Stat	A macrolide antibiotic effective primarily against Gram-positive. Effective against <i>Chlamydia trachomatis</i> . Also used for pneumococcal and mycoplasma pneumonia, <i>N. gonorrhea</i> , and <i>H. influenzae</i> .	Usual GI complaints, plus superinfection with yeast, nonsusceptible bacteria, and fungi. Also causes ototoxicity (reversible vertigo, hearing loss, and tinnitus), hypersensitivity reactions, and cholestatic hepatitis syndrome.
Esomeprazole	Nexium	Similar to omeprazole (isomer of Prilosec). A proton pump inhibitor, it inhibits H+K+-ATPase (acid production from parietal cells of stomach). Used for erosive esophagitis, GERD, and in concert with antibiotics for <i>H. pylori</i> infection with duodenal ulcer management.	May cause headache, nausea, vomiting, constipation, abdominal pain, and dry mouth.

Estrogen (conjugated) and Esterified	C.E.S. Premarin Cenestins Progens Estratab Menest Menrium Neo-Estrone Kestrone	A short-acting estrogen used in the treatment of atrophic vaginitis, postmenopausal symptoms, postmenopausal osteoporosis, abnormal bleeding, and palliative treatment of both breast and prostate carcinoma.	May cause libido changes, depression, nausea, mastodynia, hypertension, and thromboembolic disorders.
Estrogen-Progestin combinations	<i>Monophasic</i> Alesse Demulen Desogen Levlite Levora Loestrin Necon Nordene Ogestrel Others <i>Biphasic</i> Jenest Kariva Mircette Others <i>Triphasic</i> Ortho-Cept Triphasil Trivora Others	In addition to oral medications listed to the left, there are transdermal (ortho-Evra), intravaginal (Nuva-Ring), and postcoital (Plan B, Preven) contraceptives. Monophasic has the estrogen, and progestin amounts remain the same. Biphasic has the estrogen remain the same with progestin initially less in first half of cycle, and increased in second. Triphasic has the progestin vary and the estrogen remain the same or vary. Prevents ovulation and creates a hostile environment for sperm.	May cause early or midcycle breakthrough bleeding, nausea, gallstones, thrombotic disorders such as thrombophlebitis, decreased glucose tolerance, pyridoxine deficiency, vaginal candidiasis, weight gain, paresthesias, hypertension, and chloasma.
Eszopiclone	Lunesta	Used for the treatment of insomnia. It is a nonbenzodiazepine hypnotic; however, its main effects seem to relate more to GABA receptor complexes which may be coupled to benzodiazepine receptors. It shortens sleep latency and improves sleep maintenance.	May cause anxiety, confusion, depression, headache, tachycardia, pericardial infarction, left ventricular systolic dysfunction, dysmenorrhea, dry mouth, nausea, rash, or pruritus.
Etanercept	Enbrel	A recombinant DNA substance that binds to tissue necrosis factor (TNF)-alpha receptors. TNF is a cytokine that induces an inflammatory action through interleukins. Effective in the management of Crohn's disease and inflammatory arthritic disorders such as RA and psoriatic arthritis.	May cause the usual GI disturbances, headache, dizziness, fatigue, loss of hair, pruritus, and rarely may cause MI, serious infections, or pancytopenia.

Ethosuximide	Zarontin	A succinimide anticonvulsant used in the treatment of seizures. Specifically, absence seizure, myoclonic and akinetic epilepsy. Acts to depress the motor cortex and elevate CNS threshold for stimulation.	May cause drowsiness, hiccups, ataxia, dizziness, headaches, lethargy, sleep disturbances, myopia, nausea, vomiting, epigastric discomfort, eosinophilia, thrombocytopenia, positive direct Comb's test, hirsutism, pruritic skin rash, gingival hyperplasia, and weight loss.
Etidronate	Didronel	Bisphosphonate; antiresorptive used in the treatment of osteoporosis and Paget's disease. Decreases vascularity of bone with Paget's. These medications inhibit bone resorption but eventually reduce bone formation due to a decrease in overall bone turnover. A standard intermittent treatment program with parathyroid hormone is intended to increase bone formation; however, it also increases bone resorption. The net effect though is bone formation. It is clear that prolonged exposure to parathyroid hormone, such as in hyperparathyroidism, causes osteoporosis.	May cause hypocalcemia, hyperphosphatemia, or elevated serum phosphatase. GI effects include esophageal irritation/ulceration with abdominal pain, nausea, vomiting, diarrhea/constipation, arthralgias, myalgias, headache, and rash. Dairy products decrease absorption.
Ezetimibe and Simvastatin	Vytorin Zocor	Used for patients with primary (heterozygous familial and nonfamilial) hypercholesterolemia or mixed hyperlipidemia.  Ezetimibe is a selective inhibitor of intestinal cholesterol and phytosterol absorption combined with simvastatin, an HMG-CoA reductase inhibitor.	May cause urticaria, arthralgia, myalgias, angioedema, anaphylaxis, elevated liver transaminases, hepatitis, pancreatitis, cholelithiasis, thrombocytopenia, GI signs or symptoms such as nausea, abdominal pain, constipation, diarrhea, etc. Also a rare cause of rhabdomyolysis or myopathy.
Ezetimibe	Zetia Ezetrol	Used alone or in combination with statins (HMG-CoA reductase inhibitors) for the treatment of primary hypercholesterolemia.  At the lining of the small intestine, it inhibits absorption of cholesterol but does not inhibit cholesterol synthesis in the liver.	May cause fatigue, arthralgia, myalgia, dizziness, headache, abdominal pain, angioedema, or rhabdomyolysis. (Monitor liver enzymes when used with a statin.)
Famotidine	Pepcid	An H <sub>2</sub> (histamine) inhibitor blocking gastric acid secretion, raises pH of the stomach, decreasing pepsin secretion. Used as an OTC medication in the management of ulcers, GERD, and Zollinger-Ellison syndrome.	May cause dizziness, headache, confusion, diarrhea, constipation, thrombocytopenia, rash, and may increase uric acid, BUN, and creatinine.
Fexofenadine	Allegra	An antihistamine (H <sub>1</sub> receptor antagonist used for the management of seasonal allergic rhinitis and chronic urticaria).	May cause headache, nausea, fatigue, dyspepsia, or throat irritation.
Finasteride	Propecia Proscar	A 5-reductase inhibitor of the enzyme necessary for conversion of testosterone into DHT. Used in the management of benign prostatic hypertrophy and male pattern baldness.	May cause decreased libido, impotence, or decreased volume of ejaculation.

Fluoxetine	Prozac	An SSRI making more serotonin available in the CNS. Used in the treatment of depression and obsessive-compulsive disorders.	About 15% of patients discontinue use due to nausea, anxiety, diarrhea, insomnia, or headache.
Flurazepam HCL	Apo-flurazepam Dalmane Durapam Novo-flupam	A benzodiazepine used for the management of sleep problems. Reduces stage 4 NREM sleep while increasing total sleep time. Sedative effects in CNS at limbic and subcortical levels.	May cause residual sedation effects, but also irritability, nervousness, nightmares, hyperactivity, euphoria or depression, and coma with overdose.
Fluticasone	Flonase Flovent Cutivate	A synthetic corticosteroid used for the management of nasal symptoms for allergic and nonallergic rhinitis.	May cause nosebleeds, nasal sores, nasal or oral fungal infections, glaucoma, or cataracts.
Fluticasone Propionate with Salmeterol	Advair	An inhaled medication for the treatment of asthma and chronic bronchitis. A combination of a long-acting beta-2 agonist (salmeterol) and oral corticosteroid. Not used for acute asthma attacks.	May increase the risk of asthma-related deaths. May cause dizziness, headache, palpitations, sinus tachycardia, respiratory arrest, or long-term steroid use effects.
Furosemide	Lasix Fumide Luramide Furomide	A sulfonamide "loop" diuretic that inhibits reabsorption of sodium and chloride at the loop of Henle and proximal and distal renal tubules. Used in the management of hypertension, fluid reduction for CHF, hepatic cirrhosis, and renal dysfunction.	May cause hypokalemia (supplement with potassium), GI complaints, circulatory collapse, or aplastic types of anemia.
Gabapentin	Neurontin	Related to gamma aminobutyric acid (GABA). Used as an adjunctive treatment of seizures; also used for herpes zoster.	May cause lethargy, ataxia, dizziness, or other CNS effects.
Gemfibrozil	Lopid	Through blocking lipolysis of stored triglycerides and inhibiting uptake by the liver of fatty acids, there is a reduction in VLDL, LDL, total cholesterol, and triglyceride synthesis and an increase in VDL. Used in the management of patients with high triglyceride levels including familial hypercholesterolemia	May cause GI upset, headache, dizziness, musculoskeletal pain, rash, or hypokalemia.
Gentamycin	Garamycin Genoptic	A broad-spectrum, usually bactericidal, antibiotic effective against primarily Gram-negative and some Gram-positive organisms. Some include <i>Klebsiella</i> , <i>Proteus</i> , <i>E. coli</i> , <i>Enterobacter</i> , <i>Pseudomonas</i> , among others. Usually reserved for serious infections when other less toxic antibiotics are ineffective.	Is ototoxic, hepatotoxic, and nephrotoxic with associated indications on lab testing. May cause a variety of hypersensitivity reactions, neuromuscular blockade, hypokalemia and hypomagnesaemia with muscle cramps/weakness.
Glipizide	Glucotrol Glucotrol XL	A sulfonylurea hypoglycemic agent used in the initial management of type 2 diabetes after dietary management without medication has failed. Has the effects of sensitizing functioning pancreatic beta cells to release insulin, and indirectly increasing the number and sensitivity of insulin receptors.	May cause hypoglycemia, heartburn, pruritus, nausea/ vomiting, hepatic porphyria, hypersensitivity, and visual disturbances.
Glyburide	DiaBeta Glynase Micronase Euglucon	A sulfonylurea hypoglycemic agent used in the initial management of type 2 diabetes after dietary management without medication has failed. Has an effect of sensitizing functioning pancreatic beta cells to release insulin.	May cause hypoglycemia, heartburn, pruritus, nausea, or vomiting.

