*Differential Diagnosis and Management for the Chiropractor: Protocols and Algorithms, Fifth Edition* is an independent publication and has not been authorized, sponsored, or otherwise approved by the owners of the trademarks or service marks referenced in this product.

There may be images in this book that feature models; these models do not necessarily endorse, represent, or participate in the activities represented in the images. Any screenshots in this product are for educational and instructive purposes only. Any individuals and scenarios featured in the case studies throughout this product may be real or fictitious, but are used for instructional purposes only.

The authors, editor, and publisher have made every effort to provide accurate information. However, they are not responsible for errors, omissions, or for any outcomes related to the use of the contents of this book and take no

responsibility for the use of the products and procedures described. Treatments and side effects described in this book may not be applicable to all people; likewise, some people may require a dose or experience a side effect that is not described herein. Drugs and medical devices are discussed that may have limited availability controlled by the Food and Drug Administration (FDA) for use only in a research study or clinical trial. Research, clinical practice, and government regulations often change the accepted standard in this field. When consideration is being given to use of any drug in the clinical setting, the health care provider or reader is responsible for determining FDA status of the drug, reading the package insert, and reviewing prescribing information for the most up-to-date recommendations on dose, precautions, and contraindications, and determining the appropriate usage for the product. This is especially important in the case of drugs that are new or seldom used.

**INDEX**

# ACKNOWLEDGMENTS

I would like to express my appreciation to those who have contributed to editing the *Fifth Edition*. This includes many of the academic deans and department chairs at various chiropractic colleges and suggestions from practitioners and students. As usual, a task this size is not possible without the dedication and hard work of the editorial and production staff at Jones & Bartlett. Special thanks to Kayla Dos Santos, Joanna Lundeen, Ryan Angel, Vastavikta Sharma, Julie Searls, and everyone else who assisted in this project.

# INTRODUCTION

**I**n the five years since the previous edition of this book, there have been dramatic changes to the U.S. healthcare system that, in concept and evolution, will be placing more demand on evidence and outcomes. The literature has been exponentially growing, providing more evidence not only in the area of diagnostic accuracy but also outcomes. With that carries a larger responsibility for the average practitioner who has little time to keep up with these advances. The intention, always, with this text is to provide a predigested and critiqued summary of what is known and is likely to be relevant to the practicing chiropractor as well as to students who will need to understand processes of critical thinking and also have a quick option for evaluating complaints.

Chiropractors are finally positioned to become part of what is coined the Patient-Centered Medical Home (PCMH) or whatever future evolution this may involve. As part of a healthcare team, chiropractors can not only participate as spine specialists but also apply their broader knowledge to be participants in a well-integrated support group for patients.

In 2013, the North American Spine Society, in its guidelines for lumbar disc-related radiculopathy, listed manipulation as a viable option.<sup>1</sup> This is a monumental advance when one considers that not long ago, chiropractors were often accused of causing disc herniation and were considered off-limits by most MDs for the management of “complicated” low back pain with radiation below the knee. The literature in the last two years has in

fact demonstrated that for both cervical and lumbar radiculopathy, manipulation may be a safe and effective alternative.<sup>2, 3</sup> In addition, other approaches such as directional-preference exercise approaches are good adjunctive and safe procedures.

In the field of physiotherapy and rehabilitation, some new approaches, or older approaches with new evidence, are dominating the discussion, including the use of shockwave therapy, low-level laser treatment, injections such as plasma rich protein (PRP), and vibration therapy, among others. The literature is growing and indicates that these alternatives are possible options to surgical management.

At the same time, gene-related approaches in both medication selection and surgical options are growing. In the case of stem-cell research, with advances in the use of adipose-derived cells, new opportunities for replacing worn-out or damaged tissues have become a potential reality in the near future.

## **New to this Edition**

As usual, there have been a number of major revisions and additions to this new edition. These include but are not exclusive to the following:

- An additional 500 references
- Clinical summaries of the diagnostic literature for orthopaedic areas (see Translations Into Clinical Practice [TIPS]) at the end of orthopaedic-related chapters.
- For select chapters, a new graphical representation of likelihood ratios for tests involving the cervical and lumbar spine, the shoulder, and the knee.
- A widely expanded Pharmacology for the Chiropractor appendix. This expansion focuses on the mechanisms

of common categories of medications prescribed for common complaints encountered in clinical practice by most chiropractors.

- A new appendix on how to incorporate literature evidence into practice and how to interpret the literature. There is a special emphasis on how practitioners can measure in their own practices; the scientist-clinician.
- Updated algorithms
- Expanded sections on:
  1. Pain
  2. Weakness
  3. Stroke
  4. Concussion

The reader is also directed to the list of websites that follows, which provides valuable resources for chiropractic-related sites, evidence-based sites, practice guideline sites, and links to databases and search engines for keeping up with our ever-expanding knowledge base.

## **Instructor Resources**

As a benefit and an incentive for using this textbook, and to save the instructor valuable time in the preparation and instruction of this course, the publisher is pleased to provide for the first time the following resources to accompany Differential Diagnosis and Management for the Chiropractor: Protocols and Algorithms, Fifth Edition:

- Learning Objectives
- Lecture Outlines in PowerPoint format
- Sample Syllabus
- Test Bank
- Image Bank

- Transition Guide

## Video Updates

Readers are encouraged to subscribe to Dr. Souza's update videos at <http://www.coffeebreaku.com>. These concise, timely video presentations will keep you current between editions with short, informative reviews of the most significant articles relevant to chiropractic practice. Subscribers will receive new video summaries each month and have access to a growing video library archive.

Students are directed to <http://www.jblearning.com/catalog/9781284022308/> for an access code to be redeemed on <http://www.coffeebreaku.com> and a discounted subscription.

# Musculoskeletal Complaints

# CHAPTER 1

## General Approach to Musculoskeletal Complaints

### Context

The approach to a patient's musculoskeletal complaint is a standardized, often sequential search for what can and what cannot be managed by the examining doctor. There is always an ultimate decision: rule in or rule out referable conditions.

- The crucial decision with acute traumatic pain is to rule out fracture (and its complications such as neural or vascular damage), dislocation, and gross instability.
- The crucial decision with nontraumatic pain is to rule out tumors, inflammatory arthritides, infections, or visceral referral.

There appears to be a misinterpretation regarding the amount of information necessary to make diagnostic or management decisions. One error is to think of all joints as distinctly different because the names of structures, disorders, or orthopaedic tests are different for each joint. Another error is to make the assumption that the joint operates as an independent contractor without accountability to other joints. The first error leads to an overspecialization effort that often leaves the doctor

unwilling to attack the vast amount of individual information for each joint. The second error leads the examiner to an approach that excludes important information that may contribute to the diagnosis of a patient's complaint. Each is an error in extremes: the first is that too much knowledge is assumed necessary; the second assumes that too little baseline information is needed for making diagnostic and treatment decisions.

A general approach to evaluation of any joint (and surrounding structures) utilizes the perspective that a joint is a joint. Although a specific joint may function differently because of its bony configuration, structurally, it is composed generally of the same tissues. Most joint regions have bone, ligaments, a capsule, cartilage and synovium, surrounding tendons and muscles, associated bursae, blood vessels, nerves, fat, and skin. All of these structures may be injured by compression or stretch. Compression may lead to fracture in bones or neural dysfunction in nerves. Stretch leads to varying degrees of tendon/muscle, ligament/capsule, neural/vascular, or bone/epiphyseal damage ranging from minor disruption to full rupture. Joints can be further divided into weight-bearing and non-weight-bearing. Non-weight-bearing joints may be transformed into weight-bearing joints through various positions such as handstands or falls with the upper extremity, hyperextension of the spine, or any axial compression force to the joint. Weight-bearing joints are generally more susceptible to chronic degeneration and osteoarthritis.

Bones and joints are also susceptible to nonmechanical processes that involve seeding of infection or cancer as well as the development of primary cancer and the immunologically based rheumatoid and connective tissue disorders. Clues to rheumatoid and seronegative arthritides include a pattern of involvement with a specific predilection to a joint or groups of joints coupled with laboratory investigation.

The approach to evaluation of a neuromusculoskeletal complaint is also directed by a knowledge of common conditions affecting specific structures (regardless of the specific names). Following is a list of these structures and the disorders or conditions most often encountered with each:

- Bone

- 1.** tumor, primary or metastatic
- 2.** osteochondrosis/apophysitis
- 3.** fracture
- 4.** osteopenia (osteoporosis)
- 5.** osteomyelitis

- Soft tissue

- 1.** muscle
  - strain or rupture
  - trigger points
  - atrophy
  - myositis ossificans
  - muscular dystrophy
- 2.** rhabdomyolysis tendon
  - tendinitis
  - tendinosis paratenonitis
  - rupture
- 3.** ligament
  - sprain or rupture
- 4.** bursa
  - bursitis
- 5.** fascia
  - myofascitis

- Joint

- 1.** arthritis
- 2.** subluxation/fixation (chiropractic)
- 3.** synovitis
- 4.** infection
- 5.** joint mice
- 6.** dislocation/subluxation (medical)

# General Strategy

## History

Clarify the onset.

- Is the complaint traumatic?
- Is there a history of overuse?
- Is the onset insidious?

Clarify the type of complaint.

- Is the complaint one of pain, numbness or tingling, stiffness, looseness, crepitus, locking, or a combination of complaints?
- Localize the complaint to anterior, posterior, medial, or lateral if applicable.

Clarify the mechanism if traumatic (for extremities see **Table 1-1**).

- If there was a fall onto a specific region or structure within that region, consider fracture, dislocation, or contusion.
- Determine whether there was an excessive valgus or varus force, internal or external rotation, or flexion or extension. Consider ligament/capsule or muscle/tendon.
- If there was sudden axial traction to the joint, consider sprain or subluxation.
- If there was axial compression to the joint, consider fracture or synovitis.

<b>Table 1-1</b> Joint-Specific Injury Mechanism
--

--	--

<b>Mechanism</b>	<b>Possible Structure(s) Damaged</b>
<b>Shoulder</b>	
Fall on an outstretched arm (extended elbow)	Rotator cuff tear Glenoid labrum tear Posterior dislocation Clavicular fracture
Arm forced into abduction/external rotation	Anterior dislocation Anterior musculature strain
Blow to the shoulder area	Fracture Acromioclavicular separation Dislocation
Fall onto top of shoulder	Shoulder pointer Acromioclavicular separation Distal clavicular fracture
Traction injury to arm	Plexus injury Medical subluxation
<b>Elbow</b>	
Direct fall on tip of elbow or fall on hand with elbow flexed	Olecranon fracture
Fall on hand with extended elbow	Radial head fracture
Hyperextension injury to elbow	Elbow dislocation Supracondylar fracture in children
Severe valgus stress	Capitellum fracture Avulsion of medial epicondyle Medial collateral ligament sprain or rupture
Sudden traction of forearm	Radial head subluxation

<b>Wrist/hand</b>	
Fall on dorsiflexed hand	Navicular fracture Epiphyseal and torus fractures in children Carpal dislocation, or instability
Hyperextension or abduction of thumb	Gamekeeper's thumb (ulnar collateral ligament damage)
Axial compression of thumb	Bennett's fracture Dislocation
Hyperextension of finger	Volar plate injury Jersey finger (rupture of flexor digitorum profundus) Dislocation
Hyperflexion of finger	Avulsion of central slip Mallet finger (rupture of extensor tendon)
Valgus/varus stress injury to finger	Collateral ligament or volar plate injury
Axial compression	Capsular irritation Fracture
<b>Hip</b>	
Fall on hip	Fracture Synovitis Hip pointer Trochanteric bursitis
Blow to flexed, abducted hip	Posterior dislocation
<b>Knee</b>	
Hyperextension	Anterior cruciate ligament tear
Sudden deceleration	Anterior cruciate ligament tear

Blow to a flexed knee at proximal tibia or hyperflexion	Posterior cruciate ligament tear
Blow to anterior knee/patella	Irritation of plica Patellar fracture Bursitis Infrapatellar fat pad irritation
Valgus force	Medial collateral ligament tear Pes anserine strain
Rotational injury with foot fixed on ground	Meniscus
Rotational injury with a valgus force	Anterior cruciate ligament, meniscus, medial collateral ligament
<b>Foot/ankle</b>	
Plantarflexion, inversion of ankle	Ankle sprain with possible associated bifurcate ligament damage, fracture, or peroneal tendon snapping from torn retinaculum
Eversion injury to ankle	Deltoid ligament sprain or rupture Fracture Dislocation
Hyperextension of great toe	Turf-toe injury to capsular ligaments
Landing on heels	Fat pad irritation Ankle or tibial fracture

Determine whether the mechanism is one of overuse.

- In what position does the patient work?
- Does the patient perform a repetitive movement at work or during sports activities? Consider muscle strain, tendinitis, trigger points, or peripheral nerve entrapment.

If insidious, determine the following:

- Are there associated systemic signs of fever, malaise/fatigue, lymphadenopathy, multiple affected

areas, etc.?

- Are there local signs of inflammation including swelling, heat, or redness?
- Is there local deformity?
- Is there associated weakness, numbness, tingling, or other associated neurologic dysfunction?

Determine whether the patient has a current or past history or diagnosis of his or her complaint or other related disorders.

- Are there associated spinal complaints or radiation from the spine? Consider subluxation, nerve root entrapment, or compression.
- Does the patient have a diagnosis of another arthritide, systemic disorder such as diabetes, or past history of cancer?
- Does the patient have “visceral” complaints such as abdominal or chest pain, fever, weight loss, or other complaints?

## Evaluation

- With trauma, palpate for points of tenderness and test for neurovascular status distal to the site of injury; obtain plain films to rule out the possibility of fracture/dislocation.
- Palpate for swelling, masses, and warmth.
- Determine whether swelling is present and if so, whether it is intra- or extra-articular. If extra-articular, attempt to differentiate between bursal versus vascular inflammation.
- If deformity or mass is evident, attempt to differentiate between soft versus bony tissue. The most common

soft tissue causes would include lipomas, neuromas, and ganglions (or other cysts), or fascial herniation.

- With no history of trauma or overuse, consider the use of special imaging, including MRI or CT; bone scan for cancer seeding screen or for stress fracture; electrodiagnostic studies if persistent neurological findings are present; laboratory if systemic findings are present; or synovial fluid analysis if swelling is present or if an arthritide is suspected but in need of differentiation (see **Table 1-2**).
- Palpate and challenge the ligaments and capsule of the joint.
- Challenge the musculotendinous attachments with stretch, contraction, and a combination of contraction in a stretched position.
- Measure the functional capacities of the region involved; determine any associated biomechanical faults that may be contributing to the problem.

**Table 1-2** Synovial Fluid Examination

Type	Examples	Color	Clarity	WBC (per $\mu\text{L}$ )	PMNs	Culture	Glucose	Volume
Normal		Clear	Transparent	<200	<25%	Negative	Nearly = to serum	<3.5
Group I (Noninflammatory)	DJD Trauma Osteochondritis dissecans PVS Osteochondromatosis Neuropathic arthropathy	Yellow	Transparent	200–300	<25%	Negative	Nearly = to serum	Often >3.5
Group II (Inflammatory)	RA Active crystal-induced (gout, pseudogout) Seronegatives (AS, Reiter's psoriatic) Enteropathic (IBD) Rheumatic fever SLE Scleroderma Tuberculosis Mycotic infection	Yellow to opalescent	Transparent to opaque	3,000– 50,000	50% or more	Negative	>25; lower than serum	Often >3.5
Group III (Purulent)	Pyogenic bacterial infection	Yellow to green	Opaque	>50,000	75% or more	Usually positive	<25; much lower than serum	Often >3.5

*Note:* Joint aspiration findings for hemorrhagic causes, including hemophilia, trauma (with or without fracture), neuropathic arthropathy, PVS, and benign neoplasms (e.g., hemangioma) are dominated by blood in the joint. *Legend:* WBC = white blood cell; PMN = polymorphonuclear leukocytes; PVS = pigmented villonodular synovitis; IBD = inflammatory bowel disease (includes ulcerative colitis and regional enteritis)

## Management

- Refer fracture/dislocation, infection, and tumors for orthopaedic management.
- Refer or comanage rheumatoid and connective tissue disorders.
- If the problem is one of instability without ligament rupture, stabilize the joint through an appropriate

exercise program using a brace initially, if necessary, to assist.

- If the problem is weakness, strengthen the associated muscle.
- Functionally retrain the individual for a return to daily activities and occupational or sport requirements.
- Use manipulation/mobilization for articular dysfunction.

## History

A mnemonic approach to the patient's complaints may be helpful in organizing the vast number of possibilities.

Beginning with a description of the patient's complaint, a list of common causes may be attached. WIRS Pain is a mnemonic for **w**eakness, **i**nstability, **r**estricted movement, **s**urface complaints, and **p**ain.

## Weakness

Weakness may be due to pain inhibition, muscle strain, or neurologic interruption at the myoneural junction, peripheral nerve, nerve root, or spinal cord and above. Weakness may be a misinterpretation by the patient when instability or a "loose" joint is present or the patient has stiffness that must be overcome by increased muscular activity.

## Instability

Instability is due to either traumatic damage to ligamentous or muscular support or due to the inherent looseness found in some individuals' joints. This inherent looseness is usually global and can be identified in other joints or acquired as a result of repetitive overstretch positioning. Instability is

most apparent when the joint is positioned so that muscles have less mechanical advantage (e.g., overhead shoulder positions) or when a quick movement demand is faster than the reaction time for the corresponding muscles (e.g., cutting or rotating knee movements).

### **Restricted Movement**

Restricted movement may be due to pain, muscle spasm, stretching of soft tissue contracture, or mechanical blockage by osteophytes, joint mice, fracture, or effusion.

## **Surface Complaints**

Superficial complaints include skin lesions, cuts/abrasions, swelling, and a patient's subjective sense of numbness or paresthesias.

## **Pain**

Pain is nonspecific; however, the cause usually will be revealed by combining a history of trauma, overuse, or insidious onset with associated complaints and significant examination findings. It is important to determine local pain versus referred pain. Following are some guidelines: • Referred pain from scleratogenous sources: Scleratogenous pain presents as a nondermatomal pattern with no hard neurologic findings such as significant decrease in myotomal strength or deep tendon reflex changes. Although the term is used broadly, here we are referring mainly to facet- and disc-generated pain.

- Referred pain from visceral sources: In most cases a historical screening of patients will reveal primary or secondary visceral complaints. It is important to know

the classic referral zones, such as scapular/shoulder pain with cholelithiasis and medial arm pain with cardiac ischemia.