Gold Sodium Thiomalate	Myochrysine	An injectable water-soluble gold compound used in the treatment of rheumatoid arthritis. Appears to have immunosuppressant and anti-inflammatory properties possibly through inhibition of inflammatory prostaglandins.	May cause photosensitivity, dizziness, syncope, proteinuria, stomatitis, GI symptoms, grey to blue discoloration of skin, hypersensitivity, and erythema dermatitis.
Haloperidol	Haldol Peridol	A butyrophenone derivative similar to phenothiazines but with more extrapyramidal effects and less hypotensive and sedative effects. Used for psychotic disorders, tics, Tourette's syndrome, management of agitated states with Alzheimer's, and severe behavioral problems with children.	May cause extrapyramidal effects such as Parkinsonian symptoms, tardive dyskinesias, or neuroleptic malignant syndrome, agranulocytosis, laryngospasm, hyponatremia, hyperglycemia, and EEG changes.
Heparin Dalteparin	Hepalean Heparin Hep-Lock Lipo-Hepin Liquaemin	Prepared from bovine lung tissue and porcine intestinal mucosa, this potent mucopolysaccharide anticoagulant enhances the inhibitory actions of antithrombin III. Used for the treatment of venous thrombosis and pulmonary embolism, prevention of thrombi/emboli following surgeries, and also used for the treatment of disseminated intravascular coagulation (DIC).	May cause spontaneous bleeding, transient thrombocytopenia, bronchospasm, anaphylaxis, osteoporosis, and hypoadosteronism.
Hepatitis B Immune Globulin	H-BIG Hep-B-Gammagee HyperHEP	Sterile human-based solution of IgG used to provide passive immunity for hepatitis B or post-exposure prophylaxis.	May cause a hypersensitivity reaction, muscle stiffness and aching, fever, dizziness, malaise, rash, or leg cramps.
Hydrocodone/ Acetaminophen	Vicodin Vicodin ES Anexsia Lorcet Lorcet Plus Norco	Narcotic pain reliever and cough suppressant similar to codeine (CNS depression). The acetaminophen component is a non-narcotic pain reliever and fever reducer.	May cause dry mouth, nausea, vomiting, lightheadedness, dizziness, euphoria, dysphoria, some respiratory depression, and rash.
Hydromorphone Hydrochloride	Dilaudid Dilaudid-HP	Similar to morphine but with a much stronger analgesic effect. Used for mild to moderate pain and cough suppression.	May cause dry mouth, nausea, vomiting, lightheadedness, dizziness, euphoria, dysphoria, some respiratory depression, and rash.
Hydroxyzine	Vistaril Atarax Vistacon Vistajet	An antihistamine with anticholinergic and sedative properties. Tranquilizing effect mainly due to depression of hypothalamus and brainstem reticular formation. Primarily used to treat allergic reaction and to relieve nasal congestion and other symptoms.	May cause drowsiness, dizziness, headache, urticaria, dyspnea, wheezing, rash, or hypotension.
Ibandronate	Boniva	A nitrogen-containing bisphosphonate used in the management of osteoporosis. Bisphosphonates inhibit osteoclast-mediated bone resorption. Advantage over other similar medications is the once-per-month dosage. Requires adequate intake of calcium and vitamin D.	May cause upper GI problems such as esophagitis, dyspepsia, or esophageal or gastric ulcers.
Imipramine	Impril Tofranil	Used for endogenous and sometimes reactive depression. Works by blocking reuptake of norepinephrine and serotonin by presynaptic neurons (classified as a tricyclic antidepressant). Reduces REM sleep and increases stage 4 NREM sleep.	May cause upper GI problems such as esophagitis, dyspepsia, or esophageal or gastric ulcers.

Immune Globulin	Baygam Gamimune Gammagard Gammar P Iveegam Sandoglobulin Venoglobulin	A sterile concentrated human globulin solution used either as prophylaxis or to modify the severity of a number of diseases, including rubella, rubeola, varicella zoster, type A hepatitis, idiopathic thrombocytopenia purpura, among others.	Side effects related to site of injection. Also may cause hypersensitivity reactions, headache, GI symptoms, chest tightness, or wheezing.
Indomethacin	Indameth Indocid Indocin Indocin SR	NSAID use to reduce pain and fever. May reduce activity of PMNs, development of cellular exudates, and vascular permeability when tissue is damaged.	Hypersensitivity possible with rash, dyspnea, asthma syndrome if patient is an aspirin-sensitive asthmatic, edema, or hypotension. Also, concern of GI bleeding and rarely, an aplastic anemia effect or renal function impairment.
Infliximab	Remicade	An IgG1-K monoclonal antibody that binds to TNF-alpha. TNF is a cytokine that induces an inflammatory action through interleukins. Effective in the management of Crohn's disease and inflammatory arthritic disorders such as RA and psoriatic arthritis.	May cause the usual GI disturbances, headache, dizziness, fatigue, etc., lupus-like syndrome, loss of hair, pruritus, and increased liver enzymes.
Insulin (many types)	NovoLog (RCA) Lantus (RCA) Humulin Novolin Iletin II Humalog (RCA)	These are recombinant human analogs (RCA) extracted from pork used in the treatment of diabetes. Effects are to lower blood sugar levels by increasing peripheral uptake in muscle and fat, and promoting conversion of glucose to glycogen (and inhibiting reverse).	Side effects related to hypoglycemia, profuse sweating, hunger, tremors, palpitations. Also, coma is possible.
Interferon Alfa n-1 Alfacon-1 Alfa 2a Alfa 2b	Wellferon Infergen	A variety of medications used in the management of hepatitis C. Actions include suppression of cell proliferation and augmentation of lymphocyte natural killer cells.	Common to have side effects including headache, fever, chills, anxiety, nervousness, GI disturbances, alopecia, abnormal mood, emotional lability, and confusion. Possible lab effects on thrombocytes and granulocytes.
Interferon Beta 1a and 1b	Avonex Rebif Betaseron	A recombinant DNA medication with effects that are antiviral, antitumor, antiproliferative, and immunomodulatory. Used in the management of relapsing multiple sclerosis.	Common to have side effects including headache, fever, chills, anxiety, nervousness, GI disturbances, alopecia, abnormal mood, emotional lability, and confusion. Possible lab effects on thrombocytes and granulocytes.
Isoniazid	INH Isotamine Laniazid Nydrazid Teebaconin	An anti-TB medication that interferes with the synthesis of bacterial proteins, lipids, and nucleic acids. Used also for high-risk individuals as a preventive. Additional use for tremors with multiple sclerosis.	May cause paresthesia, peripheral neuropathies, tinnitus, dizziness, hallucinations, increased liver enzymes, decrease in B vitamin absorption, RA and SLE-like syndromes, or possible agranulocytosis and aplastic anemia (rare).

Isoproterenol	Isuprel Dispose-a-Med	Used primarily as a bronchodilator with asthma. A $\beta_1$ adrenergic agonist that causes increased expectoration, increased ciliary motility, and bronchodilation with increase in cardiac output and strength. Also used for cardiac stimulation with cardiac arrest, and various arrhythmias.	May cause anorexia, tumors, palpitations, tachycardia, flushing, or ventricular arrhythmias.
Kaolin-Pectin	Kaopectate Kaolin w/Pectin	Kaolin as an aluminum silicate may have adsorbent and demulcent actions. Pectin may help to consolidate stool. Used for mild to moderate diarrhea.	May cause mild constipation.
Ketoconazole	Nizoral	Cell membrane function is disrupted by inhibiting sterol (ergosterol) synthesis in fungi. Used for serious systemic fungal infections such as Candida, coccidiomycosis, histoplasmosis, blastomycosis, and similar infections. Also used for superficial treatment of mycosis such as the "tineas."	May cause usual GI disturbances, anaphylaxis, gynecomastia, decreased libido, hair loss, acute hypoadrenalism, rarely hepatic necrosis, and may change multiple lab values such as decreases in cholesterol and triglycerides, and low serum testosterone.
Labetalol	Trandate Normodyne	An antihypertensive that acts as an alpha-adrenergic blocker and nonselective beta blocker. Results are decreased peripheral resistance, decreased conduction at sinus node, AV node, and ventricular muscle. Often used with thiazide diuretics.	May cause postural hypotension, bronchospasm, dizziness, fatigue, malaise, tremors, and GI disturbance. May cause positive on ANA testing and SLE-like syndrome.
Lamotrigine	Lamictal	May have an affect on glutamate/aspartate release and help in stabilizing neurons. Used in the treatment of seizures; in particular, partial seizures.	May cause dizziness, headache, nausea, diplopia, blurred vision, ataxia, lethargy.
Levodopa (L-Dopa)	Dopar Larodopa	L-dopa is the metabolic precursor to dopamine. Its advantage is that it crosses the blood-brain barrier. Helps restore levels of dopamine in extrapyramidal areas of the brain. Used in the treatment of Parkinson's.	May cause choreiform and other involuntary movements, increase tremor and cause bradykinetic episodes (on-and-off phenomenon). Many other side effects occur including hallucinations, paranoid delusions, severe depression, and suicide tendencies. There are a host of other system effects that include possible dark sweat or urine and all the other common side effects of many medications.
Levothyroxine Sodium	Eltroxin Synthroid Levoxyl Levothroid Unithroid	A synthetic version of thyroxine (T4) used to treat hypothyroidism and to suppress thyroid hormone release with cancerous thyroid nodules.	May cause similar effects of hyperthyroidism related to increased metabolism including palpitations, hypertension, agitation, insomnia, heat intolerance, weight loss, leg cramps, arrhythmias, headache, and menstrual irregularities such as anovulatory bleeding.

Lidocaine	Anestacon Dilocaine L-caine Lidopen Octocaine Nervocaine Xylocaine Xylocard	Acts as both a local anesthetic and also antiarrhythmic blocking automaticity of His-Purkinje system. Used both for rapid control of ventricular arrhythmias and also as an injectable local anesthetic.	May cause difficulty breathing, anaphylaxis, respiratory depression, numbness, paresthesias, confusion, disorientation, or cardiovascular collapse in rare cases.
Liothyronine (T3)	Cytomel Triostat	Replaces T3 in hypothyroid patients. Used in the 3 suppression test. Main use is for those patients who do not respond to levothyroxine (synthroid).	Overdose effects are signs/symptoms of hyperthyroidism.
Lisinopril	Zestril	An ACE inhibitor. Blocks the conversion of rennin to angiotensin II thereby decreasing the release of aldosterone. This blocks the potent vasoconstriction effects of these substances resulting in a decrease in blood pressure without a compensation of increased heart rate or cardiac output	May cause headache, dizziness, fatigue, postural hypotension, chronic cough, hoarseness, and rash. May increase potassium levels, BUN, or creatinine.
Lithium	Cibalith-S Lithonate Lithane Lithobid Eskalith	Competes with other ions and as a result accelerates catecholamine breakdown, inhibits the release of neurotransmitters, and decreases the sensitivity of post-synaptic receptors. Used in the treatment of acute mania and manic phase of mixed bipolar disorder.	May cause headache, lethargy, fatigue, recent memory loss, nausea, vomiting, abdominal pain, nephrogenic diabetes insipidus, fine hand tremors, muscle weakness, and reversible leukocytosis. Rare peripheral vascular collapse.
Loperamide	Imodium Maalox antidiarrheal Pepto Diarrhea Control	Synthetic piperidine derivative that inhibits GI peristaltic activity. OTC medication used in the treatment of acute diarrhea or chronic diarrhea associated with inflammatory bowel disease.	Toxic megacolon with overuse, may cause drowsiness, CNS depression, dizziness, bloating, constipation, or abdominal pain.
Loratadine	Claritin Claritin RediTab	An antihistamine used in the treatment of allergies, hives (urticaria), and other allergic inflammatory conditions. A long-acting selective peripheral H1 receptor blocker (prevents release of histamine).	May cause dry mouth, dizziness, fatigue, changes in salivation, flushing, hypotension, palpitations, tachycardia, arthralgias, myalgias, blurred vision, rash, and photosensitivity.
Lorazepam	Ativan	A benzodiazepine used for anti-anxiety. Acts to enhance the effects of GABA particularly in the thalamus, hypothalamus, and limbic areas. It is the most potent of the benzodiazepines, but has fewer interactions and is less toxic than most other benzodiazepines. Also used for insomnia and panic attacks.	Many side effects disappear with continued use including anterograde amnesia, weakness, dizziness, sedation, restlessness, hallucinations, hyper- or hypotension, blurred vision, or depressed hearing.
Lovastatin	Mevacor	A statin: An HMG CoA reductase inhibitor. This blocks the enzyme that controls production of cholesterol in the liver. Therefore used in the treatment of hyperlipidemia. Lowers both total cholesterol and LDL cholesterol while increasing HDL cholesterol.	May cause GI upset, headache, myalgia, weakness, rhabdomyolysis, ocular and liver toxicity. Should have liver enzymes monitored.

Mannitol	Rectisol Osmitol	An osmotic diuretic causing increased excretion of sodium, potassium, and chloride. Used in the management of oliguric phase of acute renal failure, for ascites, increased intraocular or intracranial pressure, to help in the excretion of toxic substances, and pulmonary edema.	May cause fluid and electrolyte imbalance, in particular hyponatremia, headache, dizziness, hypotension, convulsions, and transient muscle rigidity.
Memantine	Axura Namenda	An uncompetitive NMDA-receptor antagonist (anti-glutamatergic), memantine has been shown to be effective in reducing clinical deterioration in moderate to severe Alzheimer's.	May cause emotional agitation, confusion, stomach upset, and nervousness.
Meperidine	Demerol Pethadol Pethidine HCL	An opiate receptor agonist having the effects of analgesia, respiratory depression, and sedation.	May cause dizziness, sedation, nausea, constipation, allergic reaction, respiratory depression, convulsions, or cardiovascular collapse.
Metformin	Glucophage Glucophage XR	Biguanide hypoglycemic agent (not a sulfonylurease). Does not increase insulin production, but helps bind insulin to insulin receptors and potentiate insulin activity. Used in the treatment of type 2 diabetes. Sometimes used in combination with a sulfonylurease.	May cause abdominal complaints of pain, nausea, or vomiting. May interfere with absorption of folic acid and B <sub>12</sub> or amino acids. Patient may complain of a bitter or metallic taste. Caution for lactic acidosis.
Methimazole	Tapazole	Blocks transformation of inorganic iodine to organic iodine. Blocks conversion of T <sub>4</sub> and T <sub>3</sub> . Often used to produce a euthyroid state prior to radiation or surgery. Long-term use may produce euthyroid state in half of patients.	May cause headache, vertigo, nausea, vomiting, hepatitis, myelosuppression, leukopenia, and rarely agranulocytosis. May elevate prothrombin time and liver enzymes.
Methotrexate	Rheumatrex Trexall	An antimetabolite that blocks the metabolism of fast-growing cells. Blocks folate reduction through inhibitory effect on dihydrofolate reductase. Used in the treatment of cancer and rheumatoid-like conditions such as psoriatic arthritis and RA. Cancers include acute lymphocytic leukemia; osteogenic sarcoma, Burkitt's lymphoma; non-Hodgkin's lymphoma; cancer of the brain, head, neck; and small-cell lung choriocarcinoma. Also used to induce miscarriage (e.g., ectopic pregnancy).	May cause bone marrow suppression, GI ulcers, nephrotoxicity, hepatotoxicity, nausea, diarrhea, or pulmonary infiltrates.
Methyldopa	Aldomet	An $\alpha_2$ adrenergic agonist used as an antihypertensive. It decreases cardiac output, heart rate, and blood pressure.	May cause dry mouth, possible postural hypotension, and sedation. May experience nightmares or psychic disturbances.
Methylphenidate	Ritalin Concerta	Causes the release of norepinephrine, dopamine, and serotonin from storage vesicles, resulting in CNS stimulation. This causes an increase in performance, coordination, and energy. There is a decrease in appetite with an increase in blood pressure. Used for narcolepsy and attention deficit disorder.	May cause restlessness, insomnia, dizziness, anorexia, psychic disturbances, and arrhythmias.