- Bone pain: Bone pain is deep pain, commonly worse in the evening. Trauma may indicate an underlying fracture requiring radiographic evaluation. An overuse history may be suggestive of a stress fracture requiring a radiographic evaluation. If results of the radiograph are negative, but a stress fracture is still suspected, a bone scan is warranted.

A careful history will usually indicate the diagnosis or, at the very least, narrow down the possibilities to two or three. Physical examination and imaging studies more often are used as a confirmation of one's suspicion(s). Generalizing a history approach allows the doctor to address any complaint regardless of region. Generally speaking, damage to structures locally is due to (1) exceeding the tensile stress of ligaments, capsule, muscles, and tendons; (2) compression of bone; (3) demineralization of bone; or (4) intrinsic destructive processes involving arthritides (e.g., pannus formation with rheumatoid arthritis [RA], crystal deposition with gout or pseudogout), infections, or cancer). Although the first two categories are almost always the result of trauma or overuse, the latter two are more commonly insidious. Traumatic and overuse disorders are classically local with regard to signs and symptoms, whereas arthritides and cancer are often either generalized or stereotypical based on the type.

Suspicion of specific structures is based on a basic knowledge of what causes damage to any similar structure regardless of which region or joint is involved. Ligament or capsular injury is often the result of excessive force on the opposite side of the ligament/capsule. For example, a valgus stress (outside to inside force) to the knee will cause an injury to the medial collateral ligament; a varus force, the

lateral collateral ligament. Although more dramatically evident in an acute injury, it must be remembered that low-level, chronic stresses are often the cause of ligamentous or capsular sprain. Muscle injury can be divided into stretch injury and contraction injury. Often when ligaments are damaged, muscle/tendon groups are also involved. Muscles/tendons often act as static stabilizers simply because when they cross the joint, they are in the way when outside forces stretch that joint. Additionally, muscles will often contract in an attempt to protect the joint and either incur damage or impose more damage to the joint. This occurs especially when a joint is in extension (such as the knee and elbow) or in neutral (such as the wrist and ankle). Contraction injury is divided into concentric and eccentric. Usually an overexertion problem, concentric injury often occurs when too heavy a weight is lifted or a sudden explosive muscle activity is required. Concentric injury occurs as the muscle is shortening. Eccentric injury occurs while the muscle is lengthening. Although eccentric injury may occur with lifting, this pattern is frequently seen with overuse or repetitive activity and/or injuries that challenge the decelerator or stabilizer role of the muscle.

Tendons are susceptible primarily to overstrain from a sudden, forceful muscle contraction or from overuse. Occasionally, direct trauma may damage or inflame the tendon or its sheath. Rheumatoid and connective tissue disorders can also affect the synovial lining or paratenon. Sometimes the use of various terminologies in the description of tendon disorders is confusing. Newer terminology replacing older nomenclature causes some of this difficulty, coupled with new theories as to the types of tendon pathology that occur related to its structure and function.<sup>1</sup> Following is an updated list:

- Paratenonitis—This term is replacing tenosynovitis, tenovaginitis, and peritendinitis. It is characterized by inflammation of only the paratenon (lined by synovium or not). Clinical signs are

swelling, pain, crepitation along the tendon, local tenderness, and warmth.

- **Tendinitis**—Now used in place of strain or tear of a tendon. This term refers to symptomatic degeneration of a tendon with vascular disruption and an inflammatory repair response. Stages include: acute, < 2 weeks; subacute, 4–6 weeks; and chronic, > 6 weeks. Three subgroups include: (1) purely inflammatory with acute hemorrhage and tearing, (2) inflammation that is in addition to preexisting degeneration, and (3) calcification and tendinosis that is chronic.
- **Tendinosis**—The newer term used to indicate intratendinous degeneration due to atrophy (due to aging, microtrauma, vascular compromise, etc.). This is considered noninflammatory with hypocellularity, variable vascular ingrowth, local necrosis, and/or calcification, with accompanying fiber disorientation. Palpable nodules can be found, such as in the Achilles, with or without tenderness.
- **Paratenonitis with tendinosis**—This describes a paratenon inflammation associated with intratendinous degeneration. Unlike tendinosis, this combination of pathologies presents clinically with a possible palpable tendon nodule, with accompanying signs of swelling and inflammation.

Bursae are protective cushions placed strategically at points of friction, particularly between muscle/tendon and bone. Although there are standard bursae in most individuals, adventitious bursae may develop at sites of repetitive friction in individuals performing specific activities. Bursae may be deep or superficial. Superficial bursae are susceptible to direct traumatic forces. Deep bursae are more susceptible to compression by bone or soft tissue structures. Compression is often position-specific,

such as during overhead movements with the shoulder. Bursitis may be secondary to other soft tissue involvement such as calcific tendinitis.

When musculoskeletal pain does not have an obvious mechanical or traumatic cause, a search is initiated for myofascial disorders, arthritides, psychological factors, connective tissue disorders, cancer, and infection (see **Table 1-3**).

Arthritis has a “geriatric” connotation, yet it may affect any age group. The term simply means that the joint is affected. Generally, arthritis is due to degeneration or destruction that is age-related or trauma-related, infectious, inflammatory, and/or autoimmune. Based on the cause, arthritis may present as a monoarthropathy (i.e., single joint), an oligoarthropathy (2–4 joints), or a polyarthropathy ( $\geq 5$  joints). When a single joint is involved, gout (first toe), infectious (direct infection or indirect spreading from another source such as gonococcal), or trauma should be considered. When multiple joints are involved a distinction in thinking occurs differentiating degenerative, inflammatory (primarily rheumatoid and rheumatoid variants), and crystalline induced (primarily gout, pseudogout, amyloidosis, etc.). Seronegatives and enteropathic arthropathies tend to be oligoarticular, whereas RA and LE tend to involve more joints.

When considering arthritis as a cause of joint pain, there are several other general factors that when considered separately and then clustered together provide a good tool for narrowing the large list of possibilities. The sequence of how these factors are considered may change given the presentation of the patient, yet the discussion will begin with age. There are very few arthritides that affect the young. Primarily, juvenile rheumatoid arthritis or arthritis secondary to other diseases would be considered. For the young to middle-aged adult, primarily inflammatory and/or autoimmune arthritides are considered, including: •

Seronegative arthritides (i.e., negative for rheumatoid factor) including ankylosing spondylitis (AS), Reiter's, and psoriatic • Rheumatoid arthritis (RA)

- Scleroderma
- Lupus erythematosus (LE)
- Osteitis condensans illi
- Synoviochondrometaplasia

For onset in the senior, the primary considerations include:

- Degenerative joint disease; osteoarthritis (OA)
- Diffuse idiopathic skeletal hyperostosis (DISH)
- Hypertrophic osteoarthropathy
- Gout
- Pseudogout; calcium pyrophosphate dihydrate (CPPD) deposition disease

Considering gender, males are more prone toward AS, Reiter's, gout, hypertrophic osteoarthropathy, and secondary OA. Females are more prone toward juvenile and adult RA, LE, scleroderma, and osteitis condensans illi, as examples. Further distinction can be made from a pattern of joint involvement. For example, OA tends to affect large joints such as the knee and hip, with eventual involvement in the hands (specifically first metacarpal phalangeal and distal interphalangeal joints), whereas RA tends to affect the metacarpal and proximal interphalangeal joints of the hand first and then larger joints. Gout tends to affect the first toe and knees primarily. The seronegatives tend to affect the sacroiliac joint or spine with possible affect in peripheral joints. Finally, associated systemic signs may help relate the arthritis to disorders such as LE, scleroderma, enteropathic arthritides (i.e., arthritis associated with inflammatory bowel disease), and so on.

**Table 1-3** Selected Arthritic Disorders

Type	Features	Management Issues
<b>Degenerative</b>		
Primary osteoarthritis	<p><b>Age of Onset</b>—Generally &gt; 45 y/o</p> <p><b>Gender Predominance</b>—Ratio of female to male = 10:1</p> <p><b>Common Joints Involved</b>—Hips, knees, SI joint, AC joint, first MCP, first MC trapezium, DIP joints of hands</p> <p>Often initially asymptomatic; gradual increase in joint stiffness and pain. Deformity may be apparent (e.g., Heberden's nodes in hands). May eventually lead to joint subluxation and instability.</p> <p>Radiographically: The distribution is asymmetric, with nonuniform loss of joint space, osteophyte formation, subchondral sclerosis (eburnation), subchondral cysts.</p>	Management in early and middle stages should include strengthening around involved joints. If weight-bearing joint, begin with non-weight-bearing and progress cautiously to weight-bearing if possible. Maintenance of normal joint motion and function may be facilitated by adjusting/manipulation or mobilization. Dietary approaches include glucosamine and chondroitin sulfate. Medical management may include recommendations for NSAIDs, in particular, COX-2 inhibitors. Some medical specialists may recommend viscosupplementation (injection of hyaluronic acid into the degenerative joint). This is of questionable value. In some joints, joint replacement is necessary.
Secondary osteoarthritis	<p><b>Age of Onset</b>—&gt; 25 years</p> <p><b>Gender Predominance</b>—Equal</p> <p><b>Common Joints Involved</b>—GH, AC, SI, hip, elbow, knee, foot, hand</p> <p>Cause is secondary to other disorders or diseases/injuries such as trauma, septic or inflammatory arthritis, slipped epiphyses, dysplasias, fracture/dislocation, avascular necrosis, ochronosis, and acromegaly. Similar radiographic presentation.</p>	Management in early and middle stages should include strengthening around involved joints. If weight-bearing, begin with non-weight-bearing and progress cautiously to weight-bearing if possible. Maintenance of normal joint motion and function may be facilitated by adjusting/manipulation or mobilization. Dietary approaches include glucosamine and chondroitin sulfate. Medical management may include recommendations for NSAIDs, in particular, COX-2 inhibitors. Some medical specialists may recommend viscosupplementation (injection of hyaluronic acid into the degenerative joint). This is of questionable value. In some joints, joint replacement is necessary.
Erosive osteoarthritis	<p><b>Gender Predominance</b>—Female</p> <p><b>Common Joints Involved</b>—Interphalangeal joints of hand</p> <p><b>Age of Onset</b>—40–50 y/o</p> <p>Inflammatory variant of DJD characterized by cartilage degeneration and synovial proliferation. Acute episodes that appear similar to inflammatory/synovial arthritis; chronically may evolve to subluxation and development of Heberden's nodes. Radiologically similar to OA with additional finding of central erosions.</p>	<p>Management in early and middle stages should include strengthening around involved joints. If weight-bearing, begin with non-weight-bearing and progress cautiously to weight-bearing if possible. Dietary approaches include glucosamine and chondroitin sulfate. Medical management may include recommendations for NSAIDs, in particular, COX-2 inhibitors. In addition, the following anti-inflammatory medications may be suggested:</p> <ul style="list-style-type: none"><li>• DMARDs—Disease-modifying antirheumatic drugs (e.g., methotrexate [Rheumatrex and Trexall], hydroxychloroquine [Plaquenil], and leflunomide [Arava]). These are toxic and may take weeks to months to work, yet are highly effective.</li><li>• Biologic agents—reduce the production of tissue necrosis factor (TNF) (e.g., Enbrel and Remicade sometimes given together with methotrexate).</li></ul>

Degenerative spine disease	<p><b>Age of Onset</b>—&gt; 30 y/o</p> <p><b>Gender Predominance</b>—Equal</p> <p><b>Common Joints Involved</b>—Specific spinal involvement at C5–C7, T2–T5, T10–T12, L4–S1 with additional involvement of uncovertebral, costovertebral, discovertebral, and apophyseal (facet) joint involvement. Range from asymptomatic to severely symptomatic with pain and stiffness. Radiographic to clinical correlation is poor. May contribute to IVF narrowing and spinal stenosis. Common radiographic findings include disc space narrowing, hypertrophy of smaller joints such as facets and costovertebral, synovial cysts, Schmorl's nodes, and intradiscal vacuum phenomena. In middle stages, joint and capsular laxity may lead to subluxation and listhesis.</p>	<p>Management in early and middle stages should include strengthening of the spinal muscles with a focus on abdominal strengthening and extensor strengthening and stretching. The three-joint complex model stresses the need to consider the interrelationship of facets joint and intervertebral disc joints in the progression of DJD of the spine. Maintenance of normal joint motion and function may be facilitated by adjusting or manipulation or mobilization. Dietary approaches include an anti-inflammatory dietary regimen and use of glucosamine and chondroitin sulfate. Medical management may include recommendations for NSAIDs, in particular, COX-2 inhibitors for pain management.</p>
Diffuse idiopathic skeletal hyperostosis (DISH) (synonyms: ankylosing hyperostosis, Forestier's disease)	<p><b>Age of Onset</b>—50 y/o and older</p> <p><b>Gender Predominance</b>—Male</p> <p><b>Common Joints Involved</b>—Spine; predominantly T7–T11 (calcification of anterior longitudinal ligament) with 30% peripheral joint involvement. Found in 25% of men and 15% of women &gt;50 y/o (common). May be asymptomatic; when symptomatic, similar complaints associated with DJD such as stiffness and pain; 20% of patients report dysphagia; occasional complaints involving the Achilles tendon, extensor wad of wrist/forearm, plantar fascia, and quadriceps tendon (may find enthesophytes at corresponding sites); about a quarter of patients have diabetes. Radiographically: Diffuse, thick, hyperostosis primarily along the anterolateral aspect of spine ("flowing wax" appearance); 50% of patients also have ossification of the PLL, especially in the cervical spine.</p>	<p>Management in early and middle stages should include strengthening of the spinal muscles with a focus on abdominal strengthening and extensor strengthening and stretching. Dietary approaches include an anti-inflammatory dietary regimen and use of glucosamine and chondroitin sulfate, yet DISH appears to follow its own course of progression specific to the individual but generally always progressive. Medical management may include recommendations for NSAIDs, in particular, COX-2 inhibitors for pain management.</p>
Neuropathic (neurotrophic) arthropathy	<p><b>Age of Onset</b>—Variable</p> <p><b>Gender Predominance</b>—Variable</p> <p><b>Common Joints Involved</b>—Knee, hip, ankle, spine, shoulder, elbow, wrist, foot.</p> <p>Variable upper motor and lower motor lesions cause a combination of loss of proprioception and pain perception leading to joint destruction. Conditions include syringomyelia, diabetes, tabes dorsalis, multiple sclerosis, Charcot-Marie-Tooth disease, prolonged use of intra-articular corticosteroids, pernicious anemia, and leprosy, among others. A somewhat separate but related cause is spinal cord damage resulting in paraplegia or quadriplegia, which results in usually asymptomatic bony ankylosis. Radiographically neuropathic arthropathy is seen as joint collapse, pseudarthrosis, fragmentation, and deformity.</p>	<p>Treatment is directed toward the primary disease. If in weight-bearing joints, mechanical assistance is often required. In severe cases, amputation is necessary.</p>
Synoviochondrometaplasia (idiopathic synovial osteochondromatosis)	<p><b>Age of Onset</b>—30–50 y/o</p> <p><b>Gender Predominance</b>—Ratio of male to female = 3:1</p> <p><b>Common Joints Involved</b>—Knee, hip, ankle, elbow, wrist.</p> <p>Synoviochondrometaplasia, as the name implies, is a synovial metaplasia that results in the formation of cartilage that then forms loose bodies in the joint. This process is usually idiopathic but may be the result of trauma. The patient will report increasing pain, swelling, crepitus, and locking due to the loose bodies. Radiographically the loose bodies can be seen if radiopaque. Sometimes erosion may occur as in the "apple-core" deformity of the hip.</p>	<p>Synovectomy for most patients. Joint replacement may be recommended for older patients.</p>
<b>Inflammatory</b>		
Positive for Rheumatoid Factor (Seropositive)		
Rheumatoid arthritis (RA)	<p><b>Age of Onset</b>—25–55 y/o</p> <p><b>Gender Predominance</b>—Female to male ratio = 2:1 to 3:1</p> <p><b>Common Joints Involved</b>—Hand, foot, wrist, knee, elbow, GH joint, AC joint, and cervical spine (atlantoaxial). A symmetric, bilateral, polyarticular disorder of the synovial membrane resulting in joint pain, swelling, and destruction. Also involved are ligaments, tendons, and bursae. The diagnostic criteria includes: Deformities such as Boutonniere, swan-neck, phalangeal deviation, and arthritis mutilans; morning stiffness that lasts longer than 1 hour, specific swelling of several joints (including the PIP joints, MCP joint, and wrist), rheumatoid nodules, positive for rheumatoid factor, and radiographic evidence that includes erosions or periarticular osteopenia or both in hands or wrists or both. Need four or more of the above for at least 6 weeks.</p> <p>Additional symptoms may include fatigue, anorexia, weight loss, and muscular pain/stiffness.</p> <p>Special concern is for atlantoaxial instability due to ligament erosion and a resulting risk of excessive movement leading to spinal cord compression.</p>	<p>Caution with rheumatoid conditions is unpredictable flare-ups. Given that some of the therapies employed by chiropractic are mechanical, including adjusting, soft tissue therapy, and physiotherapy, it is important to keep in mind that this is an inflammatory condition and can be exacerbated by these therapies.</p> <p>Incorporate an anti-inflammatory diet regimen (see Table 1–9).</p> <p>Medical management includes:</p> <ul style="list-style-type: none"> <li>• NSAIDs—COX-1 inhibitors (e.g., ibuprofen, naproxen) or COX-2 inhibitors (e.g., Celebrex).</li> <li>• Corticosteroids</li> <li>• DMARDs—disease-modifying antirheumatic drugs (e.g., methotrexate [Rheumatrex and Trexall], hydroxychloroquine [Plaque-nil], and leflunomide [Arava]). These are toxic and may take weeks to months to work, yet are highly effective.</li> <li>• Biologic agents—Reduce the production of tissue necrosis factor (TNF) (e.g., Enbrel and Remicade sometimes given together with methotrexate). May be administered as infusion therapy.</li> </ul>