Methysergide	Sansert	An ergot derivative, methysergide competes with serotonin receptors, decreasing the pro-inflammatory and vasoconstrictive effects of peripheral serotonin. Used in the treatment of migraine headaches.	May cause postural hypotension, nausea, vomiting, abdominal pain, heartburn, diarrhea, and the common side effects of most medications.
Metoprolol	Lopressor Toprol XL	Beta-blocker: A $\beta$ adrenergic antagonist blocking primarily $\beta_1$ receptors (less bronchoconstriction effect than $\beta_2$ blockers), decreases heart rate and rennin release. Used in the treatment of hypertension.	CNS depressive effects with concerns for those with diabetes, heart block and heart failure, asthma, and emphysema.
Metaproterenol	Alupent	$\beta_2$ agonist used in the treatment of asthma. Causes bronchodilation without secondary vascular and cardiac effects.	May cause anorexia, tachycardia, nausea, arrhythmias, tremor, hypertension, muscle cramps, convulsions, weakness, hallucinations, or postural hypotension.
Metronidazole	Flagyl Metizol Metro-Gel Protostat Noritate	A synthetic agent that is effective against a wide variety of organisms including <i>Trichomonas vaginalis</i> , <i>Entamoeba histolytica</i> , and Giardia. Antibacterial anaerobic bacteria, and some Gram-negatives. Used with other antibiotics (triple antibiotic regimen) for duodenal ulcers. Topical may be used for rosacea.	May cause a Candida infection (overgrowth), hypersensitivity, nausea and other GI symptoms, polyuria, dysuria, vertigo, headache, and a metallic or bitter taste. May decrease AST levels (interferes with chemical reaction).
Miconazole	Monistat (Derm, 3, 7) Femizole M-Zole Micatin Tetterine Fungoid Lotrimin Desenex	A broad-spectrum antifungal that inhibits absorption of essential material for cell reproduction, growth, and cell wall integrity. Used primarily for Candida, common dermatophytes, and tinea versicolor. Used for a variety of body sites: vaginal Candida infection, athlete's foot (tinea pedis), and similar "tinea" caused by dermatophytes.	May cause a Candida infection (overgrowth), hypersensitivity, nausea and other GI symptoms, polyuria, dysuria, vertigo, headache, and a metallic or bitter taste. May decrease AST levels (interferes with chemical reaction).
Milrinone	Primacor	A new type of drug that is an isotropic/vasodilator inhibitory against cyclic-AMP phosphodiesterase. Increases cardiac output while decreasing pulmonary wedge pressure. Used in the short-term management of CHF.	May cause arrhythmias such as PVCs, supraventricular and ventricular tachycardias, or hypotension.
Montelukast	Singulair	Used as prophylactic treatment of chronic asthma, exercise-induced bronchospasm, and allergic rhinitis. A leukotriene receptor antagonist.	May cause sinusitis, nausea, diarrhea, dyspepsia, otitis, viral infection, or laryngitis.
Nadolol	Corgard	Beta-blocker: Blocks both $\beta_1$ and $\beta_2$ adrenergic receptors, decreases heart rate and rennin release. Used in the treatment of hypertension. Also has bronchoconstriction effect due to $\beta_2$ blockade.	May cause CNS depressive effects with concerns for those with diabetes, heart block and heart failure, asthma, and emphysema. Transient hypertension due to blockage of $\beta_2$ receptors (which normally dilate large arteries).
Naproxen Naproxen sodium	Aleve Apo-naproxen Anaprox Naprosyn Naprolen	NSAID. Similar to ibuprofen, ketoprofen, etc. Inhibits inflammatory prostaglandin synthesis. Actions include analgesic, anti-inflammatory, and antipyretic. Inhibits platelet aggregation and prolongs bleeding time but does not affect clotting.	May cause headache, drowsiness, dizziness, anorexia, heartburn, nausea, GI bleeding, and rarely agranulocytosis.

Natalizumab	Antegren	A humanized monoclonal antibody used to treat multiple sclerosis and Crohn's disease. A receptor blocker that binds to alpha-4-beta-1 and alpha-4-beta-7 integrins, natalizumab prevents lymphocytes and eosinophils from moving from the bloodstream to outer tissue sites involved in inflammation. For multiple sclerosis it is used in combination with interferon beta 1-a.	Most common side effects are abdominal pain and headache.
Neostigmine Bromide and Methyl sulfate	Prostigmin	Prolongs effects of acetylcholine at cholinergic synapses (reversible cholinesterase inhibition) and has a direct stimulant action on voluntary muscle fibers and possibly on autonomic ganglia and CNS. Used in the treatment of myasthenia gravis.	Generalized cholinergic responses including constriction of bronchi and ureters with stimulation of salivary and sweat glands. May cause cramps, muscle facilitations, nausea, tight chest, generalized, weakness, hypotension, but increased BP.
Niacin (Nicotinic acid)	NiAc Nicobid Nicolar Novo-Niacin	Vitamin B <sub>3</sub> is used in the management of hypercholesterolemia. It has vasodilation effects on vascular smooth muscle and inhibits hepatic synthesis of VLDL, cholesterol and triglycerides, and LDL. May also be used in the treatment of pellagra.	May cause a generalized flushing, sensation of warmth, transient headache, tingling in the extremities, increased sebaceous gland activity, hyperuricemia, hyperglycemia, abnormalities of liver function, and jaundice.
Nifedipine	Adalat	A calcium channel blocker that causes smooth muscle relaxation of coronary and peripheral blood vessels decreasing peripheral resistance without affecting serum calcium levels. Used in the management of hypertension usually in combination with a diuretic and also vasospastic (Prinzmetal or variant) angina.	May cause dizziness, lightheadedness, postural hypotension, facial flushing, palpitations, peripheral edema, hepatotoxicity, sore throat, and various GI symptoms.
Norfloxacin	Chibroxin Noroxin	A strong broad-spectrum antibiotic that alters DNA-gyrase inhibiting protein synthesis. Used primarily for UTIs and conjunctivitis. Effective against many organisms including <i>Klebsiella</i> and other pneumonias, <i>Salmonella</i> , <i>Shigella</i> , <i>Pseudomonas</i> , <i>S. aureus</i> , among others.	May cause joint pain, swelling, and erosions in weight-bearing joints. Usual GI complaints, headaches, dizziness, pruritus, elevated liver enzymes, and immunosuppressed swelling of ankle and hip with tendon tenderness and swelling of third finger bilaterally after one month of continuous therapy.
Nortriptyline	Aventyl Pamelor	A tricyclic antidepressant that acts as a serotonin reuptake inhibitor and to a lesser degree norepinephrine. Used in the management of depression and anxiety.	May cause drowsiness, orthostatic hypotension, dry mouth, metallic taste, photophobia, urinary retention, or weight gain.
Nystatin	Mycostatin Nadostine Nilstat Nyaderm Nystex	An antifungal antibiotic that binds to cell membrane and causes leakage of intracellular components. Used primarily for Candida infections.	May cause nausea, vomiting, epigastric pain, or diarrhea.

Omeprazole	Prilosec Losec	A proton pump inhibitor, it inhibits H <sup>+</sup> K <sup>+</sup> -ATPase (acid production from parietal cells of stomach). Used for erosive esophagitis, GERD, and in concert with antibiotics (usually metronidazole and amoxicillin) for <i>H. pylori</i> infection with duodenal ulcer management.	May cause headache, nausea, vomiting, constipation, abdominal pain, and dry mouth.
Orlistat	Xenical	An enzymatic blocker (gastrointestinal lipase) that inactivates pancreatic and gastric lipase reducing the absorption of fat. Used in the management of obesity.	May cause headache, dizziness, hypertension, oily discharges, and abdominal pain and cramping.
Oxybutynin Chloride	Ditropan Ditropan XL	A synthetic amine used for neurogenic bladder or detrusor instability (unstable bladder). Effects are antispasmodic through inhibition of muscarinic effect of acetylcholine on smooth muscle.	May cause drowsiness, blurred vision, dry mouth, constipation, urinary hesitation, dizziness, weakness, or skin rash.
Oxycodone	Roxicodone Percolone Oxycontin Oxyfast	Binds to stereospecific receptors in the CNS having the effects of a potent analgesic; ten times more potent than codeine. Used in the management of pain with fractures, bursitis, dislocations, post-surgery, and postpartum.	May cause sedation, constipation, respiratory depression, or hepatotoxicity.
Paroxetine	Paxil	An SSRI making more serotonin available in the CNS. Used in the treatment of depression and obsessive-compulsive disorders.	May cause nausea, vomiting, weakness, dizziness, agitation, insomnia, headaches, or abnormal ejaculation.
Pemoline	Cylert	Causes the release of norepinephrine, dopamine, and serotonin from storage vesicles resulting in CNS stimulation. This causes an increase in performance, coordination, and energy. There is a decrease in appetite with an increase in blood pressure. Used for attention deficit disorder.	May cause restlessness, insomnia, dizziness, anorexia, psychic disturbances, and arrhythmias.
Penicillamine	Cuprimine Depen	Forms a chelate with various metals such as zinc, copper, iron, lead, mercury, and perhaps other heavy metals. Used in the management of Wilson's disease (causes excretion of excess copper), management of RA (mechanism unknown), and prevention of cystinuria.	During initial use, patients with Wilson's disease may have a worsening of neuropathy. May cause excessive skin wrinkling, regular GI complaints, fever, arthralgia, SLE-like syndrome, thrombophlebitis, myasthenia gravis syndrome, optic neuritis, thrombocytopenia, skin reactions including rash and pruritus, pancreatitis, proteinuria, and hematuria.
Penicillin (including G Benzathine, G Potassium, G Sodium, G Procaine, and V/V Potassium)	Bicillin Permapen Megacillin Pentids Pfizerpen Cryptocillin Benzylpenicillin Wycillin	An antibiotic in many different forms used for different infections:  Penicillin G benzathine—mild to moderate infections, syphilis, and prophylaxis for rheumatic fever.  Penicillin G potassium or sodium—moderate to severe infections, meningococcal meningitis.  Penicillin G procaine—moderate to severe infections, pneumococcal pneumonia, uncomplicated gonorrhea, and syphilis.  Penicillin V & V potassium—mild to moderate infections and endocarditis prophylaxis.	Anaphylaxis is common, hypersensitivity symptoms, common GI disturbances, SLE-like syndrome, hypotension, rarely circulatory collapse, Löffler's syndrome, thrombocytopenia, hemolytic anemia, and delayed skin rashes.

Pentazocine	Talwin Talwin NX	A synthetic analgesic, narcotic, CNS depressant used in the management of moderate to severe pain and preoperative sedation.	Not to be used with head injury. Will cause drowsiness, lightheadedness, and sedation. May cause dizziness, nausea/vomiting, constipation, urinary retention, rash, respiratory depression, or shock.
Phenelzine	Nardil	A MAO inhibitor in the management of depression. Increases available levels of serotonin and norepinephrine. Also may affect the hepatic microsomal enzymes that metabolize drugs, prolonging the effects of these drugs.	May cause orthostatic hypotension, dry mouth, dizziness, constipation, anorexia, blurred vision, tremors, or muscle twitching. Caution for hypertensive crisis when ingesting foods containing tyramine.
Phenobarbital	Barbital Luminal Solfoton	A long-acting barbiturate used primarily for the management of epilepsy (grand mal). Inhibits the reticular activating system, causes CNS depression, and raises the threshold for stimulation of the cerebral cortex. Also used for pre- and postoperative sedation in pediatrics and pylorospasm in infants.	Causes CNS depression with possible extreme of coma and death. May cause usual GI symptoms, hyperkinesis, insomnia, nightmares, headaches, bradycardia, syncope, megaloblastic (macrocytic) anemia, agranulocytosis, thrombocytopenia, folic acid or vitamin D deficiency; if taken during pregnancy, birth defects (10%).
Phentermine	Adipex-P Fastin Ionamin Obenix Oby-Trim	Appetite suppressant similar to amphetamines, acting as a CNS stimulant. Used for a short period along with diet and exercise, and behavioral training for weight loss.	Most side effects are those of CNS stimulation including agitation, nervousness, tremor, hypertension, arrhythmias, etc. In addition, hypersensitivity reactions are possible and all of the common side effects reported for most drugs related to GI complaints and CNS effects, such as headache, dizziness, etc.
Phenytoin	Dilantin	Sodium, potassium, and calcium currents are reduced across neuronal membranes, decreasing neuronal transmission. Used in the treatment of epilepsy (except absence seizures).	CNS toxicity including sedation, dizziness, imbalance (ataxia), nausea, diplopia (nystagmus), also birth defects, hepatotoxicity, bone marrow suppression, and GI disturbances. Usually these are transient. Morbilliform rashes occur in 5% to 7% of patients. In young patients, gingival hyperplasia and hirsutism.
Physostigmine	Antilirium	An anticholinesterase inhibitor making more acetylcholine available at cholinergic sites. Used to reverse the overdose/toxic effects of tricyclic antidepressants, atropine, scopolamine, or diazepam.	May cause sweating, abdominal pain, diarrhea, nausea, salivation, weakness, convulsions, and rarely respiratory collapse.
Pilocarpine	Absorbocarpine Isopto carpine Minims pilocarpine Miocarpine Ocusert Pilocar	A tertiary amine that mimics acetylcholine causing miosis, spasm of accommodation, and decreased intraocular pressure. Used for both open-angle and closed-angle glaucoma.	May cause salivation, blurred vision, sweating, headache, dizziness, or in rare cases, retinal detachment.

Pravastatin	Pravachol	A statin: An HMGCoA reductase inhibitor. Blocks the enzyme that controls production of cholesterol in the liver. Therefore, used in the treatment of hyperlipidemia. Lowers both total cholesterol and LDL cholesterol while increasing HDL cholesterol.	GI upset, headache, myalgia, weakness, rhabdomyolysis, ocular and liver toxicity. Should have liver enzymes monitored.
Prazosin	Minipress	Alpha blocker: a adrenergic antagonist causing dilation of arteries and veins used for the treatment of hypertension.	Postural hypotension, dry mouth, edema, congestion, headache, sexual dysfunction, and lethargy.
Prednisone	Dethasone Liquid Pred Prednisolone Pediapred Oral Liquid Medrol	Synthetic oral corticosteroid used to suppress immune system reaction including inflammation. These medications mimic actions of cortisol (hydrocortisone) produced by the adrenal gland. Used in the treatment of inflammatory arthritis, colitis such as Crohn's and ulcerative colitis, asthma, bronchitis, some skin rashes, and allergic or inflammatory conditions affecting the nose and eyes.	Long-term use may cause suppression of bone growth, osteopenia and resultant fractures, Cushing's syndrome (osteoporosis, skin atrophy, abnormal glucose tolerance, anemia, behavioral abnormalities, etc.). Increased risk of Candida (yeast) infection.
Pregabalin	Lyrica	Used in the management of neuropathic pain (diabetic peripheral neuropathy), postherpetic neuralgia, adjunctive therapy for partial seizures, and fibromyalgia.	May cause dizziness, sleepiness, edema, blurred vision, weight gain, or difficulty with concentration.
Probenecid	Benemid Benuryl Probalan	Used as an anti-arrhythmic, especially for atrial fibrillation and flutter. Decreases excitability of myocardium and increases refractory time with possible peripheral vasodilation effect.	May cause headache, GI complaints, hemolytic anemia, respiratory depression, and rarely hepatic necrosis.
Procainamide	Procan Procanbid Pronestyl	Used as an anti-arrhythmic, especially for atrial fibrillation and flutter. Decreases excitability of myocardium and increases refractory time with possible peripheral vasodilation effect.	May cause SLE-type syndrome, polyarthralgias, ventricular fibrillation, or agranulocytosis with prolonged use.
Procaine	Novocain	Used as a local anesthetic to block sensation and motor activity in local injection area. Blocks sodium into nerve cell. Also used for spinal anesthesia and nerve blocks.	There is a known hypersensitivity to procaine. May cause respiratory distress, anaphylactic reaction, arthralgias, tremors, convulsions, or headache.
Progesterone	Crinone Gel Gesterol Progestasert Prometrium Progestaject	A phenothiazine derivative that has alpha-adrenergic blocking effects, an antiemetic effect through depression on chemoreceptor trigger zone, and antipsychotic effects through actions (blocks postsynaptic dopamine receptors) in the hypothalamus and reticular formation. Used in the management of manic phase of manic depression, for psychotic disorders such as schizophrenia, and for severe nausea and vomiting. Also, sometimes used for behavioral disorders in attention deficit disorder in children.	May cause breakthrough bleeding, many GI symptoms, migraine headache, weight change, dizziness, and possible thromboembolic disorders.
Propranolol	Inderal	Beta-blocker: Blocks both $\beta_1$ and $\beta_2$ adrenergic receptors, decreasing heart rate and rennin release. Used in the treatment of hypertension. Also has bronchoconstriction effect due to $\beta_2$ blockade.	CNS depressive effects with concerns for those with diabetes, heart block and heart failure, asthma, and emphysema. Transient hypertension due to blockage of $\beta_2$ receptors (which normally dilate large arteries).