Juvenile chronic arthritis	<p><b>Age of Onset</b>—5–10 y/o</p> <p><b>Gender Predominance</b>—Variable based on specific disorder</p> <p><b>Common Joints Involved</b>—Hand, foot, wrist, knee, elbow, heel, hip, and cervical spine.</p> <p>Several types including:</p> <ul style="list-style-type: none"> <li>• Juvenile-onset adult RA—same findings as RA</li> <li>• Still's disease—more of a systemic disease</li> <li>• Juvenile onset of seronegative arthropathies—see each disorder</li> </ul> <p>Radiographically similar with the possible addition of growth disturbances of bone and epiphyseal compression fractures.</p>	<p>Caution with rheumatoid conditions is unpredictable flare-ups. Given that some of the therapies employed by chiropractic are mechanical, including adjusting, soft tissue therapy, and physiotherapy, it is important to keep in mind that this is an inflammatory condition and can be exacerbated by these therapies.</p> <p>Medical management includes:</p> <ul style="list-style-type: none"> <li>• NSAIDs—COX-1 inhibitors (e.g., ibuprofen, naproxen) or COX-2 inhibitors (e.g., Celebrex).</li> <li>• DMARDs—disease-modifying antirheumatic drugs (e.g., methotrexate [Rheumatrex and Trexall], hydroxychloroquine [Plaque-nil], and leflunomide [Arava]). These are toxic and may take weeks to months to work, yet are highly effective.</li> <li>• Biologic agents—Reduce the production of tissue necrosis factor (TNF) (e.g., Enbrel and Remicade are sometimes given together with methotrexate). May be administered as infusion therapy.</li> <li>• Corticosteroids—Rarely needed.</li> </ul>
Negative for Rheumatoid Factor (Seronegative)		
Ankylosing spondylitis (AS)	<p><b>Age of Onset</b>—15–35 y/o</p> <p><b>Gender Predominance</b>—Male to female ratio = 4:1 to 10:1</p> <p><b>Common Joints Involved</b>—SI joint, thoracolumbar spine, cervical spine, symphysis pubis, hip, shoulder, and heel.</p> <p>Complaints often begin with SI pain and progress to low back and thoracic stiffness.</p> <p>Eventually there may be a decrease in chest expansion. Peripheral joint involvement occurs in approximately 50% as does radiating pain to the lower extremity. Areas of concern include iritis (20% of cases), aortic insufficiency, aneurysms, pulmonary fibrosis, pleuritis, IBD, and amyloidosis.</p> <p>Laboratory findings include an increased ESR during active phases, negative for RA and LE factors; HLA B-27, positive in 80% (positive in 6–8% of general population).</p> <p>Radiographically there are classic signs, including symmetrical involvement of the SI joints, ligament calcification, and marginal syndesmophytes, eventually leading to “trolley-track” sign, and bamboo spine.</p>	<p>Caution with rheumatoid conditions is unpredictable flare-ups. Given that some of the therapies employed by chiropractic are mechanical, including adjusting, soft tissue therapy, and physiotherapy, it is important to keep in mind that this is an inflammatory condition and can be exacerbated by these therapies.</p> <p>Medical management includes:</p> <ul style="list-style-type: none"> <li>• NSAIDs—COX-1 inhibitors (e.g., ibuprofen, naproxen) or COX-2 inhibitors (e.g., Celebrex).</li> <li>• DMARDs—disease-modifying antirheumatic drugs (e.g., methotrexate [Rheumatrex and Trexall], hydroxychloroquine [Plaque-nil], and leflunomide [Arava]). These are toxic and may take weeks to months to work, yet are highly effective.</li> <li>• Biologic agents—Reduce the production of tissue necrosis factor (TNF) (e.g., Enbrel and Remicade are sometimes given together with methotrexate). May be administered as infusion therapy.</li> <li>• Corticosteroids—Rarely needed.</li> </ul>
Reiter's syndrome	<p><b>Age of Onset</b>—15–35 y/o</p> <p><b>Gender Predominance</b>—Male to female ratio = 5:1 to 50:1 depending upon study</p> <p><b>Common Joints Involved</b>—SI joint, foot, heel, ankle, knee, hip, spine; more rarely the upper extremity.</p> <p>Urethritis and other eye complaints often following a STD or gastrointestinal infection.</p> <p>Keratitis, keratoderma, and keratosis of nails may be found. Systemic findings may include fever, weight loss, thrombophlebitis, or amyloidosis. Lab findings may include positive HLAB27 (75%), leukocytosis, anemia, and elevated ESR. Radiographically SI joint is prominent, atlantoaxial instability, nonmarginal syndesmophytes. Similar to psoriatic arthritis, a single digit may be involved (sausage finger) and enthesopathies are common as in AS. Monitor for aortic regurgitation in chronic cases.</p>	<p>Caution with rheumatoid conditions is unpredictable flare-ups. Given that some of the therapies employed by chiropractic are mechanical, including adjusting, soft tissue therapy, and physiotherapy, it is important to keep in mind that this is an inflammatory condition and can be exacerbated by these therapies.</p> <p>Medical management includes:</p> <ul style="list-style-type: none"> <li>• NSAIDs—COX-1 inhibitors (e.g., ibuprofen, naproxen) or COX-2 inhibitors (e.g., Celebrex).</li> <li>• DMARDs—disease-modifying antirheumatic drugs (e.g., methotrexate [Rheumatrex and Trexall], hydroxychloroquine [Plaque-nil], and leflunomide [Arava]). These are toxic and may take weeks to months to work, yet are highly effective.</li> <li>• Biologic agents—Reduce the production of tissue necrosis factor (TNF) (e.g., Enbrel and Remicade are sometimes given together with methotrexate). May be administered as infusion therapy.</li> <li>• Corticosteroids—Rarely needed.</li> </ul>
Psoriatic	<p><b>Age of Onset</b>—20–50 y/o</p> <p><b>Gender Predominance</b>—Generally equal</p> <p><b>Common Joints Involved</b>—Hand, foot, SI joint, thoracolumbar spine, and cervical spine.</p> <p>Only about 5% of those with skin disease have the joint involvement. There are various patterns, yet many times the proximal and distal IP joints are involved. A deforming type may lead to arthritis mutilans. In addition to possibly having scaly patches of skin (psoriasis) on the extensor surfaces of the knees and elbows, patients may also have nail changes, including pitting, discoloration, and splintering. In some cases hyperostosis occurs at the SC joint. Other skin lesions may occur in the hands and feet. Lab includes HLA-B27 antigen (60% of cases), mild anemia, elevated ESR during active periods, occasionally elevated uric acid levels. Radiographically the involvement of the hands is similar to RA. In addition, one digit is often affected (sausage finger) and tuft resorption and proliferation (ivory phalanx) occur. In the spine, nonmarginal syndesmophytes may be seen.</p>	<p>Caution with rheumatoid conditions is unpredictable flare-ups. Given that some of the therapies employed by chiropractic are mechanical including adjusting, soft tissue therapy, and physiotherapy, it is important to keep in mind that this is an inflammatory condition and can be exacerbated by these therapies. When arthritis is present, cyclosporine, methotrexate, and acitretin are used. Methotrexate is associated with hepatic toxicity; cyclosporine associated with hypertension and nephrotoxicity; and acitretin is associated with elevated serum lipids, mucocutaneous toxicity, and teratogenicity. New drugs are being marketed that, although highly promising, are extremely expensive. These drugs are part of a new class of medications called immune modulators (also known as biological response modifiers or “biologics”). The mechanism for these new drugs is either to block and reduce abnormal T-lymphocyte activity or the inflammatory response. Examples are alefacept and etanercept. (The “-cept” ending is an indication of the drug's effect, which is fusion of a receptor to the Fc portion of human IgG.)</p>

Enteropathic (associated with inflammatory bowel disease [IBD])	<p><b>Age of Onset</b>—Variable</p> <p><b>Gender Predominance</b>—Variable</p> <p><b>Common Joints Involved</b>—SI joint and spine; occasionally peripheral joint involvement.</p> <p>Many inflammatory disorders affecting the GI tract may result in an arthritis similar to the seronegative arthritides. Disorders include Crohn's, ulcerative colitis, Whipple's disease, and infections, including Salmonella, Shigella, and Yersinia. Intestinal bypass surgery may also be related.</p> <p>The frequency of IBD and AS is about 15%. Laboratory reveals HLA-B27 in 90% of those with IBD and arthritis. Radiographic findings are similar to AS, including SI involvement and the spine.</p>	<p>Caution with rheumatoid conditions is unpredictable flare-ups. Given that some of the therapies employed by chiropractic are mechanical, including adjusting, soft tissue therapy, and physiotherapy, it is important to keep in mind that this is an inflammatory condition and can be exacerbated by these therapies. Use anti-inflammatory approaches in diet and supplement recommendations and physiotherapy management. Medical management includes:</p> <ul style="list-style-type: none"> <li>• NSAIDs—COX-1 inhibitors (e.g., ibuprofen, naproxen) or COX-2 inhibitors (e.g., Celebrex).</li> <li>• DMARDs—disease-modifying antirheumatic drugs (e.g., methotrexate [Rheumatrex and Trexall], hydroxychloroquine [Plaque-nil], and leflunomide [Arava]). These are toxic and may take weeks to months to work, yet are highly effective.</li> <li>• Biologic agents—Reduce the production of tissue necrosis factor (TNF) (e.g., Enbrel and Remicade are sometimes given together with methotrexate).</li> <li>• Corticosteroids.</li> </ul>
Systemic lupus erythematosus (SLE)	<p><b>Age of Onset</b>—20–45 y/o</p> <p><b>Gender Predominance</b>—Female more than male</p> <p><b>Common Joints Involved</b>—Hand and osteonecrosis, specifically of femur (head and condyles) and sometimes shoulder (humeral head).</p> <p>A systemic autoimmune disorder characterized by multisystem involvement resulting in generalized findings such as fever, anorexia, weight loss, malaise, and weakness. Visceral inflammation occurs. Skin affects include rashes (e.g., butterfly malar rash). Polyarthritis is common.</p> <p>Like many patients with autoimmune rheumatoid conditions, tendons are weakened and may rupture. Laboratory reveals anemia with leucopenia and plasma protein abnormalities (protein electrophoresis usually ordered due to globulin increase). Antinuclear antibody and LE cells present. A false-positive syphilis test may occur. Radiographically a symmetric, nonerosive yet deforming arthropathy is seen. Osteonecrosis may be seen due to the disease or due to treatment (corticosteroids).</p>	<p>Given that some of the therapies employed by chiropractic are mechanical, including adjusting, soft tissue therapy, and physiotherapy, it is important to keep in mind that this is an inflammatory condition and can be exacerbated by these therapies. Protection of the skin includes avoiding sunlight, and it is important when exposed to use a sunblock with SPF 15 or higher. Primary treatment is prednisone for joint pain, cutaneous lesions, and renal and CNS involvement. Other medical therapies include antimalarials (hydroxychloroquine) and NSAIDs. Infection is common due to immunosuppression and is the cause of death in one-third of cases. Blacks and Hispanics fare worse. Pericarditis is found in 25% of patients. Also, screening for renal function is important to determine disease activity.</p>
Scleroderma (progressive systemic sclerosis)	<p><b>Age of Onset</b>—20–30 y/o</p> <p><b>Gender Predominance</b>—Female more than male</p> <p><b>Common Joints Involved</b>—Hand, wrist, foot, ribs, and, more rarely, the spine.</p> <p>There are two types of this collagen-vascular disease: one with systemic involvement (progressive) and one without (localized). Scleroderma is characterized by involvement of multiple organs including skin, heart,</p>	<p>Management is for various aspects of the disease. Following are combinations of medical and conservative approaches:</p> <p><i>Raynaud's</i></p> <ul style="list-style-type: none"> <li>• Calcium channel blockers</li> <li>• Peripheral adrenergic blockers</li> <li>• Protective measures against cold, cessation of smoking, and decreased use of caffeine and other sympathomimetics</li> </ul>

lungs, kidneys, GI tract, and musculoskeletal system; therefore, signs and symptoms are quite variable. Muscle weakness, including dysphagia; Raynaud's phenomenon; hyperpigmentation; vitiligo and telangiectasias; and thickening and tightening of the skin of the face, hands, and feet. Laboratory findings include an elevated ESR (60–70%), positive RF (20–40%), positive ANA (35–96%), and a high protein level in synovial fluid. Radiographically there are periarticular and subcutaneous calcifications including paraspinal, phalangeal tuft, and superior rib erosions.

#### *Renal*

- Initially ACE inhibitors; may lead to dialysis or kidney transplant

#### *Pulmonary hypertension*

- May require oxygen or lung transplant in serious cases

#### *Esophageal reflux*

- Avoid large meals and a recumbent position after meals
- Avoid sympathomimetic substances and certain foods
- H2 inhibitors and/or proton-pump inhibitors

#### *Arthralgias*

- NSAIDs

Given that some of the therapies employed by chiropractic are mechanical, including adjusting, soft tissue therapy, and physiotherapy, it is important to keep in mind that this is an inflammatory condition and can be exacerbated by these therapies.

Dermatomyositis and polymyositis	<p><b>Age of Onset</b>—5–10 y/o and again at 20–50 y/o</p> <p><b>Gender Predominance</b>—Female to male ratio = 2:1</p> <p><b>Common Joints Involved</b>—Soft tissues primarily of the thigh, leg, and arm. Dermatomyositis affects skin and muscle, whereas polymyositis affects primarily muscle. The affect is inflammation and degeneration of striated muscle with a laying down of sheet-like calcifications in soft tissue. About half of patients have arthritis while one-third have Raynaud's phenomenon. Disability occurs due to progressive symmetric, proximal muscle weakness. Laboratory findings include CPK elevations and elevations in urinary creatinine levels. EMG reveals a proximal myopathy as does muscle biopsy. Radiographically, there is soft tissue atrophy coupled with sheet-like soft tissue calcifications and sometimes ossification. Like other inflammatory conditions, there is phalangeal tuft resorption.</p>	<p>Given that some of the therapies employed by chiropractic are mechanical, including adjusting, soft tissue therapy, and physiotherapy, it is important to keep in mind that this is an inflammatory condition and can be exacerbated by these therapies. Protection of the skin with sunblock of SPF 15 or higher is important; provide physical therapy to keep muscle stretch and strength. If dysphagia is present, speech therapy should be employed. Inflammatory aspect may be managed medically with prednisone, immunosuppressive therapy such as methotrexate or azathioprine. Approximately 50% go into remission in 5 years, with an approximate 75% 8-year survival. Those who do not remiss remain on therapy.</p>
Mixed connective tissue disease	<p><b>Age of Onset</b>—20–50 y/o</p> <p><b>Gender Predominance</b>—Female more than male</p> <p><b>Common Joints Involved</b>—Hand, wrist, and foot.</p> <p>This group of conditions is an overlap of several specific diseases such as RA, SLE, dermatomyositis, and scleroderma. Laboratory findings include specific findings for each disorder and presence of ribonuclease-sensitive extractable nuclear antigen. Radiographic findings are those for each disorder and include joint destruction with marginal erosions and soft tissue calcification.</p>	<p>Caution with rheumatoid conditions is unpredictable flare-ups. Given that some of the therapies employed by chiropractic are mechanical, including adjusting, soft tissue therapy, and physiotherapy, it is important to keep in mind that this is an inflammatory condition and can be exacerbated by these therapies.</p> <p>The medical management approach would include those for the underlying disorders. See management under each.</p>

Hypertrophic osteoarthropathy (Marie-Bamberger syndrome or pulmonary osteoarthropathy)	<p><b>Age of Onset</b>—40–60 y/o</p> <p><b>Gender Predominance</b>—Primarily male</p> <p><b>Common Joints Involved</b>—Fingers (clubbing); periostitis in tibia, fibula, radius, and ulna. There is a triad of peripheral arthritis with clubbing of the fingers and periostitis of the distal long bones. This process appears to be secondary to processes in thorax or abdomen, most commonly, bronchogenic carcinoma, and seems to be neurovascular due to vagus nerve dysfunction.</p> <p>Patients often have signs only of the underlying disorder. Radiographic findings include the digital clubbing and long bone symmetrical periostitis.</p>	<p>Identification of the underlying disorder directs appropriate treatment measures. In some cases the hypertrophic osteoarthropathy may improve or disappear with effective care. This may include chemotherapy for tumors or antibiotic therapy for chronic pulmonary infection. In some cases vagotomy or percutaneous vagal blockade is necessary for symptomatic relief.</p> <p>NSAIDs and similar agents are used initially for symptom control.</p>
Osteitis condensans illi	<p><b>Age of Onset</b>—20–40 y/o</p> <p><b>Gender Predominance</b>—Female to male ratio = 9:1</p> <p><b>Common Joints Involved</b>—Sacroiliac.</p> <p>This bilateral disorder affects females probably through a combination of ligament laxity (hormonally induced) and mechanical stresses that lead to sclerotic changes in the iliac subchondral bone. The process is often asymptomatic. When symptomatic, may present as low back pain with or without leg pain; however, caution must be taken when attempting to relate the radiographic changes to symptoms. The condition, if symptomatic, appears to be primarily self-limiting.</p>	<p>When symptomatic, management includes anti-inflammatory approaches. Generally self-resolving.</p>
Osteitis pubis	<p><b>Age of Onset</b>—Varies, but with females during the reproductive years</p> <p><b>Gender Predominance</b>—Female predominant</p> <p><b>Common Joints Involved</b>—Symphysis pubis.</p> <p>An inflammatory process secondary to trauma, pelvic surgery, or childbirth. This is particularly true if complicated by infection. Possibly due to intraosseous venous congestion and/or infection. Radiographically appears as joint space widening, subchondral sclerosis, localized osteoporosis, and joint erosions.</p>	<p>Initial management may be with NSAIDs and rest. More severe cases may require oral or locally injected corticosteroids. In rare cases, arthrodesis is necessary.</p>
<b>Metabolic</b>		
<b>Crystal Deposition</b>		
Gout	<p><b>Age of Onset</b>—&gt; 30 y/o (in females, postmenopausal)</p> <p><b>Gender Predominance</b>—Male</p> <p><b>Common Joints Involved</b>—First MTP joint of foot, feet, ankle, and knees</p> <p>First attack is often sudden and nocturnal, affecting the first MCP joint of foot. This may follow excess alcohol or meat intake. Fever is common during the acute attack. The joint is red and swollen. Desquamation and pruritus after the acute attack are common. Tophi (calcium urate deposits) appear after several attacks of gout and are found behind the ears, olecranon, prepatellar bursae, hands, and feet. There is a dramatic response to NSAIDs or colchicines during the acute attack. Those with gout should be evaluated for associated conditions including alcoholism, various nephropathies, myeloproliferative disorders, hypertension, and insulin resistance.</p> <p>Occurrence in 2nd and 3rd decade indicates hereditary disorders such as hypoxanthine guanine phosphoribosyltransferase deficiency. Hyperuricemia is common, especially during acute attacks; joint aspiration reveals calcium urate crystals. Radiographically, joint destruction with soft tissue swelling and radiolucent spots (urate crystals) are evident.</p>	<p>For those with single attack, lifestyle modification first.</p> <p>Diet—attention to hydration, low-purine diet (avoid meat, yeasts including beer/alcohol, beans, legumes), alcohol avoidance, lose weight.</p> <p>Medication avoidance—hyperuricemic meds such as thiazide and loop diuretics; also avoid low-dose aspirin and niacin.</p> <p>Medical approach—acute attacks; NSAIDs or corticosteroids, or colchicines (for inflammation); long-term approach incorporates drugs to reduce serum uric acid and decrease tophi deposits; primarily allopurinol (xanthine-oxidase inhibitor) and probenecid. Low-dose colchicines are acceptable as a prophylaxis for first 6 months.</p>
Calcium pyrophosphate deposition disease (CPDD)	<p><b>Age of Onset</b>—&gt; 50 y/o</p> <p><b>Gender Predominance</b>—Generally equal dependent on cause</p> <p><b>Common Joints Involved</b>—Knee, symphysis pubis, hand, wrist, hip, shoulder, elbow, spine.</p> <p>CPDD crystal deposition in soft tissue occurs due to trauma, several metabolic diseases, and other causes. The general term <i>chondrocalcinosis</i> is associated with metabolic disorders that include hemochromatosis, hyperparathyroidism, ochronosis, diabetes, hypothyroidism, Wilson's disease, among others. There are various subtypes such as pseudogout, pseudorheumatoid arthritis, and pseudodegenerative joint disease. The most common, pseudogout, may appear similar to gout; however, it occurs at a later age in most instances. May be asymptomatic or symptomatic. When symptomatic, pain and swelling occur. Joint aspiration reveals pyrophosphate crystals in synovial fluid. ESR is elevated during acute attacks.</p> <p>Calcification of intra- and extra-articular structures with eventual articular destruction and fragmentation.</p>	<p>Management may include joint aspiration, short-term use of NSAIDs or colchicines, or corticosteroid injection during acute attacks. For recurrent attacks, low-dose colchicines have been used as have corticosteroids. Antimalarial medications have also been used in some cases. Radioactive synovectomy has also been performed on some patients.</p>