Propoxyphene	Darvon Novopropoxyn	Related to methadone; a strong opioid. Used for mild to moderate pain. Also used to manage narcotic withdrawal.	Caution that use with alcohol or high doses may cause death. Also, more commonly causes drowsiness, constipation, skin reactions, GI upset, and rarely circulatory collapse or coma.
Propylthiouracil (PTU)	Propyl-Thyracil	Blocks transformation of inorganic iodine to organic iodine. Often used to produce a euthyroid state prior to radiation or surgery. Long-term use may produce euthyroid state in half of patients.	May cause headache, vertigo, nausea, vomiting, hepatitis, myelosuppression, leukopenia, and rarely agranulocytosis. May elevate prothrombin time and liver enzymes.
Psyllium	Hydrocil Instant Karasil Konsyl Metamucil Modane bulk Per Diem Plain Reguloid Serutan Silybon V-Lax	A bulk-producing laxative made from colloid of psyllium seed. Promotes peristalsis. Used for constipation.	May cause eosinophilia, nausea, abdominal cramps, and GI tract strictures (using dry form).
Pyridostigmine	Mestinon	An indirect cholinesterase inhibitor sometimes used for short-term management of myasthenia gravis and to reverse the effects of curariform muscle relaxants.	May cause muscle weakness, hypotension, convulsions, bronchospasm, or respiratory distress.
Raloxifene	Evista	Selective estrogen receptor modulator; antiresorptive used in the treatment of osteoporosis. These medications inhibit bone resorption but eventually reduce bone formation due to a decrease in overall bone turnover. A standard intermittent treatment program with parathyroid hormone is intended to increase bone formation; however, it also increases bone resorption. The net effect though is bone formation. It is clear that prolonged exposure to parathyroid hormone such as in hyperparathyroidism causes osteoporosis. Raloxifene is believed to decrease total cholesterol and LDL cholesterol but does not raise HDL or lower triglycerides. Also, the selective estrogen receptor inhibition effect prevents tissue proliferation in the uterus and breasts.	May cause flu-like symptoms, also hot flashes, migraine headache, insomnia, depression, weight gain, vaginitis, breast pain, and vaginal bleeding.
Ranitidine	Zantac	An H <sub>2</sub> (histamine) inhibitor blocking gastric acid secretion. Used as an OTC medication in the management of ulcers and GERD.	May cause usual GI symptoms, dizziness, depression, reversible leukocytosis, thrombocytopenia, and possible decreases in liver enzymes.
Reserpine	Serpalan Sk-Reserpine	Decreases binding of serotonin and synthesis of norepinephrine, and inhibits their reuptake. Decreases in these two neurotransmitters in the CNS. Primarily used in the treatment of hypertension. May also be used for the vasospastic feature of Raynaud's.	May cause drowsiness, sedation, lethargy, edema, bradycardia, nasal decongestion, hypersensitivity, menstrual irregularities, and other sexual effects. Also, orthostatic hypotension, and rarely respiratory distress.

Risedronate	Actonel	Bisphosphonate; antiresorptive used in the treatment of osteoporosis and Paget's disease. These medications inhibit bone resorption but eventually reduce bone formation due to a decrease in overall bone turnover. A standard intermittent treatment program with parathyroid hormone is intended to increase bone formation; however, it also increases bone resorption. The net effect though is bone formation. It is clear that prolonged exposure to parathyroid hormone such as in hyperparathyroidism causes osteoporosis. Risedronate is believed to be more effective than other bisphosphonates at blocking bone dissolution.	Fewer GI side effects than other bisphosphonates.
Rivastigmine Tartrate	Exelon	A cholinesterase inhibitor used in the management of mild to moderate Alzheimer's disease. Works in the cerebral cortex, blocking degradation of acetylcholine.	May cause headache, fatigue, insomnia, nausea, diarrhea, vomiting, cramps, anorexia, or muscle cramps.
Rofecoxib	Vioxx	NSAID: cyclooxygenase (COX) 2 inhibitor (does not inhibit COX-1) used primarily for arthritis (osteo and rheumatoid, and rheumatoid variants), acute pain, and menstrual cramps. Reduces fever. Also approved to prevent and reduce the size of polyps in patients with genetic disease.	May cause flu-like symptoms, peripheral edema, GI problems, dizziness, headache, pharyngitis, and rash.
Ropinirole	Requip	Used in the treatment of Parkinson's and restless leg syndrome (Ekbom syndrome) through a mechanism that causes stimulation of postsynaptic dopamine D2-type receptors (for Parkinson's specifically within the caudate-putamen).	May cause increased sweating, dry mouth, flushing, fatigue, sleeping attacks, tachycardias, orthostatic hypotension, hyperkinesias, nausea, vomiting, or anorexia.
Rosiglitazone Maleate	Avandia	An oral medication used as adjunct therapy with diet and exercise for type 2 diabetes. It acts primarily by increasing insulin sensitivity but is not related to sulfonylureas, the biguanides, or the alphagluco-sidase inhibitors.	Not to be used with nitrates. May cause hypoglycemic symptoms, edema, or exacerbation of congestive heart failure.
Salmeterol Xinafoate	Serevent	Similar to albuterol, it is a long-acting beta 2 receptor agonist. Effects include reduction of bronchospasm, increased motility of cilia, and decrease in inflammatory mediators such as histamine. Used in the treatment of asthma and hyperactive airway disease. Not used to treat acute bronchospasm.	May cause dizziness, headache, tremor, palpitations, and in rare cases, acute respiratory arrest.
Scopolamine	Hyoscine Murocoll Triptone	Resembles atropine producing CNS depression/sedation, and decreased secretions of salivary, sweat, and bronchial glands. Used as a preanesthetic.	Causes drowsiness, dry mouth and throat, constipation, dilated pupils, and decreased respiration.
Selegiline	Eldepryl	Increases dopaminergic activity, partial action due to MAO inhibition and inhibition of dopamine reuptake. Used as adjunctive treatment for Parkinson's.	May cause visual disturbances, GI symptoms, confusion, hallucinations, dyskinesia, and hypotension.
Senna (Sennosides)	Black Draught Gentlax Senexon Senokot Senolax	Dried leaf preparation that is converted to glycone, which causes an increase in peristalsis. Used for acute constipation.	May cause abdominal cramping, flatulence, diarrhea, weight loss, and associated loss of electrolytes.

Sertraline	Zoloft	An SSRI making more serotonin available in the CNS. Used in the treatment of depression and obsessive-compulsive disorders.	May cause nausea, diarrhea, dry mouth, dizziness, insomnia, fatigue, or impotence.
Sildenafil Citrate	Viagra	Used for erectile dysfunction. Causes a vasodilation effect in the corpus cavernosus of the penis through effect with nitric oxide. A phosphodiesterase-5 inhibitor.	May cause facial edema, postural hypotension, palpitations, headache (and other "cerebral signs/ symptoms"), MI, angina, dermatitis, photosensitivity, and gout.
Simvastatin	Zocor	A statin: An HMGCoA reductase inhibitor. This blocks the enzyme that controls production of cholesterol in the liver. Therefore, used in the treatment of hyperlipidemia. Lowers both total cholesterol and LDL cholesterol while increasing HDL cholesterol.	GI upset, headache, myalgia, weakness, rhabdomyolysis, ocular and liver toxicity. Should have liver enzymes monitored.
Solifenacin	VESIcare	A muscarinic receptor antagonist used in the management of overactive bladder (detrusor instability).	May cause dry mouth, constipation, or blurred vision.
Somatropin	Bio-tropin Genotropin Nutropin Humatrope Norditropin Serostim Saizen	A recombinant growth hormone used for growth hormone deficiencies, Turner's syndrome, and AIDS wasting syndrome.	May cause hypercalciuria, accelerated growth of intracranial tumors, hyperglycemia, gallstones, and myalgia.
Spironolactone	Aldactone Novospiroton	Blocks action of aldosterone by competing with receptor sites in distal renal tubules. Used as a diuretic without an effect of hyperglycemia or hyperuricemia. A potassium-sparing diuretic. Used in the management of CHF and other forms of edema, and adjunct therapy for hypertension.	May cause confusion, lethargy, rapid weight loss, gynecomastia, electrolyte imbalances, elevated BUN, gout, decreased glucose tolerance, or SLE.
Streptokinase (Tissue Plasminogen Activator: TPA is similar)	Kabikinase Streptase	Produced from beta-hemolytic streptococcus, this potent thrombolytic enzyme promotes conversion of plasminogen to plasmin. This process breaks apart clotting materials into a soluble form, clearing blocked areas in acute thrombotic or embolic situations. Used for acute treatment of deep vein thrombosis, pulmonary embolism, coronary artery thrombosis, etc.	Given that this is an antithrombotic agent, hypocoagulation exists, which may lead to bleeding at any body site. May also cause an allergic reaction, anaphylaxis, unstable blood pressure, ventricular arrhythmias, musculoskeletal pain, and flushing.
Streptomycin	Streptomycin	A bacteriostatic antibiotic effective against numerous bacteria, including Gram-positive, Gram-negative and acid-fast.	Pain, swelling, tenderness at injection site. May cause dizziness, labyrinth damage, headache, and nausea. May elevate some liver enzymes or cause decreases in hematocrit or hemoglobin.
Sucralfate	Carafate Sulcrate	Used as part of GI ulcer therapy due to effects of creating a protective mucosal "paste" and inhibits pepsin, decreases bile absorption, and blocks back diffusion of H <sup>+</sup> ions. Valuable for smokers treated for duodenal ulcers.	Very few side effects. May cause constipation.