Hydroxyapatite deposition disease	<p><b>Age of Onset</b>—40–70 y/o</p> <p><b>Gender Predominance</b>—Equal</p> <p><b>Common Joints Involved</b>—Shoulder, hip, cervical spine.</p> <p>This idiopathic process results in calcium (hydroxyapatite) deposition in tendons, bursae, and other periarticular soft tissue. In the spine this may include nucleus pulposus calcification.</p> <p>Technically not an arthritis, pain is felt around joints. It is believed that symptoms develop as the process resolves (inflammation) rather than during the deposition process.</p> <p>Radiographically, soft tissue opacities are seen around the joint.</p>	<p>Management may include joint aspiration, short-term use of NSAIDs or colchicines, or corticosteroid injection during acute attacks. For recurrent attacks, low-dose colchicine has been used as has corticosteroids. Pulsed ultrasound using iontophoresis may be of benefit.</p>
<b>Other</b>		
Sarcoidosis	<p><b>Age of Onset</b>—20–40 y/o</p> <p><b>Gender Predominance</b>—Equal</p> <p><b>Common Joints Involved</b>—Hands, wrists, and feet.</p> <p>This is a systemic disease that produces noncaseating granulomas. It is more common in Scandinavian and Black populations. Generalized symptoms/signs predominate with low-grade fever, rash, lymphadenopathy, malaise, fatigue, arthralgias, and iritis. A subgroup of patients has Löfgren's syndrome. Laboratory findings include a reverse A/G ratio, elevated ESR, hypercalcemia, and a positive Kveim test. Skeletal involvement occurs in 15% of patients.</p> <p>Radiographically, granulomas are seen in the perihilar region of the lungs with infiltrates and fibrosis. In joints there may be circumscribed, lytic, intraosseous lesions.</p>	<p>Arthritis is managed similar to rheumatoid arthritis, incorporating corticosteroids in severe cases or colchicine as is used with gout.</p> <p>Unknown whether an anti-inflammatory diet is helpful.</p>
Hemochromatosis	<p><b>Age of Onset</b>—40–60 y/o</p> <p><b>Gender Predominance</b>—Male to female ratio = 10:1 to 20:1</p> <p><b>Common Joints Involved</b>—Hip, knee, shoulder, wrist, hand.</p> <p>Rare disorder involving deposition of iron into various tissues. Triad includes bronze skin, liver cirrhosis, and diabetes mellitus. When joints are affected there may be pain, stiffness, and swelling; usually bilaterally; however, may begin in a single joint. Laboratory includes elevated ESR and serum iron, increased saturation of plasma iron binding protein transferrin, and liver biopsy findings. Radiographically, usually bilateral involvement with osteoporosis, CPDD crystal deposition (50% of patients), and involvement of MCP joints.</p>	<p>Weekly phlebotomy is the treatment approach to prolong lives.</p>
Alkaptonuria (ochronosis)	<p><b>Age of Onset</b>—30–40 y/o (present at birth though)</p> <p><b>Gender Predominance</b>—Equal</p> <p><b>Common Joints Involved</b>—Spine, hip, and knee.</p> <p>A hereditary disorder of tyrosine characterized by absence of homogentisic acid oxidase leading to deposition in tissues throughout the body. The accumulation of homogentisic acid oxidizes to form a black pigment. Ochronosis (brown-black pigmentation in connective tissue not usually seen until age 20), discoloration of urine and ochronotic arthropathy that includes acute exacerbations of arthritic pain in the spine. Cartilage of nose and ears may appear brown but blue on transillumination. Renal and prostate stones are common. Laboratory findings include urine that turns black on standing, homogentisic acid in urine. Radiographically, there is accelerated DJD of the spine with eventual bamboo spine, often beginning with calcification of the interspinous ligament.</p>	<p>Homogentisic acid accumulation could theoretically be controlled through dietary restrictions of phenylalanine and tyrosine, yet the long-term results have not proven this to be an effective treatment. Similarly, theoretically ascorbic acid supplementation could block oxidation of homogentisic acid, but the effectiveness of this approach has not been confirmed.</p>
Pigmented villonodular synovitis (PVNS)	<p><b>Age of Onset</b>—20–40 y/o</p> <p><b>Gender Predominance</b>—Male (slight)</p> <p><b>Common Joints Involved</b>—Knee, hip, elbow, ankle.</p> <p>A synovial proliferative disorder of unknown origin, although 50% of individuals report a history of trauma; usually occurs in one joint. In the hand or foot, a tendon involvement is termed giant cell tumor. Slowly developing joint pain with associated swelling, tenderness, and warmth. Aspiration may reveal hemorrhage. Radiographically, a “popcorn” appearance is seen with initial preservation of joint space. Cystic erosions with hemorrhagic joint effusion can be seen. MRI is diagnostic.</p>	<p>Treatment is complete synovectomy. Irradiation has also been used in some patients.</p>
Hemophilic arthropathy	<p><b>Age of Onset</b>—2–3 y/o</p> <p><b>Gender Predominance</b>—Male</p> <p><b>Common Joints Involved</b>—Knee and elbow commonly affected, although most other appendicular joints can be affected. Hemophilia is a group of disorders that share a problem with clotting factors and result in dysfunctional blood coagulation. The result is bleeding throughout the body, manifested externally as bruising, and prolonged bleeding, such as nose bleeds. Within joints, bleeding occurs and gradually causes changes that include swelling, contractures, fibrosis, and joint destruction. Due to the age of onset, radiographic findings include epiphyseal overgrowth, accelerated skeletal maturation, and radiolucent joint effusions. At some point the joint has a similar appearance radiographically to juvenile rheumatoid arthritis.</p>	<p>At the first sign of hemarthrosis, infusion of factor VIII or IX is initiated. The involved joint is kept in as much extension as possible while NSAIDs and local icing are used for pain control.</p> <p>COX-2 inhibitors are preferred. For chronic scenarios associated with hypertrophied synovium, synovectomy, either open or arthroscopic, may be recommended.</p>

<b>Infectious</b>	Arthritis may be secondary to bacterial, fungal, or viral infections, causing infiltration of synovial or periarticular tissues.	
	There are a number of risk factors for joint infections including: older age (over half of cases in patients over 60 years of age); joint surgery; intravenous drug use; alcoholism; diabetes; immunosuppressive illnesses or use of immunosuppressive medications; malignancy; chronic disease of the liver, lung, or kidney; or skin infections. For acute arthritis, the most common bacterial cause in adults is <i>Neisseria gonorrhoeae</i> . Others include <i>Staphylococcus aureus</i> , streptococci, and some gram-negative such as <i>Enterobacter</i> , <i>Pseudomonas aeruginosa</i> , and <i>Serratia marcescens</i> . For chronic arthritis, primary causes include mycobacterium and fungi. Early clinical signs are pain, swelling, and warmth. Radiographic changes with bacterial causes include early soft tissue and synovial swelling. After about 2 weeks, joint space narrowing and erosions begin to appear. With chronic causes, joint space is preserved longer. Synovial fluid analysis will reveal a high WBC count with a decrease in viscosity and glucose. Gram staining and culture will usually reveal the causative organism.	Antibiotic therapy is often given parenterally, and joint aspiration is performed as well as lavage and debridement dependent on degree of involvement. For fungal infections, amphotericin B and similar medications are needed.
<b>Hyperlipidemia</b>	Recurrent, migratory joint pain involving the knee and other large joints is seen in patients with familial hypercholesterolemia. The appearance is that of inflammatory process with fever, swelling, tenderness, and warmth. The onset is generally acute. The joint pain may not be in the joint itself but represent periartthritis or peritendinitis given that there is usually no joint damage. Xanthomas have been reported in the Achilles tendon, patellar tendon, and extensor tendons of the hands and feet. Diagnostic suspicion is high with a finding of familial hypercholesterolemia on laboratory evaluation coupled with the onset of recurrent migratory arthritis. Radiographs may show osteopenia and bone cysts.	Acute management is with NSAIDs or similar approaches. Long-term management may involve the use of HMG CoA reductase inhibitors; however, these may cause myalgias or polymyositis

Assembling and applying this information, if a middle-aged female presented with a polyarthropathy that included the hands but not the spine, without other systemic involvement, RA would be high on the list of differentials. If a young to middle-aged male presented with sacroiliac pain, no spinal pain, and involvement of a finger, Reiter's or AS would be high on the list of differentials.

A review article by Margaretten et al.<sup>2</sup> evaluated the ability of a clinician to determine whether their adult patient has septic arthritis. The history indicators would be whether the patient is diabetic, has rheumatoid arthritis, HIV infection, skin infection, has had joint surgery, or a hip or knee prosthesis. Joint pain, a history of joint swelling, and fever were the only findings that occurred in more than 50% of patients. Other findings such as night sweats and rigors were inconsistent and often not found with septic arthritis. However, the addition of synovial fluid analysis for WBCs and percentage of polymorphonuclear cells from arthrocentesis were needed to confirm the likelihood prior to Gram stain and culture test results.

## Examination

# Acute Traumatic Injury

An approach to acute injury evaluation initially focuses on neurovascular status distal to and local to the injury site. These neurovascular injuries often are secondary to fracture. Motor assessments with active and active resisted attempts evaluate both muscle and neural integrity. Sensory testing incorporates the use of a pin in an attempt to test pain perception and a paper clip for testing two-point discrimination in the fingers. Palpation of pulses is useful in determining major vascular injury. Although these tests are more applicable to extremity injury, injury to the spine requires the same diligent search for an intact neurovascular system. With these conditions reasonably eliminated, the specific sequence one uses is less important than the fact that the approach is comprehensive.

## General Approach

However complex the orthopaedic evaluation may become, the basics remain the same regardless of which joints and/or surrounding structures are involved (**Table 1-4**). Generally, orthopaedic testing attempts to (1) reproduce a patient's complaint (i.e., elicit pain, provoke numbness/tingling, or reproduce popping or clicking); (2) reveal laxity; (3) demonstrate weakness; or (4) demonstrate restriction (orthopaedic evaluation, in the context of a chiropractor, also includes accessory motion evaluation at a joint). The possible caveats to these attempts are that pain may be due to many factors and is therefore nonspecific (localization and injury pattern help better define); laxity

may be normal for an individual (especially if bilateral) or pathologic; weakness may be due to reflex inhibition caused by pain (relatively nonspecific), laxity, muscle injury, or neurologic damage; and restriction to movement may be due to soft tissue or bony blockage.

The mechanics of orthopaedic tests have similarities regardless of any assigned name. Testing involves one of three approaches: (1) stretch, (2) compress, or (3) contract. When performing a named orthopaedic test, reflection on what is the intended use coupled with the understanding of what other structures may be challenged is imperative to appreciate and interpret fully the variety of patient responses possible. Although a test is designed to stretch a ligament, also stretched are muscles, tendons, and nerves. The same maneuver may elicit a positive response through compression of tissues. For example, a valgus force stretches the medial knee yet compresses the lateral knee. Although not the intended response, any pain response to a maneuver may provide important information if simple biomechanics are kept in mind.

Another general principle is that similar structures are tested similarly (**Table 1-5**).

- Ligaments/capsules—Use direct palpation (if possible) and perform a stress test that usually involves stabilizing one bone while moving the neighboring bone on it (for example, drawer testing of the shoulder, knee, and ankle). In essence, motion palpation of a joint is the same as many ligament stability tests, yet the intent is different; locate restrictions, not instability.

**Table 1-4** Selective Tension Approach

Condition	Active ROM	Passive ROM	Resisted Movement	Key Points
Arthritis/capsulitis	Painful at limit of range	Painful at limit of range	Usually painless within range of motion	Often specific capsular pattern of one or two restricted movement patterns
Tendinitis Tendinosis	Variable	Pain on stretch	Painful, especially if contracted in stretched position	Insertion of tendon is often tender or slightly proximal to insertion
Tendon rupture	None	Full; painless	Weak; painless	Note displaced muscle belly
Ligament sprain	Decreased; limited by pain	Pain on stability challenge	Painless if full rupture, painful if partial	Overpressure laxity may indicate degree of damage
Muscle strain	Painful, often midrange	Passive stretch may increase pain	If resistance is sufficient, pain is produced	Check with resistance throughout full range of movement
Intra-articular body	Sudden onset of pain in a specific range of motion	Sudden onset of pain in a specific range of motion is also possible	Usually painless	An “arc” of pain with a “catching” or blockage is highly suggestive
Acute bursitis (deep)	Painful in most directions	Empty end-feel is often present	Isometric testing is often painful	Positional relief is less common than with muscle/tendon injury

**Table 1-5** General Approach Based on Structure

Structure	Initial Evaluation	Specific Imaging Evaluation
<b>Bone</b>		
Tumor—primary or metastatic	Radiograph	MRI or CT, bone scan for metastasis (nonspecific)
Osteochondrosis/apophysitis	Local tenderness and radiograph	Possible bone scan
Fracture	Palpation, percussion, tuning fork, radiograph	CT or possibly MRI
Stress fracture	Palpation, percussion, radiograph	Bone scan, SPECT scan; quantified CT, dual-energy absorptiometry
Osteopenia (osteoporosis)	Radiograph	Quantified CT, dual-energy absorptiometry
Osteomyelitis	Radiograph	MRI
<b>Soft Tissue</b>		
<i>Muscle</i>		
Strain or rupture	Active resistance	For rupture, sonography, or MRI
Trigger points	Palpation	None
Atrophy	Observation	Electrodiagnostic studies
Myositis ossificans	Palpation, radiograph	CT
Muscular dystrophy	Muscle testing, creatine kinase (CK) on lab	Electrodiagnostic studies
<i>Tendon</i>		
Tendinitis/tendinosis	Stretch and contraction	Sonography
Paratenonitis	Stretch	Sonography or MRI
Rupture	Lack of passive tension effect	Sonography or MRI
<i>Ligament</i>		
Sprain or rupture	Stability testing	MRI
<i>Bursa</i>		
Bursitis	Palpation	MRI or bursography
<i>Fascia</i>		
Myofascitis	Palpation	None
<b>Joint</b>		
Arthritis	Characteristic joint involvement, laboratory findings including rheumatoid factor, HLA-B27, ANA, and radiographic characteristics	CT for bone, MRI for soft tissue involvement
Subluxation/fixation (chiropractic)	Palpation, indirect radiographic findings	CT for facet joints (research only)
Synovitis	Capsular pattern of restriction	MRI, joint aspiration
Joint mice	Restricted ROM, radiograph	CT or MRI
Dislocation/subluxation (medical)	Observation and radiograph	CT

- Tendons—Use direct palpation and stretch into end-range (contraction at end-range stretch may also be used).
- Muscles—Use direct palpation and contraction. Although traditionally used to detect weakness, the main focus is to determine reproduction of a patient's complaint.

- Nerves—Tapping (i.e., Tinel's) and compression are direct tests for superficial nerves; indirect tests include motor and sensory evaluation of specific peripheral nerves, nerve plexus, nerve root, or central nervous system (CNS) involvement including muscle tests, deep tendon reflex testing, and sensory testing with a pin/brush or pinwheel.

Palpation is a valuable tool when accessing superficial tissues. Accessibility is limited, based on the joint and its location. The fingers and toes are thin accessible structures, whereas the hip and shoulder are not. Direct palpation of ligaments and tendons may reveal tenderness. Muscles may also be palpated for tenderness and possible associated referred patterns of pain. These trigger points have been mapped by Travell and Simons.<sup>3</sup> Their work serves as a road map for investigation.

New studies help clarify the etiology and diagnosis of trigger points. In two studies Shah et al.<sup>4,5</sup> evaluated the biochemical environment of a trigger point as compared to a normal control match. Using a microdialysis needle and sampling B21 (an acupuncture point and myofascial trigger point) they were able to measure pH, bradykinin, substance P, calcitonin gene-related peptide, tumor necrosis factor, and inflammatory fractions of interleukin, serotonin, and norepinephrine. All levels were higher in the active trigger points than in the controls. Another study of promise was conducted by Chen et al.<sup>6</sup> These researchers attempted to investigate the presence of taut bands of myofascial trigger points (MTP) using magnetic resonance elastography (MRE). There are some concerns regarding this study, but preliminary interpretation suggests that this technology may be able to identify and distinguish these MTP bands.

The reliability of soft tissue palpation has been evaluated for the spine and the extremities. In general, it is evident that soft tissue palpation findings are not as reliable as bony

palpation among examiners. When specific sites in the extremities are exposed through specific positioning, however, the reliability may increase.<sup>7</sup>

Although orthopaedic testing is the standard for orthopaedists, more involved investigations are usually added by the chiropractor and/or manual therapist. The first is based on the work of Cyriax,<sup>8</sup> which emphasizes the “feel” of soft tissue palpation, especially at end-range. Combined with this end-range determination, a selective tension approach is incorporated using the responses to active, active resisted, and passive movements to differentiate between contractile (muscle/tendon) and noncontractile (ligament/capsule and bursa) tissue. Another approach is to challenge specifically each joint to determine fixation or hypermobility. Finally, a functional approach to movement as proposed by Janda<sup>9</sup> and Lewit<sup>10</sup> is often used. This approach addresses the quality of movement and the “postural” tendencies toward imbalance of strength and flexibility of muscles.