Sulfasalazine	Azulfidine Sulfasalazine Salazopyrin S.A.S.-500	A long-acting sulfonamide used in the management of <i>Clostridium</i> and <i>E. coli</i> infections, inflammatory bowel disease, and RA. Anti-inflammatory effect may be due to inhibition of prostaglandins, and may have antibacterial effect due to conversion to sulfapyridine and 5-ASA.	May cause nausea, vomiting, bloody diarrhea, anorexia, rash, and allergic reactions.
Sulfisoxazole	Gantrisin	A bacteriostatic antibiotic that interferes with p-amino benzoic acid (PABA) which interferes with folic acid biosynthesis necessary for bacterial growth. Used primarily for chronic UTIs, acute otitis media, resistant malarial infections, conjunctivitis and corneal infections, and topically for <i>H. vaginalis</i> .	A wide variety of potential side effects including headache, peripheral neuropathy, anaphylaxis, agranulocytosis, thrombocytopenia, Stevenson-Johnson syndrome, alopecia, goiter, depression, crystaluria, hematuria, and the usual GI complaints.
Sulindac	Clinoril	An indole prostaglandin inhibitor (similar to indomethacin) used similar to aspirin with fewer GI effects than aspirin. Primarily used for inflammatory arthritis such as RA, ankylosing spondylitis, acute attacks of gout, and acute bursitis of the shoulder.	May cause dizziness, headache, abdominal pain, prolonged bleeding time, aplastic anemia, anaphylaxis, and toxic epidermal necrosis syndrome.
Sumatriptan	Imitrex	A selective serotonin receptor agonist that causes vasoconstriction of cranial arteries. Used in the management of migraine headaches (with or without aura) and cluster headaches.	Depends on mode of delivery, but may cause angina, tingling, numbness, dizziness, lightheadedness, hypo- or hypertension, nausea, or vomiting. Also, a rebound migraine headache is common.
Tacrine	Cognex	A cholinesterase inhibitor used in the management of mild to moderate Alzheimer's disease. Works in the cerebral cortex, blocking degradation of acetylcholine.	May cause headache, fatigue, insomnia, nausea, diarrhea, vomiting, cramps, anorexia, or muscle cramps.
Tadalafil	Cialis	A phosphodiesterase-5 inhibitor. Used for erectile dysfunction. Causes a vasodilation effect in the corpus cavernosus of the penis through effect with nitric oxide.	May cause facial edema, postural hypotension, palpitations, headache (and other "cerebral sign/symptoms"), MI, angina, dermatitis, photosensitivity, and gout. For some, may experience a slight bluish tinge to vision.
Tamoxifen	Nolvadex Nolvadex-D Tamofen	Competes with estradiol and estrogen receptors causing a strong antiestrogen effect. Used in the palliative treatment of advanced breast cancer in postmenopausal women and adjunctively with surgery for women with breast cancer and positive lymph nodes.	May cause hot flashes, thrombosis, leucopenia, thrombocytopenia, with nausea and vomiting occurring in about 25% of patients.
Tamsulosin	Flomax	Used in the management of prostate hypertrophy, this is an antagonist to alpha 1A adrenoceptors in the prostate.	May cause orthostatic hypotension, priapism, allergic-type reactions, constipation, or vomiting.
Tegaserod	Zelnorm	A serotonin 5-HT <sub>4</sub> receptor agonist used in the management of constipation-predominant irritable bowel syndrome. The 5-HT <sub>4</sub> receptor, a serotonin receptor, normalizes intestinal contractions. In addition, this medication acts to increase the pain threshold for distention of the colon.	May cause headache, dizziness, migraine, abdominal pain, nausea, flatulence, or back pain.

Terazosin	Hydrin	An alpha 1-adrenergic blocker used in the management of hypertension in combination with a beta-adrenergic blocker and thiazide diuretic. Also used in the management of benign prostatic hypertrophy.	May cause weakness, dizziness, headache, weight gain, or syncope.
Terbinafine	Lamisil Lamisil DermGel	Cell membrane function is disrupted by inhibiting sterol (ergosterol) synthesis in fungi. Used for superficial treatment of mycosis such as the "tineas."	May cause burning at the site of application, skin reactions, or ulcerations. Also, may cause headache, GI disturbance, liver function test abnormalities, taste abnormalities, and rarely liver failure or neutropenia.
Teriparatide	Forteo	A parathyroid hormone agonist used in the management of postmenopausal osteoporosis.	May cause pain, transient increases in calcium levels, headaches, dizziness, arthralgias, myalgias, leg cramps, rash, or swelling.
Tetracycline	Achromycin	A synthetic broad-spectrum antibiotic that is bacteriostatic (inhibits protein synthesis by binding to 30s sub-unit, blocking amino acid-linked tRNA from binding to the A site of the ribosome). Susceptible bacteria include <i>M. pneumoniae</i> , <i>C. psittaci</i> , <i>C. trachomatis</i> , and <i>N. gonorrhea</i> . Used for respiratory infections, nongonococcal urethritis (ureaplasma), Rocky Mountain spotted fever, typhus, chancroid, anthrax, syphilis, cholera, brucellosis, chlamydia, acne, and Lyme disease. Doxycycline approved for malaria prophylaxis.	GI distress, reversible nephro- and hepatotoxicity, photosensitivity, and dental staining (not used in prepubertal children).
Theophylline	Bronkodyl Elixophyllin Pulmophylline Slo-Bid Slo-phyllin Somophyllin Theo-Dur Theospan Uni-Dur	A xanthine derivative that causes the relaxation of smooth muscle, stimulates the medullary respiratory center and the myocardium. Used primarily in the management of bronchospasm and prophylactic and acute attacks of asthma. Also may be used for edema associated with CHF.	May cause gastric upset, irritability, anorexia, abdominal pain, dizziness, headache, drug-induced seizures, palpitations, tachycardia, albuminuria, fever, dehydration, and rarely respiratory arrest.
Timolol	Blocadren	Beta-blocker: Blocks both $\beta_1$ and $\beta_2$ adrenergic receptors, decreasing heart rate and rennin release. Used in the treatment of hypertension. Also has bronchoconstriction effect due to $\beta_2$ blockade.	CNS depressive effects with concerns for those with diabetes, heart block and heart failure, asthma, and emphysema. Transient hypertension due to blockage of $\beta_2$ receptors (which normally dilate large arteries).
Tiotropium	Spiriva	A once-a-day inhaled anticholinergic specific for muscarinic receptors used in the management of bronchospasm associated with COPD.	May cause dry mouth, constipation, increased heart rate, blurred vision, glaucoma, or urinary difficulty.
Tolterodine	Detrol Detrol A	A synthetic amine used for neurogenic bladder or detrusor instability (unstable bladder). Effects are antispasmodic through inhibition of muscarinic effect of acetylcholine on smooth muscle.	May cause drowsiness, blurred vision, dry mouth, constipation, urinary hesitation, dizziness, weakness, or skin rash.