## Selective Tension Approach

Cyriax<sup>8</sup> divided the quality of passive end-range at a joint into normal and abnormal. Some normal end-feels include the following:

- Soft tissue approximation—This is a soft end-feel that occurs when a muscle opposes another muscle; for example, when the calf muscles hit the hamstrings or the forearm hits the biceps on flexion.

- Muscular—This is an elastic end-feel that occurs when a muscle is stretched to its end-range. This occurs with straight leg raising with the hamstrings.
- Bone-on-bone or cartilaginous—This occurs when the joint anatomically stops, as occurs with elbow extension.

- Capsular—This occurs with a tight, slightly elastic feel such as occurs with full hip rotation. It is due to the elastic tension that develops in the joint capsule when stretched.

Abnormal end-feels include the following:

- Spasm—When muscle spasm is present, pain will prevent full range of motion.
- Springy block or rebound—This occurs when there is a mechanical blockage such as a torn meniscus in the knee or labrum in the shoulder. The endrange occurs before a full range of motion is attained.
- Empty—This occurs when there is an acute painful process such as a bursitis. The patient prevents movement to end-range.
- Loose—This end-feel is indicative of capsular or ligamentous damage and is in essence the end-feel that is found with a positive ligament stability test.

Many examiners probably sense these different endrange palpation findings. They have not categorized them, yet interpret them intuitively.

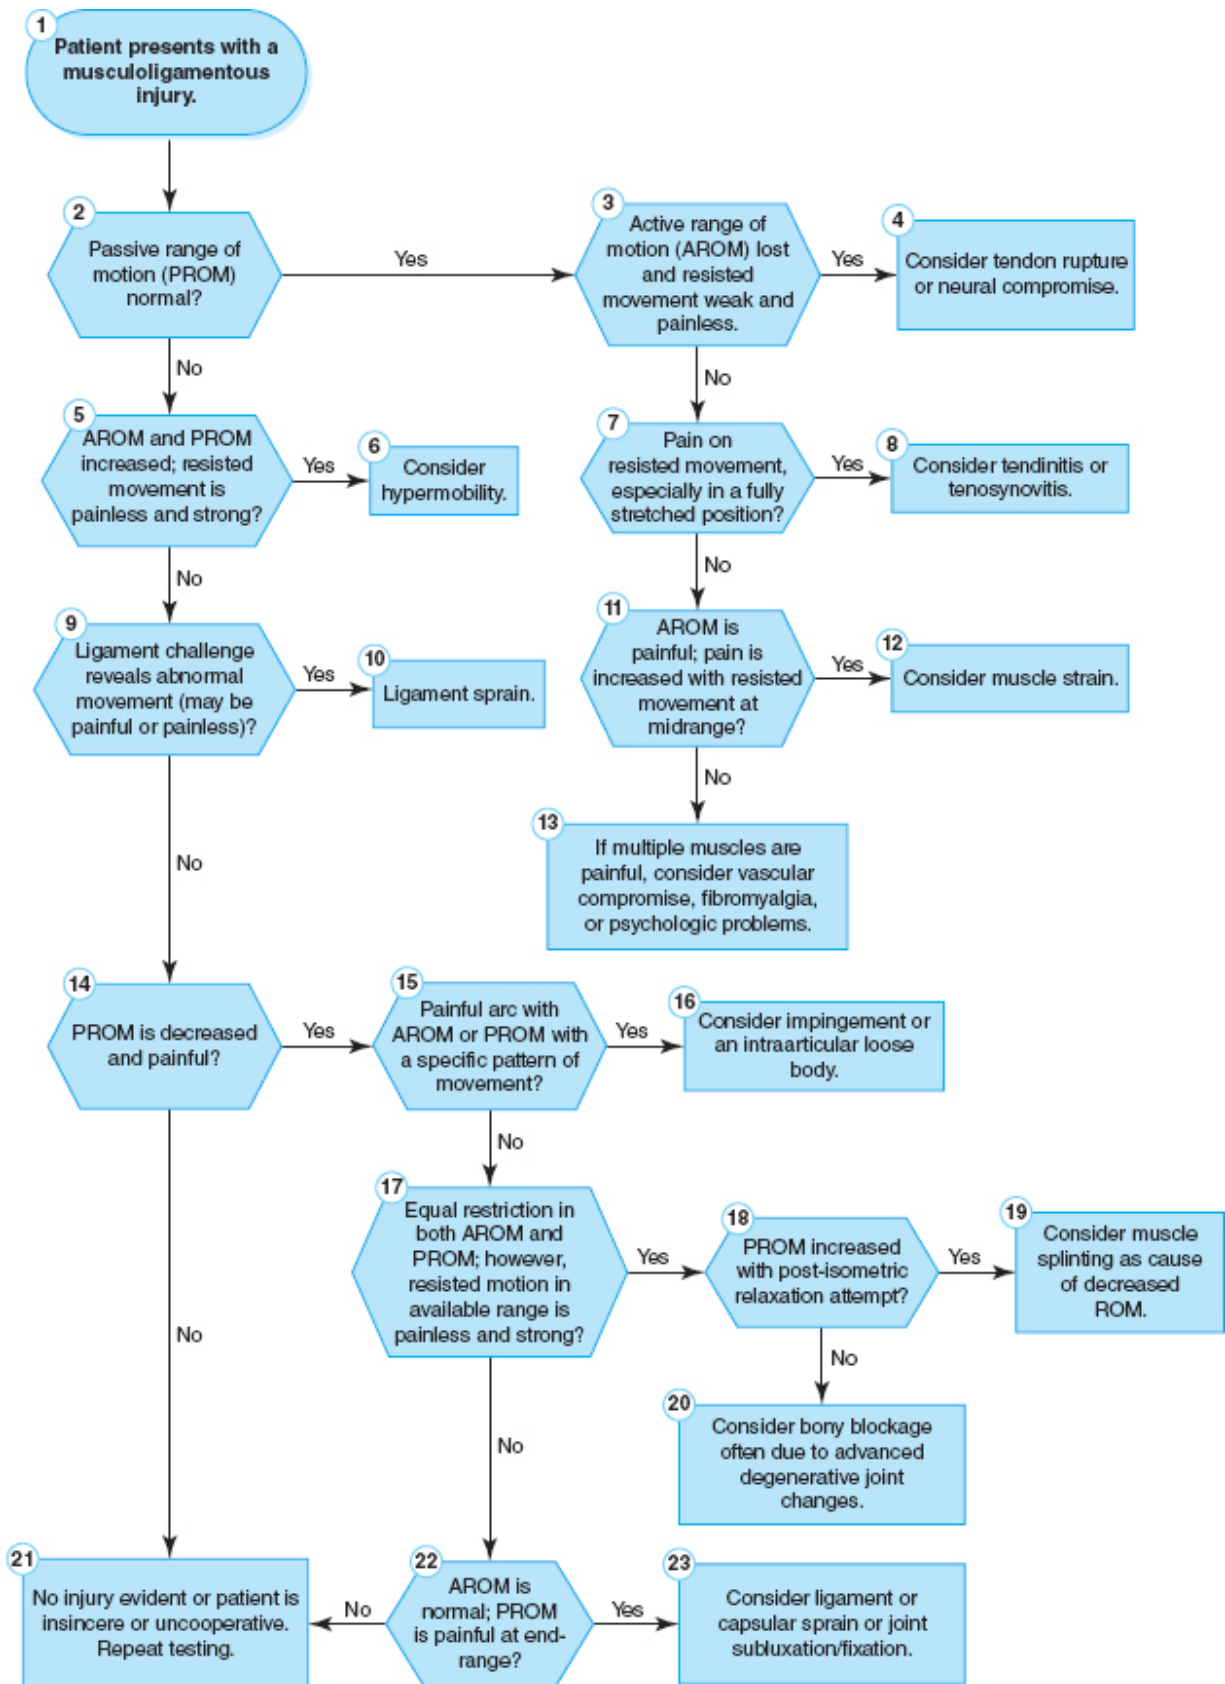

Some examiners will equate timing of the onset of pain on passive testing with staging of injury as follows:

- Pain felt before end-range is considered an acute process that would obviate the application of vigorous therapy.
- Pain felt at the same time as end-range is indicative of a subacute process and would be amenable to gentle stretching and mobilization.
- Pain felt after end-range is indicative of a chronic process that may respond to aggressive stretching and manipulation.

By taking the patient through passive range of motion (PROM) and active range of motion (AROM) and testing resisted motion, a clearer idea of contractile versus noncontractile tissue involvement may be appreciated (**Figure 1-1** and **Table 1-5**). It should be evident that contractile tissue may be painful with either stretch or midrange contraction. If both findings are present, they should be present in opposite directions (e.g., contraction into flexion hurts anteriorly while passive extension does also). If end-range stretch is not painful but contraction at end-range is, the tendon of the involved muscle is likely involved. If pain is not found with active movement but passive movement into end-range causes pain, noncontractile tissue is probably involved. Active movement should not affect most noncontractile tissue unless it is compressed. This is more likely to occur at end-range. Cyriax's selective tension approach is a logical attempt to localize the involved tissue, yet until recently it has remained unchallenged. One study demonstrated a high interexaminer reliability using these methods. The interexaminer agreement was 90.5% with a kappa statistic of 0.875.<sup>13</sup>

An extension of the selective tension approach is to determine the effect of mild isometric contractions on restricted range of motion. If a patient provides a mild resistance for several seconds to the agonist and antagonist pattern of restriction (e.g., flexion/extension) and repeats this several times followed by an attempt at stretch by the examiner, a distinction between soft tissue or bony blockage to movement may be determined. For example, if a patient presented with a restriction to abduction of the shoulder, repetitive, reciprocal contraction (minimal contraction for 5 to 6 seconds) into abduction and adduction several times will increase the available range if soft tissue is the cause (**Exhibit 1-1**). Bony blockage from OA, fracture, or a torn

labrum will result in little or no increase in motion with the same procedure.

**Figure 1-1** Assessment of Musculoligamentous Injury—Algorithm

## **Functional Approach**

Traditional muscle evaluation involves a test of muscle strength only. Janda<sup>9</sup> and Lewit<sup>10</sup> and others<sup>14</sup> advocate an approach that takes into account not only the quantity of contraction (strength) but also the quality of movement. There is a recognized natural imbalance in muscle strength. Not all muscles are created equal. It is known that small muscles are often phasic, required to react quickly to changes in the environment, whereas larger muscles are often tonic, posturally assigned. Certain movement patterns are biased. For example, supination is stronger than pronation and internal rotation of the shoulder is stronger than external rotation. This bias is in large part due to the size or number (or both) of muscles used in the movement pattern. Strength is also positionally dependent. Certain positions place at a disadvantage some muscles of a synergistic group.

There is another perspective with regard to muscle weakness and tightness that may affect evaluation and eventually management. An observation by Janda<sup>9</sup> and Lewit<sup>10</sup> is that there are crossed and layered patterns of weakness and tightness. For example, in the low back it is not uncommon to find a pattern of anterior weakness in the abdominal muscles associated with posterior tightness of the erector spinae (sagittal pattern). A vertical pattern is illustrated by the association of the tight erector spinae's being sandwiched between weak gluteal muscles inferiorly and weak lower trapezius muscles superiorly. These two planes create a "crossed" pattern whereby tightness of the erector spinae is associated with tightness of the iliopsoas, and weakness of the abdominal muscles is associated with

weakness of the gluteal muscles. This pattern is relatively consistent throughout the body and is a reflection of two concepts: (1) muscles that function to resist the effects of gravity (postural muscles) have a tendency to become tight in sedentary people, and (2) muscles that function more dynamically are underused and become weak and prone to injury. Additionally, muscles that cross more than one joint are prone toward tightness. For example, the rectus femoris, which crosses the hip and knee, is prone toward tightness, whereas the medialis obliquus, which does not cross a joint and is primarily a “dynamic” muscle, is often weak.

### **Exhibit 1-1 Postisometric Relaxation, Proprioceptive Neuromuscular Facilitation (PNF) Hold-Relax, and PNF Contract-Relax**

## **Postisometric Relaxation**

- Stretch the affected muscle to patient tolerance.
- Maintain the stretch position while the patient isometrically contracts the muscle for 6 to 10 seconds at a 25% effort against doctor's resistance.
- Instruct the patient to relax fully (taking in a deep breath and letting it out may help).
- Attempt a further stretch of the muscle with the patient relaxed.
- Repeat this procedure five or six times or until no further stretch seems possible (whichever comes first).

## **PNF Hold-Relax**

- This technique is very similar to a postisometric relaxation approach; however, classically the patient attempts a maximum contraction of either the agonist or antagonist.
- Caution must be used with maximal contractions. The author prefers to start with a postisometric approach using a 25% contraction before proceeding to more forceful resistance.

## **PNF Contract-Relax**

- This is a full isotonic contraction followed by a stretch into a new position.
- There are several variations of this technique. A popular one is called CRAC (contract-relax-antagonist-contract).

With the above concepts in mind, Lewit and Janda have focused on an observation of quality of movement with an emphasis on the timing and recruitment during a movement pattern. Often these two concepts overlap when the timing of the movement is a reflection of recruitment. For example, hip extension in a lying position requires a timing of contraction beginning with the hamstrings. This is followed by gluteal contraction, then erector spinae contraction. If the hamstrings or gluteals do not participate, the erector spinae contract, causing a weak contraction and a lordotic/compressive load to the low back. In the neck, flexion may reveal an imbalance in movement. If the patient's jaw juts forward at the beginning of the pattern, weak neck flexors with associated "strong" sternocleidomastoids are indicated.

## Functional Movement Approach to Assessment

An approach to asymptomatic individuals as well as symptomatic individuals is to examine, rate, and rank, patterns to discover and correct limitations to specific movement patterns or asymmetries in specific movement patterns. One such approach by Cook<sup>11</sup> is divided into two sequences. One is devoted to the asymptomatic individual and is called a Functional Movement Screen (FMS). This approach is not diagnostic. The second approach for symptomatic individuals is called Selective Fundamental Movement Assessments (SFMA). This uses patterns broken down into component elements (**Table 1-6**). A key concept

is to find the pattern with the most limitation or most asymmetry and remediate this “weakest” link. The reason may be joint restriction, muscle tightness, poor segmental stability, or a combination of these. The core components of the FMS include primitive movement patterns, progressing through transitional movement patterns that have a requirement for more stability and coordination, and then to higher level movement patterns. There is caution expressed in the literature that demonstrates that the intraexaminer reliability of this method is good, but the interreliability is not causing the authors of one study to suggest that this approach should not be used “indiscriminately” to screen the athlete at greatest risk for injury.<sup>12</sup>

**Table 1-6** Functional Movement Patterns of Assessment

Approach	Rating System	Movements or Evaluation	Purpose of Assessment
FMS	3 = complete movement (no issues) 2 = complete movement with compensation, deviation from standard, or both 1 = incomplete 0 = pain on any test (nullifies test)	Deep squat Hurdle step Inline lunge Shoulder mobility reaching Active SLR Trunk stability pushup Rotary Stability <i>In general focus is on Little Four first</i> <i>Asymmetrical split-side tests are more important than symmetrical tests such as the squat, trunk stability pushup</i>	Mobility and stability Both the SLR and shoulder mobility tests for mobility; the stability pushup and rotary stability for stability
SFMA		<i>All of the following have “breakout” movement assessments (largely regional)</i> Cervical spine Upper extremity Multisegmental flexion Multisegmental extension Multisegmental rotation Single leg stance Overhead deep squat Rolling patterns	

Legend: Functional Movement Screen (FMS), Selective Fundamental Movement Assessments (SFMA), Straight Leg Raise (SLR)

## Accessory Motion

One of the indicators for manipulation or adjusting is blockage of accessory motion.<sup>15</sup> Accessory motion is that subtle amount of bone-on-bone movement that is not under voluntary control. For example, although the humerus moves on the glenoid during abduction, there is a degree of movement measured in millimeters that is necessary yet not under the control of the shoulder abductor muscles. Determining whether accessory motion is available involves placing the joint in a specific position and attempting passively to move one bone on another. If the end-feel is springy, then joint play is available. If there is a perceived restriction, however, movement at the joint may be restricted. It is important to distinguish between the end-range descriptions of Cyriax<sup>8</sup> and the end-feel of accessory motion. Cyriax is referring to the end-range of an extremity or spinal movement such as flexion, extension, abduction, or adduction. Accessory motion is palpated at the joint both with the joint in a neutral or open-packed position and also with a coupled movement pattern taken to end-range actively and passively. The joint would not be restricted by the tension of the capsule or muscle with the neutral position method. The active and passive techniques take advantage of the end-range position to determine whether the accompanying accessory motion is, in fact, occurring. There are specific guidelines for both assessment and application of treatment to accessory motion barriers.

Specific patterns of extremity and spinal movement are coupled with specific accessory motion so that restrictions in active movement may be indirectly an indicator of dysfunction of the accompanying accessory motion.<sup>16</sup>

## Radiography and Special Imaging

When making choices regarding the need for radiographs or special imaging, it is important to keep one major question in mind: Is there a reasonably high expectation that the

information provided by the study will dictate or alter the type of treatment or dictate whether medical referral is needed? If the answer is no, it is important to delay ordering expensive, unnecessary studies at that given time. As time passes, the answer to the question may change. Some secondary issues with regard to further testing are as follows:

- What are the risks to the patient?

- What is the cost? Are there less expensive methods of arriving at the same diagnosis?
- What are the legal ramifications if the study or studies are or are not performed?

The decision for the use of radiographs is based on relative risk. Patients often can be categorized into high- and low-risk groups by combining history and examination data. Many groups have developed similar standards for absolute or relative indications for the need for radiographs.<sup>17-19</sup> Generally, for patients with joint pain, the following are some suggested indicators:

- Significant trauma

- Suspicion of cancer (unexplained weight loss, prior history of cancer, patients over age 50 years)
- Suspicion of infection (fever of unknown origin above 100° F and/or chills, use of intravenous drugs, recent urinary tract infection)
- Chronic corticosteroid use
- Drug or alcohol abuse
- Neuromotor deficits
- Scoliosis
- History of surgery to the involved region
- Laboratory indicators such as significantly elevated erythrocyte sedimentation rate, alkaline phosphatase, positive rheumatoid factor, monoclonal spiking on electrophoresis
- Dermopathy suggestive of psoriasis, Reiter's syndrome, melanoma, and the like
- Lymphadenopathy
- Patients unresponsive to 1 month of conservative care

- Medicolegal requirements or concerns

Choice of imaging is based on the sensitivity and specificity of a given imaging tool, the cost, and the availability (see [Table 1-6](#)). In general:

- Radiography—Signs of many conditions, including cancer, fracture, infection, osteoporosis, and degeneration, often are visible. The degree of sensitivity is quite low with early disease, however.