Topiramate	Topamax	May affect GABA or kainate/AMPA receptors. Used in the treatment of partial seizures.	May cause ataxia, dizziness, and speech and psychomotor impairment.
Tramadol	Ultram	Tramadol and its main metabolite bind to $\mu$ -opioid receptors. Also reduces uptake of norepinephrine and serotonin. A pain reliever that is similar in action to narcotics with less of a risk for addiction or abuse.	May cause constipation, dizziness, nausea/vomiting, headache, and pruritus.
Tranylcypromine	Parnate	A MAO inhibitor used as a last-choice treatment for those unresponsive to other MAO in the management of depression.	May cause orthostatic hypotension, dry mouth, dizziness, anorexia, blurred vision, tremors, or muscle twitching. Caution for hypertensive crisis when ingesting foods containing tyramine.
Trastuzumab	Herceptin	Monoclonal antibody antineoplastic used in the treatment of metastatic breast cancer for tumors that overexpress HER2 proteins.	May cause anaphylaxis, pain, fever, abdominal pain, diarrhea, congestive heart failure, insomnia, dizziness, or headache.
Trazodone	Desyrel	Inhibits the reuptake of dopamine, serotonin, and norepinephrine with the major effect on serotonin. Used in the treatment of depression and also for aggressive disorders.	May cause a decrease in appetite, rash, hypertension, or shortness of breath.
Triamcinolone	Aristocort Atolone Kenacort Kenalog-E Aristospan Cenocort Triam-Forte Articulose Trilone Tristoject	A corticosteroid with anti-inflammatory and anti-rheumatic effects. Aerosol version commonly used in the management of asthma. A spacer is used with the inhaler to prevent possible <i>Candida</i> infection of the mouth. With the inhaled version the usual side effects associated with long-term glucocorticoid use are not seen, partially due to the clearance on first pass through the liver.	With injectable type may have Cushing's-like features, growth retardation, hyperglycemia, carbohydrate intolerance, nausea, vomiting, headache, euphoria, muscle weakness, osteoporosis, aseptic necrosis of bone, and delayed wound healing.
Triamterene	Dyrenium	Blocks action of aldosterone by competing with receptor sites in distal renal tubules. Used as a diuretic. It has direct effects on distal renal tubules to prevent excretion of potassium. Decreases glomerular filtration rate and increases BUN. Used in the management of CHF and other forms of edema, and adjunct therapy for hypertension.	May cause hyperkalemia and other electrolyte imbalances, anaphylaxis, some blood dyscrasias, GI disturbances, gout, rash, or hypotension.
Triazolam	Halcyon	A benzodiazepine derivative that has hypnotic effects through blocking of limbic and cortical arousal. Used for short-term management of sleep dysfunction.	May cause drowsiness, rebound insomnia, memory impairment and anterograde amnesia, GI symptoms, headache, or dizziness.
Trimethoprim-Sulfamethoxazole	Bactrim Septra Co-Trimoxazole	A combination drug that acts as a synthetic folate antagonist acting as an enzyme inhibitor preventing bacterial synthesis. Used with <i>Pneumocystis carinii</i> pneumonitis, <i>Shigella</i> enteritis, and UTI caused by Enterobacteriaceae.	Possible toxic epidermal necrosis syndrome, pseudomembranous colitis, agranulocytosis, aplastic anemia (rare), and anorexia, nausea, and skin rash. May elevate liver enzymes and bilirubin.

Valacyclovir	Valtrex	An antiviral medication that interferes with viral DNA synthesis. Due to increased GI absorption, plasma levels are higher than acyclovir. Use for the treatment of herpes zoster (shingles) and recurrent genital herpes.	May cause headache, weakness, fatigue, nausea, vomiting, dyspepsia, abdominal pain, renal damage, or allergic reactions.
Valproic acid	Depacon	Possible augmentation of GABA neurotransmission. Used in the treatment of all seizure types.	Severe hepatotoxicity possible, thrombocytopenia, and hyperammonemia.
Vancomycin	Vancocin Vancoled	An antibiotic that interferes with cell membrane synthesis. Primarily for Gram-positive. Organisms include beta-hemolytic streptococci, staphylococci, pneumococci, enterococci, clostridia, and corynebacteria.	Is ototoxic and nephrotoxic. May cause anaphylaxis and hypersensitivity reactions, "red neck" syndrome with IV administration, thrombophlebitis, super-infections, and transient leucopenia and eosinophilia.
Vardenafil HCL	Levitra	Used in the management of erectile dysfunction in men. It acts as an enzyme blocker for phosphodiesterase type 5 (PDE-5), which results in increased blood flow to the penis.	May cause headache, facial flushing, indigestion, and nasal congestion. Contraindicated for those with heart problems or HTN.
Vasopressin	Pitressin	An extracted animal hormone from the posterior pituitary that has primarily an antidiuretic effect (no oxytocin effect). Effect is primarily due to increasing tubular reabsorption of water, creating a concentrated urine. Used in the management of diabetes insipidus, for dissipation of gas shadows on abdominal films, or reducing abdominal distention post-surgically. Has also been used as intranasal spray for maintenance treatment of diabetes insipidus and sometimes for enuresis.	Small doses may cause angina or MI and aggravate other preexisting heart conditions. May cause headache, water intoxication, and anaphylaxis, among other common drug side effects.
Varenicline	Chantix	Used in the management of smoking cessation. It is a partial agonist for alpha-1, beta-2 nicotinic acetylcholine receptors.	Is ototoxic and nephrotoxic. May cause anaphylaxis and hypersensitivity reactions, "red neck" syndrome with IV administration, thrombophlebitis, super-infections, and transient leucopenia and eosinophilia.
Verapamil HCL	Calan Covera Isoptin Verelan	A calcium channel blocker that decreases vasoconstriction (especially coronaries) and slow conduction at SA and AV nodes. Used in the management of Prinzmetal (variant) angina and various arrhythmias.	May cause headache, AV block, hypotension, constipation, elevated liver enzymes, or syncope.
Warfarin	Coumadin Panwarfin Warfilone	An anticoagulant that decreases the synthesis of vitamin K-dependent coagulation factors. Similar to heparin but actions are accumulative and prolonged. Used prophylactically for embolic and thromboembolic conditions such as deep vein thrombosis, transient ischemic attacks, prosthetic valves, pulmonary embolism, and atrial fibrillation with embolization.	May cause bleeding at any site. Caution when adjusting patients on Warfarin due to subarachnoid bleeds, bruising of skin, and other potential bleeding sites. May also cause anorexia, abdominal cramps, diarrhea, and may increase liver enzymes.

Name	Examples	Mechanism/Use	Some Side Effects/Concerns
Zafirlukast	Accolate	An oral leukotriene receptor antagonist. Leukotrienes are pro-inflammatory chemicals derived from arachidonic acid. Blocks the binding of leukotriene types D4 (LTD4) and E4 (LTE4). Used in the treatment of asthma, decreasing the inflammatory aspect of asthma.	May cause headache, GI distress, and an increase in respiratory infection in older patients.
Zidovudine	Retrovir (AZT)	When entering the host cell it is converted to triphosphate by thymidine kinase. It is then incorporated into DNA chains by reverse transcriptase, disrupting cell replication. Used in the treatment of HIV infections.	Causes many GI complaints, headache, fever, malaise, myalgia, dizziness, cough and wheezing, and bone marrow suppression.
Zoledronic Acid	Zometa	Used for hypercalcemia associated with metastasis, multiple myeloma, and Paget's. Blocks osteoclastic resorption of bone and release of calcium.	May cause fever, nausea, vomiting, abdominal or chest pain, leg edema, hypos (calcium, potassium, sodium), or pancytopenia.
Zolpidem	Ambien	A nonbenzodiazepine hypnotic medication with no muscle relaxation or anticonvulsant effects used in the short-term management of insomnia.	May cause headache upon waking, lethargy, fatigue, depression, anxiety, irritability, or dizziness. With doses greater than 10 mg, may report antegrade amnesia or memory impairment.

Didronel	1263	Evista	1275	Heparin	1265
Dilantin	1273	Exelon	1276	Hep-B-Gammagee	1265
Dilaudid	1265	Ezetimibe and Simvastatin	1263	Hep-Lock	1265
Dilaudid-HP	1265	Ezetimibe	1263	Hexadrol	1259
Dilocaine	1268	Fastin	1273	Humalog (RCA)	1266
Diphenatol	1259	Femizole	1270	Humatrope	1277
Disodium cromoglycate	1258	Fenicol	1256	Humira	1252
Dispose-a-Med	1267	Fexofenadine	1263	Humulin	1266
Ditropan	1272	Fivent	1258	Hydrin	1279
Ditropan XL	1272	Flagyl	1270	Hydrocil	1275
Diuril	1256	Fleet	1254	Hyoscine	1276
Dizmiss	1270	Flexeril	1258	HyperHEP	1265
Dopar	1267	Flonase	1264	Ibandronate	1265
Drospirenone and Estradiol	1260	Fluticasone	1264	Iletin II	1266
Dulcolax	1254	Fluticasone Propionate with Salmeterol	1264	Illocyin	1262
Duloxetine	1260	Fosamax	1252	Imipramine	1265
Durapam	1264	L-Caine	1268	Medrol	1274
Imitrex	1278	Lestid	1258	Megacillin	1272
Imodium	1268	Levitra	1281	Menest	1262
Indameth	1266	Levlite	1262	Menrium	1262
Inderal	1274	Levora	1262	Mestinon	1275
Indocid	1266	Levothroid	1267	Metamucil	1275
Indocin	1266	Levoxyl	1267	Methylmorphine	1258
Indocin SR	1266	Libritabs	1256	Methylphenidate	1269
Infergen	1266	Librium	1256	Metizol	1270
INH	1266	Lidopen	1268	Metro-Gel	1270
Instant	1275	Lipo-Hepin	1265	Mevacor	1268
Intal	1258	Lipitor	1254	Micatin	1270
Invinex	1276	Liquaemin	1265	Micronase	1264
Ionamin	1273	Liquid Pred	1274	Midamor	1253
Isoptin	1281	Lithane	1268	Minims Pilocarpine	1273
Isopto Carpine	1273	Lithobid	1268	Minipress	1274