- Magnetic resonance imaging (MRI) is extremely valuable in evaluating soft tissue such as tendons, ligaments, and discs. In evaluating the volume of tumor or infection involvement, MRI is also valuable. Spinal cord processes such as multiple sclerosis or syringomyelia are well visualized on MRI ([Table 1-7](#)).
- When attempting further to clarify the degree of bony spinal stenosis, the extent of fracture, or other bony processes, computed tomography (CT) is often a sensitive tool—better than MRI in many cases. Recent cerebrovascular events and some tumors are well visualized with CT.
- When the search is for stress fracture, metastasis to bone, or avascular necrosis, bone scans often provide valuable information.
- When determining the degree of osteoporosis in a patient, dual x-ray radiographic absorptiometry is more sensitive than standard radiography.

**Table 1-7** Magnetic Resonance Imaging for the Chiropractor

<b>MRI Better</b>	<b>MRI Equal to CT</b>	<b>CT Better Than MRI</b>
-----------------------	----------------------------	-------------------------------

<b>Than CT</b>		
<b>MRI of the Head</b>		
Severe headaches Visual disturbance Sensory-neural hearing loss Primary brain tumor Metastatic brain tumor Intracranial infection Age-related CNS disease Multiple sclerosis Dementia Chronic subdural hematoma Posttraumatic evaluation of the brain Intracranial hemorrhage older than 3 days Cerebral infarction older than 3 days	Hydrocephalus Brain atrophy	Fracture of the calvaria Fracture of the skull base Cholesteatoma of inner ear Intracranial hemorrhage 1-3 days old Cerebral infarction 1-3 days old Intracranial calcifications
<b>MRI of the Cervical and Thoracic Spines</b>		
Tumors or masses at the level of the foramen magnum	Spinal stenosis	Occult fracture of a vertebra

In late 2007, a set of diagnostic imaging practice guidelines for musculoskeletal complaints in adults was released.<sup>20</sup> The guidelines were the result of years of research including an extensive literature search, an external review by 12 chiropractic specialists for external review, and finally, a two-round modified Delphi process

involving 149 international experts. The agreement on recommendations was quite high (approximately 85%). Generally, these guidelines are intended to inform clinicians as to the best scientific evidence currently available, and are intended to be used in conjunction with sound clinical judgment and experience. The hope is that in addition to identifying patients in need of further diagnostic workup, unnecessary use of radiographs, and therefore the time and cost for health care will be reduced, while maintaining or improving patient care.

A new approach being studied and utilized by physical therapists internationally is rehabilitative ultrasound imaging (RUSI).<sup>21-28</sup> The concept is to use diagnostic ultrasonography (US) to evaluate morphological changes while therapy is being applied. By determining the best position for stretch or for the effects of care, RUSI is being advocated as an important adjunct to musculoskeletal management. For example, RUSI would be used to measure the cross-sectional area of a muscle or tendon.

## Management

Recently, a growing focus for many practitioners involved in a manual therapy, physical medicine/therapy approach is a basic science explanation for why these approaches are effective and may be necessary alternatives to the often short-term goal effects of various surgical solutions to common musculoskeletal problems. The concept is an old one but is resurfacing as a generalized concept of approach called mechanotherapy. The premise of this general and broad concept is mechanotransduction where a mechanical stimulus or loading is converted into cellular responses. As a result of this mechanical input, processes are set into play to promote structural change. In an article by Khan and Scott<sup>29</sup> in 2009 published in the *British Journal of Sports*

*Medicine*, the authors review and categorize the main steps in this transduction of mechanical stimulus to cellular response. They break down the process into three steps: (1) mechanocoupling, which involves the mechanical trigger; (2) cell-cell communication throughout the tissue to communicate the loading message; and (3) the effector response at a cellular level to set into play the production of necessary materials in the correct alignment of that tissue. For the communication via cell signaling to occur, an “information network” of messenger proteins, ion channels, and lipids must be present. The signaling substances include calcium and inositol triphosphate. Specific changes have been demonstrated, including in tendons there is an up-regulation of insulin-like growth factor (IGF-I) associated with cellular proliferation and matrix remodeling within the tendon. Other growth factors and cytokines in addition to IGF-I also are likely to play a role.<sup>30</sup> In a study<sup>31</sup> involving rehabilitation of Achilles tendinosis, after a follow-up of almost four years many of the tendons exposed to an eccentric loading approach to rehabilitation demonstrated normal structure. Taken together, these illustrate that the body’s normal response to stimulus is to adapt and make an attempt at recreating normal structure.

Conservative management of a musculoskeletal problem is based on several broad principles.

- Initial management involves a greater degree of passive care with a transition into active care dominance over time.
- The goals for patient management vary based on the acuteness of the problem.
- Rehabilitation progresses in a sequence: passive motion to active motion to active resisted motion (begins with isometrics and progresses to isotonic) to functional training.

Although traditionally it was the doctor's role to be active and the patient's to be passive with treatment, it is becoming clear that there is a point at which role switching is necessary. When a patient has acute pain, the goal is to reduce the pain and assist healing. Many of the treatment methods used with acute pain employ procedures that are doctor-dependent. As the patient progressively improves, there should be a focus on the patient's active participation in restoring normal function. Nelson<sup>32</sup> has outlined some criteria for passive care (**Figure 1-2**). These include a history of recent trauma, acute condition or flare-up, inflammation, or dependency behavior. There are generally four types of care that may overlap, as follows: **1.** Care for inflammation might include the traditional approach of protection, rest, ice, and, if appropriate, compression and elevation. Modalities that are available include high-voltage galvanic stimulation, ultrasound, therapeutic heat, contrast baths, and nonsteroidal anti-inflammatory drugs (NSAIDs), or enzyme alternatives.

- 2.** Options for care for pain include manipulation, mobilization, trigger-point therapy, transcutaneous electrical nerve stimulation (TENS), interferential stimulation, (**Table 1-8**), ice, cryotherapy, acupuncture, and NSAIDs.
- 3.** Care for hypomobility includes various forms of stretch, manipulation, mobilization, and soft tissue approaches such as myofascial release techniques.
- 4.** Care for hypermobility includes protection with taping, casts, splints, or various braces.

---

## **Low-Level Laser Therapy (LLLT)**

There are many types of lasers. Those used therapeutically can be divided into several subtypes. Those without a strong thermal effect are often referred to as *cold lasers*. These are divided into two types based on wavelength. Far-

red to infrared wavelengths (longer than 800nm) penetrate deeper and are therefore indicated for treatment of deep acupuncture points, trigger points, and large muscles. The second type, visible red wavelengths (shorter than 800nm) are more appropriate for more superficial tissue because they do not penetrate as far.

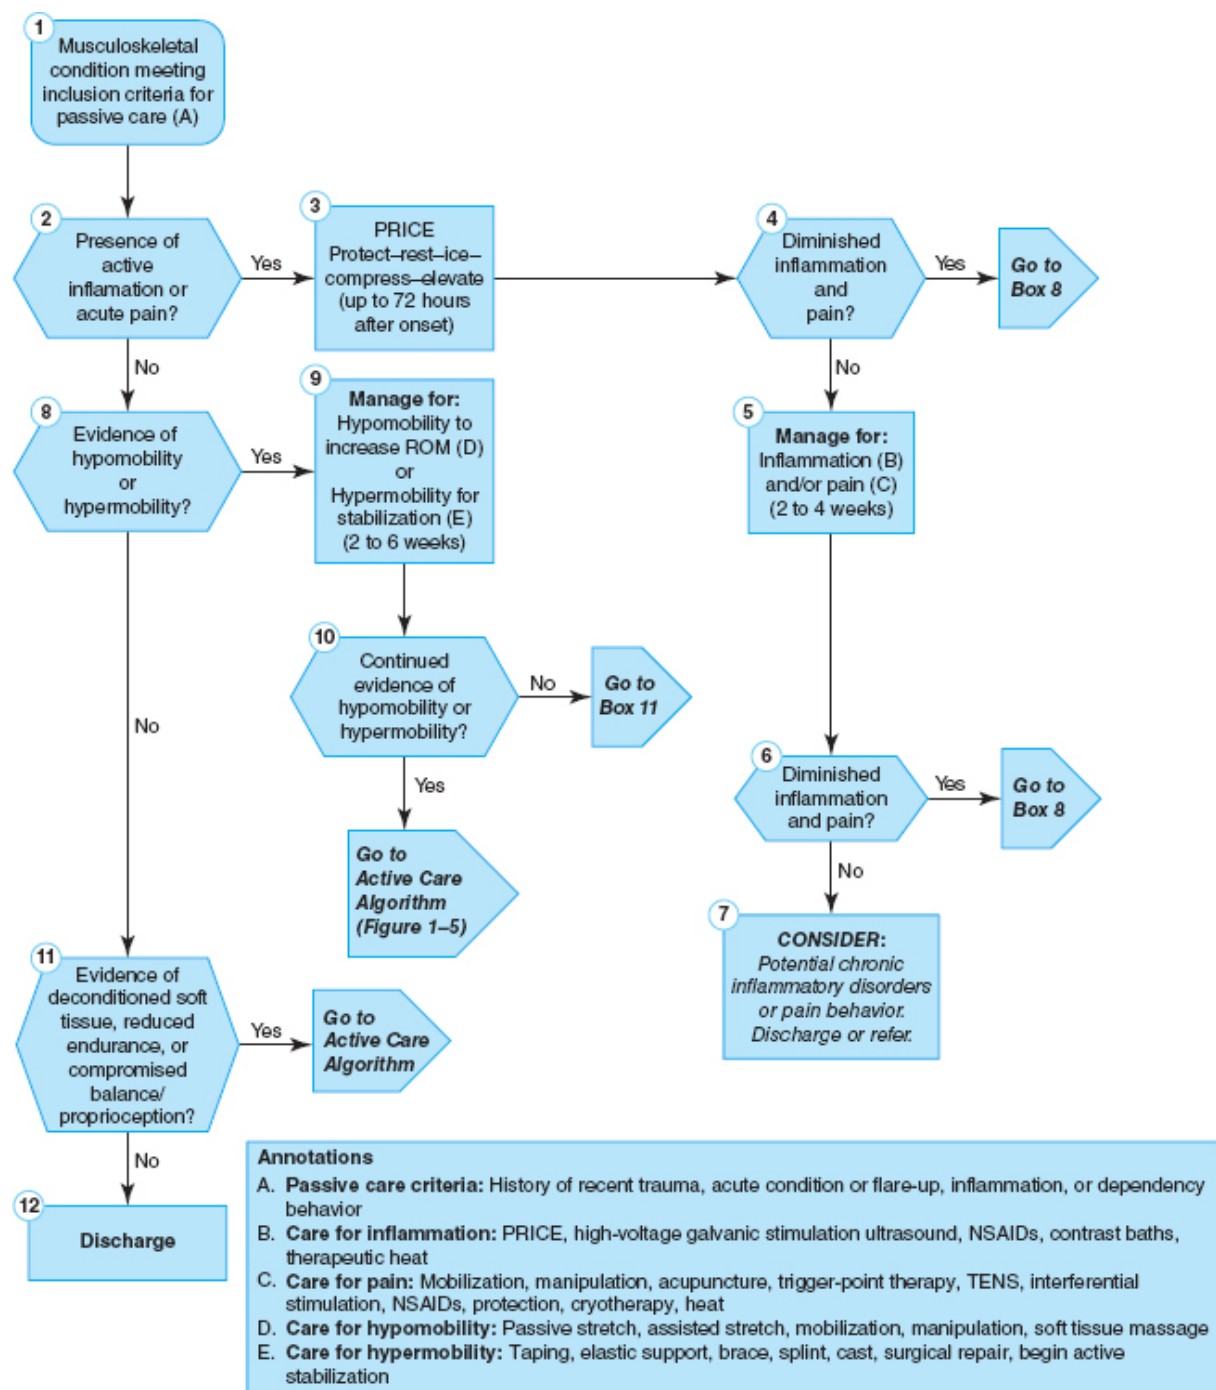

There are a number of proposed effects of LLLT, which include:

- Reduction of pain through inhibition of fast axonal transmission in small- and medium-diameter A $\delta$  and C fibers
- Potentially reduces peripheral nociceptive afferent input to the dorsal horn and possible reorganization of synaptic connections in the CNS that modulate pain
- Improve oxidative metabolism
- Increase production of endogenous opioids, reduce swelling, reduce prostaglandin E<sub>2</sub> levels, and inhibition of cyclooxygenase 2

If the output power (mW) and beam area (cm<sup>2</sup>) are known, one can calculate the remaining parameters that determine dosage. The output refers to the number of photons emitted at the particular wavelength of the laser diode. The thermal effect of photons at the treatment area is measured as the Power Density. Energy Densities in the range 0.5 to 4 J/cm<sup>2</sup> are most effective in producing a photobiological stimulating response. Dosages of 8 to 12 J/cm<sup>2</sup> and higher are proposed to cause bioinhibition, and may be effective with pain management. To change dosages it is recommended to maintain a fixed output power and alter the emission time.

In a Cochrane Review<sup>33</sup> published in 2008 the reviewers cautioned that there was insufficient evidence to draw firm conclusions about LLLT for nonspecific low back pain. They state that although three small studies showed statistically significant differences, they did not show clinically important differences. They did conclude though that real LLLT is

perhaps better than sham LLLT but not better than exercise for pain and disability in the short term. They indicate that two small studies demonstrated that the relapse rate was significantly lower for patients treated with LLLT at six months compared to the control group.

**Figure 1-2** Passive Care Management—Algorithm

Reproduced from D.L. Nelson, *Topics in Clinical Chiropractic*, Vol. 1, No. 4, p. 75, © 1994, Aspen Publishers, Inc.

Although a review<sup>34</sup> in *Lancet* in 2009 concluded that LLLT reduces pain immediately after treatment for acute neck pain and for patients with chronic pain up to 32 weeks

after treatment with LLLT, there were limitations to strength of these conclusions. Three of the studies quoted and utilized in the review that had the largest reported mean differences in favor of LLLT had limitations or errors:

**Table 1-8** Physiotherapy Approaches for Musculoskeletal Complaints

Various Transcutaneous Electrical Nerve Stimulation (TENS) Approaches				
Type	Pulse Width (pps)	Pulse Rate	Amplitude	Treatment Time
High frequency	High: 75–100	< 200	Increase to discomfort	20 min.–24 hrs
Low frequency	Low: < 10	200–300	Increase to elicit strong rhythmic contractions	30–60 min.
Brief and intense	TENS—150	150	Increase to strong but comfortable contraction	20–60 min.
Pulsed High-Volt Galvanic				
Treatment Effect	Mode	Frequency (pps)	Type of Stimulation	Time (min.)
Reduce edema	Continuous	High: 80–100	Sensory	20
Reduce muscle spasm	Continuous	High: 80–120	Sensory/motor	20–30
Autonomic response	Uninterrupted/pulse	High: 80–100	Sensory	20–30
Neuro/hormonal	Uninterrupted/pulse	Low: 2–5	Motor (twitch)	30–60
Muscle pumping	Surged 1:3	Low: 30–50	Motor	20–30

- Two studies had significant baseline differences in favor of the active treatment.
- A typing error indicated a significant mean difference when in the original study, there was no significant difference.
- Pooling of data for nonspecific neck pain, myofascial pain syndrome, and cervical osteoarthritis may be inappropriate because each may represent a different set of patient types and clinical responses.

## Shockwave Therapy

Shockwave therapy (SWT) is utilized in a number of musculoskeletal as well as visceral disorders. Commonly used for kidney stones and gallstones management, a

similar approach to tendon, muscle, and ligament problems has been successfully utilized over the last decade or so.

By definition, shock waves involve a sequence of single sonic pulses with the following characteristics:

- High peak pressure (100 mPa)
- A fast rise in pressure (< 10 nanoseconds)
- A short life cycle (10 microseconds)

Therapeutically, SWT is applied based on energy output and frequency of impulses. SWT is generally classified according to two energy levels with different effects: • Low-energy SWT—defined as having an energy flux density (EFD) of less than 0.12 mJ/mm<sup>2</sup>. Shock-wave therapy at an EFD lower than 0.09 mJ/mm<sup>2</sup> is reported to produce a neoangiogenic effect by increasing expression of vascular endothelial growth factor (VEFG) and its receptor.

- High-energy SWT—defined as having an EFD between 0.12 and 0.38 mJ/mm<sup>2</sup>. At the higher ends of high-energy SWT, local anesthesia is often necessary.

A distinction must be made between two types of SWT. The first is called focused SWT and may be generated via electrohydraulic, electromagnetic, or piezoelectric mechanisms. Based on how the energy is generated, the focal area and tissue penetration and their effects on tissue vary. Focused shockwaves are concentrated through focusing reflectors to the target site. The other type is termed radial shockwave therapy or radial pulse therapy (RPT). Radial “shock” waves are not actually shockwaves being generated by a ballistic source and so therefore, do not have the characteristics of real medical shockwaves. Their effect is superficial; they do not have a penetrating effect on tissue.

Short-term effects of real SWT include analgesic and anti-inflammatory results likely due to removal of inflammatory

mediators coupled with nociceptive inhibition through a gate-control mechanism. Longer term healing-effects may be related to acute vessel rupture and subsequent angiogenesis in soft tissues. EFD between 0.04 and 0.22 mJ/mm<sup>2</sup> have very few side effects as reported in the literature including pain, erythema, local soft tissue swelling, and local subcutaneous hematomas among others. High-energy SWT is quite uncomfortable without local anesthetic.

At the current time, based on literature evidence, treatment parameters appear empirical. The clinician weighs the advantage of high-energy treatment with the comfort level of low-energy treatment. It does appear that both high- and low-energy protocol procedures are equally effective if the total energy applied is approximately the same. The compensation then is to utilize a low-energy protocol but use more impulses over more treatment sessions to achieve a similar result to high-energy treatment protocols, especially when administered by chiropractors who are not able to utilize local anesthetic in-office.

Common uses for SWT include calcific tendinitis, lateral epicondylitis, patellar tendinitis, and plantar fasciitis.<sup>27c, 27d, 27e</sup>

## **Platelet-Rich Plasma (PRP) and Other Injections for Soft Tissue**

A relatively new therapy has gained popular attention due to its use with well-known athletes. However, until recently, there has been little data to support the myriad claims. The approach is sometimes classified as a form of prolotherapy involving injection into a joint, muscle, tendon, or ligament. Although there is a heterogeneous group of injectables, the most popular is an injection that contains platelet-rich plasma (PRP). It is autogenic, meaning it is created by taking a patient's own blood and spinning it down into a

platelet concentrate. The theory is that PRP is rich in growth factors and will help in healing and repair. Although this approach has been used for the conditions listed below, most studies are small and without randomization.

- acute ligament injury involving medial collateral ligament rupture of knee and elbow, lateral collateral ligament rupture of ankle, etc.
- chronic tendon problems such as rotator cuff tear, lateral epicondylitis of elbow, patellar tendinosis, Achilles tendinitis, plantar fasciitis, etc.
- chondromalacia or osteoarthritis of the knee, shoulder, and SI joint

Concerns about the underlying principle and theory of PRP injection include:

- For chronic processes, most of the growth factors are expressed within one hour after intraarticular PRP injection, so it is unlikely that it has a significant effect on the existing damage from chronic diseases.
- The pain relief seems consistent across studies but comparison to control groups is rarely utilized in the study design.<sup>38</sup>
- The basic science support is largely based in rat research that has demonstrated that PRP increased the number of collagen fibers and fibroblasts in the early phase of the healing process after damage to tendons.
- PRP has also been shown to stimulate the synthesis of hepatocyte growth factor (HGF) and vascular endothelial growth factor (VEGF) found within tendon cells, which increases cellular proliferation and vascular regeneration. However, only demonstrated in in-vitro studies, PRP affected human osteoarthritic chondrocytes by inhibiting the action of inflammatory cytokines such as IL-1 and NF-kB.<sup>39</sup>

There are mixed results that may be based on a balance of formulation of PRP. One study<sup>39</sup> suggests that rather than a focus on increasing platelets in an effort to maximize anabolic signaling, reducing leukocytes to minimize catabolic signaling may be more important. Although increasing the platelet concentration within IrPRP preparations results in the more anabolic growth factor delivery and less proinflammatory cytokines, the biological tradeoff is an effect on tendons of diminished metabolism indicated by a decrease in the synthesis of both COL1A1 and COL3A1. Therefore a balance must be accomplished where minimizing leukocytes in PRP becomes more important than maximizing platelet numbers with an overemphasis on concentration. This refocus should result in decreasing inflammation while enhancing matrix gene synthesis.

Following is a list of conclusions from recent reviews:

- In a systematic review of studies comparing PRP to a control group none of them showed any benefit of an autologous growth factor injection when compared with a control group.<sup>40</sup>
- Another systematic review of a number of injection therapies including corticosteroid, sclerosing agents, glycosaminoglycans, botulinum toxins, and PRP concluded that corticosteroid injection is beneficial in the short term for the treatment of tendinopathies (potentially worse than other treatments in the intermediate and long terms). There was no clear evidence of benefit of other injections including PRP, except for sodium hyaluronate in the short and long term in overall improvement and pain reduction of lateral epicondylalgia.<sup>41</sup>

Another claim is a change in osteoarthritis progression with an injection of PRP. In a 2012 study,<sup>42</sup> investigators utilized

MRI to detect whether PRP therapy for early knee osteoarthritis altered or stalled osteoarthritic changes as seen on MRI. They also measured clinical outcomes such as pain and function. Qualitative MRIs demonstrated no change in at least 73% of cases at one year. This is in contrast to some longitudinal studies that suggest annual decreases of up to 4 to 6% of cartilage volume in knee osteoarthritis. This suggests a benefit at prevention but more studies are necessary given there was no control group. Noteworthy is that the American Academy of Orthopaedic Surgeons (AAOS) have approved PRP protocols only for use in research, and that PRP is not recommended for treatment purposes.<sup>43</sup> Also, some countries, including Korea, state that the use of PRP is illegal. Their concern is that there is not enough science to back up claims, yet hospitals and other groups are using this procedure as a major revenue source.<sup>44</sup>

## Stretching of Soft Tissue

Numerous techniques for stretching and soft tissue pain control are used. **Exhibits 1-2** through **1-4** outline many of these approaches, including rhythmic stabilization, postisometric relaxation, proprioceptive neuromuscular facilitation (PNF) hold-relax and contract-relax techniques, cross-friction massage, spray and stretch, myofascial release techniques (MRT or active resistive technique [ART]<sup>45</sup>), and Graston technique. These are further discussed below.

### Exhibit 1-2 Rhythmic Stabilization

A variation of hold-relax, this technique uses a reciprocal contraction of the agonist and the antagonist following the approach outlined below:

- Stretch the involved muscle to patient tolerance.

- Use a physician's contact on both sides of a joint.

- Ask the patient to contract with a 25% contraction in the direction of agonist contraction for 5 to 8 seconds.
- Without resting, ask the patient to contract into the opposite direction for 5 to 8 seconds.
- Repeat this procedure five or six times.
- Ask the patient to relax.
- Stretch into new position.
- Repeat the above five or six times or until no more stretch appears available (whichever comes first).

## **Exhibit 1-3 Cross-Friction Massage and Spray and Stretch**

### **Cross-Friction Massage**

Cross-friction massage is a technique popularized by Cyriax.<sup>8</sup> The rationale behind its use is somewhat dependent on the patient's presenting phase of injury. For example, in subacute injury the intent is to align collagen for stronger scar formation. With chronic conditions the cross-friction approach is used to break up adhesions and increase blood supply. A secondary effect of cross-friction massage is a pressure anesthesia, which occurs after a couple minutes of application. There are several suggestions for the proper use of cross-friction massage: • It appears to be most effective with tendons and ligaments.

- The tendon or ligament should be placed under slight tension (by stretching the involved structure) while cross-friction is performed.
- The contact is skin on skin with no lotion.
- The pressure is applied as a transverse motion (90° to the involved structure).
- Monitoring the patient every 2 minutes for a total of 6 to 9 minutes is recommended.
- Prior to application, some practitioners recommended ice; others recommend moist heat for approximately 5 minutes.
- Treatment is given every other day for 1 to 2 weeks (up to 4 weeks maximum).

### **Spray (Cold) and Stretch**

Although the technique of using fluoromethane spray for stretching muscles was popularized by Travell and Simons,<sup>3</sup> concerns over damage to the ozone layer and increasing unavailability of the spray have led to a return to the use of ice. With the use of either tool, the technique of application has several common protocol components: • The muscle being stretched is placed in a position of mild to moderate stretch. Maintain this stretch while applying the cold stimulus.

- The cold stimulus is applied in a series of linear strokes to the skin overlying the muscle and its associated pain referral zone. This is applied in the direction of pain referral.
- Gradually increase the stretch while applying the cold.
- Following the stretch, the skin should be briefly rewarmed with a moist heat pack.
- The muscle should then be put through a full range of motion, passively and then actively (this is an attempt to avoid posttreatment soreness).

## **Exhibit 1-4 Myofascial Release Techniques (MRTs)**

Several techniques have been developed and popularized under different technique names. Most techniques involve a stripping motion of a muscle. A combination of these techniques is found with MRT (or ART) as proposed by Leahy and Mock.<sup>45</sup> These techniques are best used when a muscle is determined to be dysfunctional. This is accomplished through a combination of palpation, range of motion (ROM) findings, and muscle testing. This technique is not intended for acute injury (within 24 to 36 hours) or for ligaments and tendons that respond better to cross-friction massage. In essence, this is an extension of other myofascial or trigger-point approaches. Skin lotion should be used when possible. Following is a summary of this approach. There are four levels. Use the highest level that patient tolerance permits.

### **Level 4**

- Place the muscle in its shortest position.
- Apply a firm contact to the muscle just distal to the site of palpable adhesion.
- Ask the patient to move the limb actively through an antagonist pattern (if the joint is in extension, the patient flexes), elongating the muscle.
- Always maintain a fixed contact on the patient so that the adhesions are forced under the contact point.

### **Level 3**

- Place the muscle in its shortest position.
- Apply a firm contact to the muscle just distal to the site of palpable adhesion.
- Passively move the limb through an antagonist pattern, elongating the muscle.
- Always maintain a fixed contact on the patient so that the adhesions are forced under the contact point.

## Level 2

- Place the muscle in a stretched position (creating tension).
- Apply muscle-stripping massage (along the direction of muscle fibers) using a broad contact, concentrating on areas of adhesion.

## Level 1

- Place the muscle in a neutral position (no tension).
- Apply muscle-stripping massage, concentrating on areas of adhesion.

Treatment usually involves several passes over the muscle, treatment every other day, and resolution within the first few treatments.

Adjunctive care involves prescription of exercises for the involved muscle, starting with facilitation.

Recommendations for the frequency of manual therapy generally have been outlined by the Mercy Guidelines (**Figures 1-3** and **1-4**).<sup>50</sup> A brief summary follows: • If the condition is acute (<6 weeks) and uncomplicated (no red flags indicating referral), there may be an initial trial treatment phase of 2 weeks at a frequency of three to five times per week.

- At 2 weeks the case is reevaluated (unless there is progressive worsening); if improving, the patient is given an education program regarding activities of daily living (ADL) and a graduated program of exercise and stretching, with treatment continuing for up to 8 weeks depending on the patient's progress; if not improved, a 2-week trial with a different treatment plan is suggested.
- If after the second 2-week trial, the patient has not improved, consultation or referral is suggested.
- Cases that will likely have a prolonged recovery include those with symptoms lasting longer than 8 days, severe pain, more than four previous episodes, or preexisting structural or pathologic conditions.

Active care criteria include decreasing pain and inflammation and an improvement in range of motion and joint mobility (**Figures 1-5** and **1-6**). There is a phase where passive and active care coexist. During this stage, isometrics performed in limited arcs are helpful initiators and facilitators for a progressive exercise program. Progressing through a graded program involves setting criteria for passing each stage. The most common criteria are range of motion, strength levels, and performance without pain.

Active care elements include training to increase range of motion, strengthening primary and secondary stabilizers of a given joint or region, increasing the endurance capabilities of the muscles, proprioceptively training for balance and reaction time, and finally, functionally training for a specific sport or occupational task. Each element involves different training strategies (**Table 1-9** and **Exhibits 1-5** through **1-7**).

## Strength and Endurance

Strengthening begins with facilitation. This is accomplished either through isometrics performed at every 20° to 30° or rhythmic stabilization using elastic tubing, performing very fast, short-arc movements for 60 seconds or until fatigue or pain limits further performance. Strengthening may then progress to holding end-range isometrics with elastic tubing for several seconds, and slowly releasing through the eccentric (negative) contraction. In some cases, these end-range isometrics may be performed initially against only gravity. If these elements are strong and pain free, progressing to full-arc isotonic using weights or elastic tubing may be introduced. It is best to begin with three to five sets of high repetitions (12 to 20) using 50% to 70% of maximum weight. After 1 to 3 weeks of this training,

progression through a more vigorous strengthening program may be determined by the daily adjustable progressive resistance exercise (DAPRE) approach<sup>48</sup> (although the exercises are performed every other day). This is a pyramid approach using lower weight with more repetitions and progressing through sets to higher weight and fewer repetitions. The last number of repetitions performed determines the working weight for the next workout.

## Proprioceptive Training

Proprioceptive training incorporates various balance devices such as wobble boards, giant exercise balls, and mini trampolines. The intention is to have the body part react to changing support as quickly as possible and to integrate the rest of the body in this attempt.

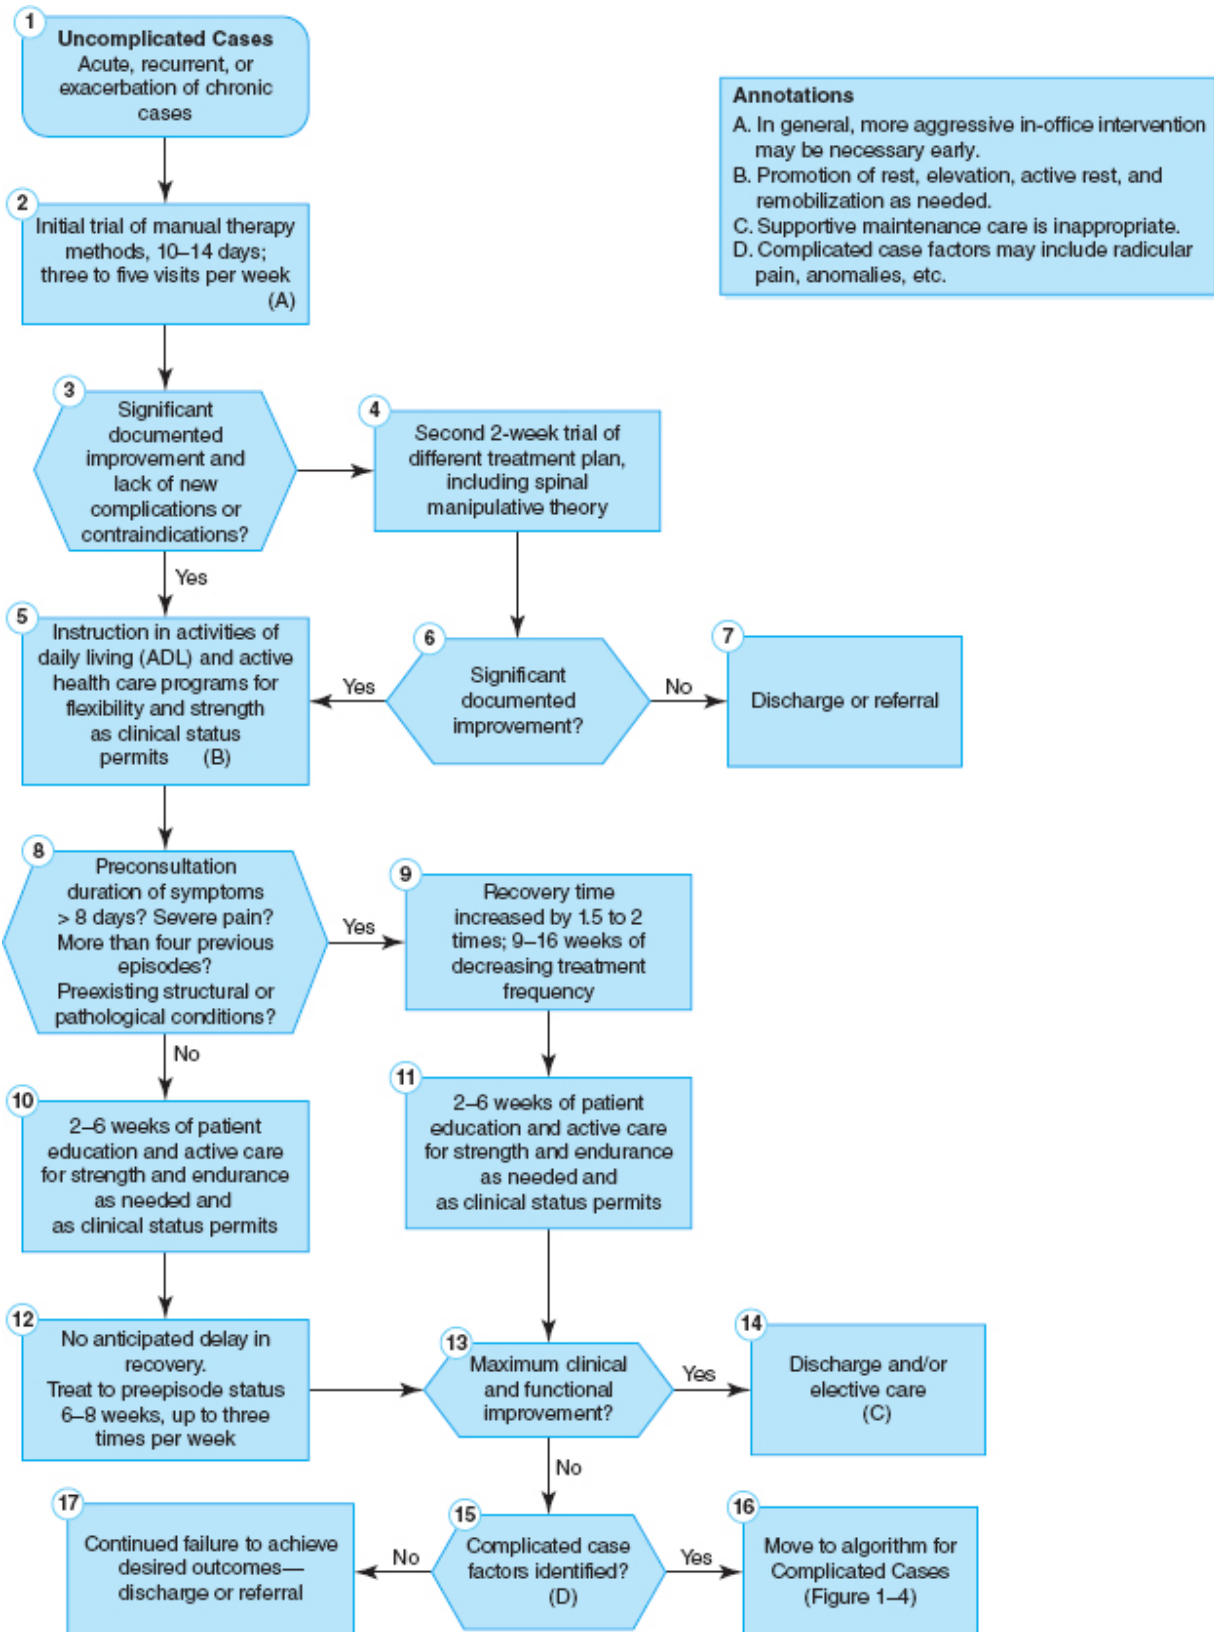

### **Functional Training (also see Functional Movement Evaluation earlier in this chapter)**

Functional training is based on the requirements of a given sport or occupational activity and requires a knowledge of the biomechanics involved. Various PNF techniques may be employed. Simulated task performance is another approach for occupational retraining.

### **Whole-Body Vibration Therapy**

Whole body vibration (WBV) has become a popular approach in the physiotherapy and rehabilitation arena. It is applied through a broad contact area that involves a sitting or standing platform. The vibration is in the range of 0.5 to 80 Hz. Aliases include *biomechanical stimulation (BMS)*, *vibration therapy*, and *biomechanical oscillation (BMO)*.

**Table 1-9** The Daily Adjustable Progressive Resistance Exercise (DAPRE) Approach

<b>Set</b>	<b>Weight</b>	<b>Repetitions</b>
1	½ working weight	10
2	¾ working weight	6
3	Full working weight	Maximum
4	Adjusted working weight (based on Set 3)	Maximum
<ul style="list-style-type: none"> <li>• Use the following table to determine working weight for Set 4 (based on number of repetitions in Set 3).</li> <li>• Full working weight (Set 3) of the next training session is based on number of repetitions performed in the Set 4.</li> </ul>		
<b>No. of Repetitions</b>	<b>For Set 4</b>	<b>Next Session Full Working Weight</b>
0-2	Decrease 5-10 lb	Decrease 5-10 lb
3-4	Decrease 0-5 lb	The same
5-6	The same	Increase 5-10 lb
7-10	Increase 5-10 lb	Increase 5-15 lb
11 or more	Increase 10-15 lb	Increase 10-20 lb

As with most therapies, it is not as simple as one therapy—there are a multitude of types, brands, protocols, and

claims. General parameters include the direction and force of vibration matched to the intention. Machines may vibrate in one or more than one direction: sideways (x), front and back (y), and up and down (z). The z-axis has the largest amplitude and is the most defining component in generating and inducing muscle contractions. Machines that offer side alternation (x-axis) usually can provide a larger amplitude of oscillation and a frequency range of about 5 to 35 Hz.

Following are some standard divisions based on type and use:

- High Energy Lineal (HVL), commonly found in gyms and vibration training centers. HVL machines focus on the vertical or upward movement of the platform, which is intended to increase gravity's effect eliciting a strong stretchreflex contraction in muscles. Linear/upright systems deliver lower amplitudes but higher frequencies in the range of 20 to 50 Hz.
- Premium Speed Pivotal, basically a teeter-totter movement, often used for exercise workouts at speeds up to 30 Hz.
- Other types include Medium Energy Lineal, which accounts for the majority of lineal platforms produced. Often made of plastic, their construction may be less durable.
- Low Energy/Low Amplitude Lineal and Low Energy/High Amplitude Lineal, used primarily for the older population with the intended outcomes of improved circulation, osteoporosis prevention, and minimal fitness maintenance.

Although WBV has been proposed for a multitude of disorders ranging from musculoskeletal disorders (including tendinosis, osteoporosis, strength training), stroke, neurological disorders (including multiple sclerosis, cerebral palsy, Parkinson's, spinocerebellar ataxia), and even the

metabolic profile of metabolic syndrome and diabetes, there appears to be no clear evidence at this time that it leads to any clinically significant changes. Many studies either show no difference between groups randomized to placebo or WBV or only statistically significant changes; not clinically significant. An example would be for a 10-m or Timed Up and Go Test, the differences amount to 1 second or less and, although passing the test of statistical significance, are unlikely to make any difference to a patient. Secondly, there are no indications of what protocol to use. There are differences that include standard WBV, nonrandom rotational, or vertical higher frequency (20–50 Hz) vibration (used in most WBV research), and stochastic meaning random, low-frequency vibration (2.0–6 Hz).

A commonly tested claim of WBV proponents that it is effective in improving balance through a process whereby vibration stimulates nerves that stimulate alpha-motor neurons that cause muscle contraction at an increased rate and more effectively when compared to other approaches, there is little evidence to support such a claim.

## **Exhibit 1-5 Eccentric Exercise Protocols**

### **General Comments**

- Eccentrics are usually begun in the subacute phase of healing.
- Although there is some disagreement, the initial phase begins somewhere between 3 and 7 days after injury depending on severity.
- The superiority of eccentrics over concentrics occurs only during the first 19 days postinjury.
- A load of up to 20% above a one-repetition maximum is considered safe.
- It is suggested by the literature to perform between 3 and 20 repetitions with a three-set maximum; two to three times per week. Two times per week will probably prevent delayed-onset muscle soreness (DOMS).
- Rest periods are not as important due to the low oxygen demand. Somewhere between 30 seconds to 1 minute is sufficient.
- Training begins with slow progressing to faster repetitions.
- Two concerns are chance of overload injury and DOMS.

- Generally, there are three phases of training. An example for the lower extremity follows:
  1. Two-leg concentric/eccentric training is followed by two-leg concentric/injured leg eccentric work.
  2. Slow, submaximal, single-leg eccentrics are performed. The first two phases are usually completed in 3 weeks or less.
  3. Functional eccentrics are performed in preparation for plyometrics. This phase usually takes 2 to 3 weeks to complete.

## **Functional Eccentrics for the Lower Extremity**

A sample of a functional eccentric program would include the following:

1. One-leg step-up onto 12-inch stool; noninvolved leg steps up first, down last.
2. One-leg step-up; involved leg steps up first, down last.
3. Repeat with 18-inch step height.
4. Slow quarter squats.
5. Rapid quarter squats.
6. Slow parallel squats.
7. Rapid parallel squats.

## **Curwin and Stanish<sup>47</sup> Eccentric Protocol for Tendinitis/Tendinosis**

1. Static stretching for 15–30 seconds is repeated three to five times.

2. Eccentric exercise is begun with gravity or light weights. For the first 2 days they are performed slowly. During days 3–5 they are performed at moderate speed. On days 6 and 7 the exercises are performed quickly. Three sets of 10 are performed.
3. After the eccentric phase, a repeat of the static stretching phase is performed.
4. Follow with 5–10 minutes of icing.

Curwin and Stanish suggest that there should be some pain felt in the third set. If not, the resistance should be increased slightly. If pain is felt in the first two sets, weight should be decreased slightly.

Based on the literature, there is a limit to the strength of conclusions for most studies regarding effect. What is fairly clear at this point is that:

- Used for the purpose of weight loss, there is no support for this proposed effect.<sup>50</sup>

- Reduction or prevention of chronic low back pain is not evident from current studies.<sup>51, 52</sup>

- There is insufficient evidence of the effect of WBV training on functional performance of neurodegenerative disease patients.<sup>53</sup>

## **Exhibit 1-6 Advanced Training Approaches**

### **Russian Stimulation Protocol**

- Place one electrode over the muscle and one over the associated nerve root.
- Use a 2500-Hz carrier wave; modulate at 50 pulses per second.
- Increase intensity to patient tolerance.
- Use 10-second maximum contraction with 50-second rest periods equaling 10 contractions in 10 minutes.
- Use three to five treatments per week for 5 to 7 weeks for a total of 23 to 35 treatments (2-day rest period per week).
- Protocol is used one time per year, best at night and not before or after strenuous exercise.

### **Plyometrics for the Lower Extremity**

- Plyometrics are advanced exercises used only under the following conditions:

1. Strength and flexibility are preinjury.
2. Static stability is demonstrated with the following:
  - single-leg stance
  - single-leg quarter squat
  - single-leg half squat

All can be performed for 30 seconds with eyes open and closed.

- A plyometric workout should be sport-specific and include the following (general conditioning):
  1. Warm-up for 10 to 20 minutes.
  2. Low-intensity drills: 3 to 5 exercises; 10 to 20 repetitions.
  3. Moderate-intensity drills: 3 to 4 exercises; 5 to 8 repetitions.
  4. High-intensity drills: 2 to 3 exercises; 10 to 20 repetitions.
- A plyometric protocol begins with horizontal and progresses to vertical movements.
- Horizontal progression is as follows:

1. Double-leg forward hopping in a straight line.
2. Side-to-side hopping, double leg.
3. Combination of side-to-side and forward hopping.
4. Follow with single-leg progression following the above sequence.

- Vertical progression is as follows:

1. Jump from the floor to a box and back down, starting with 6-inch box and progressing to 12-inch, then 18-inch, then 20-inch.
2. Jump in a line using boxes of variable height.

Never use plyometrics for an athlete with quadriceps or patellar tendinitis.

Most promising are the use of WBV for the following:

- Neuropathy—some improvements with diabetic neuropathy associated with increases in blood flow.<sup>54</sup>
- Adjunct to management of type 2 diabetes—including some limited information about metabolic improvement, increased blood flow, and adiposity.<sup>54, 55</sup>
- Osteoarthritis of the knee—decreases in knee pain.<sup>56</sup>
- Mild increases in osteogenic activity with variable indicators of increased bone mineral density.<sup>57</sup>

## **Exhibit 1-7 Classic Elastic Tubing Protocol**

### **Facilitation**

A fast midrange movement is performed for 30 to 60 seconds or until painful. The number of sets is determined by the overall status of the patient. When this can be performed pain free for 2 or 3 days, move on to the next phase.

### **Strength**

A slow full-range movement is performed and held for an isometric contraction of up to 30 seconds at end-range. This is followed by a slow eccentric phase (at least twice as long as the concentric). Rest for 10 seconds and perform again for up to 10 repetitions (pain or fatigue dependent). When performed for 2 or 3 days pain free, move to the next phase.

# Endurance

A fast full-range movement is performed at the rate of one per second. This may be performed for 50 to 60 seconds or until pain or fatigue is felt. Several sets may be performed with resting phases of 30 seconds. When this is possible for 2 or 3 days pain free, the patient has the option of progressing to pulley or free-weight exercise.

- The thickness and length of the tubing determine the resistance.
- Thicker, shorter tubing is more resistant and requires more patient effort.
- Resistance increases throughout the concentric contraction and decreases through the eccentric phase.

## Variations of Elastic Tubing Exercise Protocols

- Currently, short-arc, fast repetitions are used for stabilization. May be used every 20° or so or may focus on position of instability (e.g., 20° to 30° knee flexion for anterior cruciate ligament tears).
- Eccentric focus only for tendinitis. For example, place knee in final position of flexion or extension and resist tubing while lengthening the muscle. For example, extend knee, apply tubing behind, and gradually allow tubing to overcome resistance; end position of knee flexion.
- Sports cord training.
- Closed-chain exercise: squats or seated foot dragging.
- Functional PNF diagonal pattern training.

---

*Note:* Always ice after any of the above exercises.

- Postural control in the elderly, potentially preventing falls.<sup>58</sup>
- Improved blood flow in the elderly—works as a pump on the blood vessels through rapid contraction and relaxation of muscles at 20 to 50 times per second. Patients often feel a tingling sensation as a result of the increased vasodilation.<sup>59</sup>
- Benefit for the management of tendinopathy, in particular as an alternative to Achilles rehab if eccentric exercise is unsuccessful.<sup>60</sup>
- Benefits in avoiding muscle atrophy with bed rest or post-surgery for ACL reconstruction.<sup>61, 62</sup>

# Taping

There are a number of different taping approaches based on the texture and structure of the tape and its intended purpose. All taping has the potential of providing, beyond the structural support, several neurological advantages including decreased pain due to large-fiber mechanoreceptor stimulation of the skin, increased proprioception through increased stimulation to cutaneous mechanoreceptors, and changes in muscle recruitment patterns due to this stimulation.<sup>63, 64</sup>

Standard white (Zonas) taping is structurally unforgiving and is more often used for stability with ankle sprains and AC separations, yet the time frame upon which the support is provided has been shown to be rather limited. Even more rigid is Leukotape (McConnell taping) or “brown” tape, which is more supportive. This approach has been used for patellar stability among others. Yet, again the effect seems less on the stability, which does not appear to last long, but more likely based on the same neurological reflex responses seen with all tape.

Most recently there has been an interest and increased use of several types of taping that have some similar qualities. The first to gain widespread attention is Kinesio tape. This approach is less focused on support and more on the following unique characteristics and proposed mechanisms of effect in addition to standard taping:<sup>65</sup>

- It has elasticity in one direction and can be stretched to 140% of its original length. As a result there is a constant pulling (shear) force to the skin.
- It is air-permeable and water-resistant and can be worn for several days.
- There may be improved circulation of blood and lymph by eliminating tissue fluid or bleeding beneath the skin

- through constant compression and pumping effect.
- It may affect the function of fascia and muscle.

## **Instrument-Assisted Soft Tissue Mobilization**

As the original approach to instrument-assisted soft tissue mobilization (IASTM), Graston Technique utilizes a set of metal instruments to deliver a directional massage. As part of an even larger concept of tissue therapy called provocation therapy, its goal is to break down scar tissue and fascial restrictions. The practitioner performs a “scan” of the involved area and through the metal is able to perceive areas of adhesion that then direct application. Often the beveled side of the tool is used for broader areas of application and, in addition, a lotion is applied prior to treatment. Rules governing directional application are similar to standard massage (in the direction of lymphatic flow) and with caution regarding a temporary skin reaction of small petechiae, practitioners deliver a treatment session that is generally quite short. The general rule of thumb is that a response should be felt almost immediately and sustained for at least several hours. This is a prime indicator of potential long-term effectiveness. Many practitioners combine the treatment concept of IASTM with other techniques such as myofascial release or functional movement to create an approach that uses movement coupled with application of Graston or Graston-like instrument massage. Although these techniques are now quite widespread with the development of a number of modifications of the original Graston tools, other than a handful of case studies, there is still little evidence in the literature at this time to support this approach.<sup>66, 67</sup> It is hoped that new research will emerge on this new resurfacing of an age-old approach (i.e., coin therapy in Asia).

# Nutritional Support

The nutritional support needed for musculoskeletal healing is based on recommendations made by Gerber.<sup>49</sup>

- In the inflammatory phase of healing, proteolytic enzymes, bioflavonoids, and vitamins C and E are recommended. Bromelain in doses of 1200 mg/d of 2400 $\mu$  potency taken between meals for several days may be beneficial.
- In the proliferative phase, arginine, glycine, proline, vitamins A and C, pantothenic acid, and zinc may be of benefit. Connective tissue repair may be aided with glycosaminoglycans, manganese, and chondroitin sulfate.
- Fracture healing may be enhanced with adequate dietary calcium, vitamin D, phosphorus, and magnesium; microcrystalline hydroxyapatite may also be of benefit (6 to 8 g/d).

## The Anti-Inflammatory Diet

Linoleic acid from n-6 fatty acids is converted to arachidonic acid and through several steps into prostaglandin-E<sub>2</sub> (PGE<sub>2</sub>) and other pro-inflammatory eicosanoids. It may be that many chronic diseases and cancers are in part maintained or supported by this pro-inflammatory environment. Breast cancer is one example. One study indicates that women with high n6 fatty acid intake and a low n3 fatty acid intake were more prone to develop breast cancer.<sup>69</sup> N-6 fatty acids are found in high amounts in most seeds (and their oils) as well as in grains and their manufactured varieties (e.g., flours, pasta, cereal, chips, desserts). Meats, dairy fats, and shellfish are also converted to arachidonic acid, which is converted to PGE<sub>2</sub>. There is a belief that a ratio of n6 to n3

fatty acids should be close to 1:1 for humans to maintain an anti-inflammatory internal environment. Ratios in the modern diet can be as high as 10:1 to 30:1. If a diet consisted of less grain and seed and more vegetables, fruit, and fish, the proper balance of n6 to n3 would be maintained. It is possible to buy eggs and beef that have a higher n3 content.  $\Omega$ -3 fatty acids may also be supplemented in the form of fish oil (obtainable from eicosapentaenoic acid and docosahexaenoic acid (EPA/DHA) and alpha-linolenic acid (ALA) from flaxseed oil. Typical doses for EPA/DHA are 1 to 2 grams per day and for ALA, 2 grams per day.

A popular theory regarding the cause of many diseases that appear autoimmune is that both molecular mimicry and a “leaky gut” are factors in establishing an autoimmune response in the body. According to the proposed model of molecular mimicry, microbial antigens resemble self-antigens when exposed to the mucosal immune system and an auto-immune process is triggered. The process is set in play and perpetuated by the body’s own immune response and then becomes independent of exposure to the environmental trigger and is therefore self-perpetuating and irreversible.

The leaky gut theory is based on a model that proposes that the normal macromolecule trafficking dictated mainly by intestinal paracellular permeability involves alterations in intestinal permeability due to changes in the competency of barriers called tight junctions.<sup>70</sup>

The molecular mimicry theory is an extrapolation of the viral mimicry theory that is believed to be the mechanism by which some diseases such as multiple sclerosis are activated. The dietary version suggests that, in genetically susceptible individuals, certain undigested food particles can mimic human protein, such as collagen, and elicit an autoimmune response. For example, bovine serum albumin (BSA) found in cow’s milk may be considered by the body as

an antigen, and given that it is similar in sequence to human collagen may cause an autoimmune reaction.<sup>71</sup> Another example is glycine-rich protein found in grains and legumes, which has a similar protein sequence to connective tissue. Other suspected agents include wheat germ agglutinin (WGA) found in wheat, phytohemagglutinin (PHA) found in kidney beans, and peanut lectin (PNA) found in peanuts.

In addition to digestion, the gastrointestinal system, specifically the intestinal lining, provides an immune defense for the body. Immune defense is accomplished partly by the intestinal mucosa that acts as a physical barrier, by intestinal secretions (e.g., secretory IgA antibodies), and via intramural lymphocytes. One suggested test for the leaky gut syndrome is the lactulose-mannitol test.

Dietary support for providing an intact and functioning intestinal lining (see **Table 1-10**) includes:

- Glutamine—acts as a fuel source for intestinal cell maintenance and repair.

- Vitamins C and E, lipoic acid, zinc, and ginkgo biloba—act as antioxidants, protecting the mucosal lining from free-radical damage.
- Deglycyrrhizinated licorice (DGL)—thought to increase cell wall integrity of mucosal cells.
- N-acetylglucosamine (NAG)—helps to heal extracellular tissue and may decrease binding of some lectins.
- Probiotics—believed to counteract harmful bacteria.
- Hydrochloric acid and digestive enzymes—believed by some that if food particles are digested with the assistance of supplemental HCL and digestive enzymes, the less likely it will be that antigenic responses will occur.

# Modification of the Inflammatory Response

Aspirin, nonsteroid anti-inflammatories (NSAIDs), and cyclooxygenase inhibitors (COX) block the cyclooxygenase enzyme that converts arachidonic acid to prostaglandin E-2, decreasing or blocking inflammation. Also, corticosteroids inhibit phospholipase A2, which inhibits arachidonic acid release from phospholipids in the cell membrane. Cell-signaling molecules, which stimulate genes, induce the expression of the COX enzyme. Aspirin, NSAIDs, and corticosteroids inhibit binding of cell-signaling molecules such as NFκ-B, which reduces inflammation (see **Exhibit 1-8**). Conversely, NFκ-B activation induces COX-2 activation, which leads to inflammation. The expression of the coding gene for COX-2 for the production of prostaglandins is transcriptionally regulated by NFκ-B. It is in the cytoplasm and is bound to its inhibitor. Free radicals release NFκ-B from the inhibitor, which then moves into the nucleus to activate genes responsible for COX-2 activation.

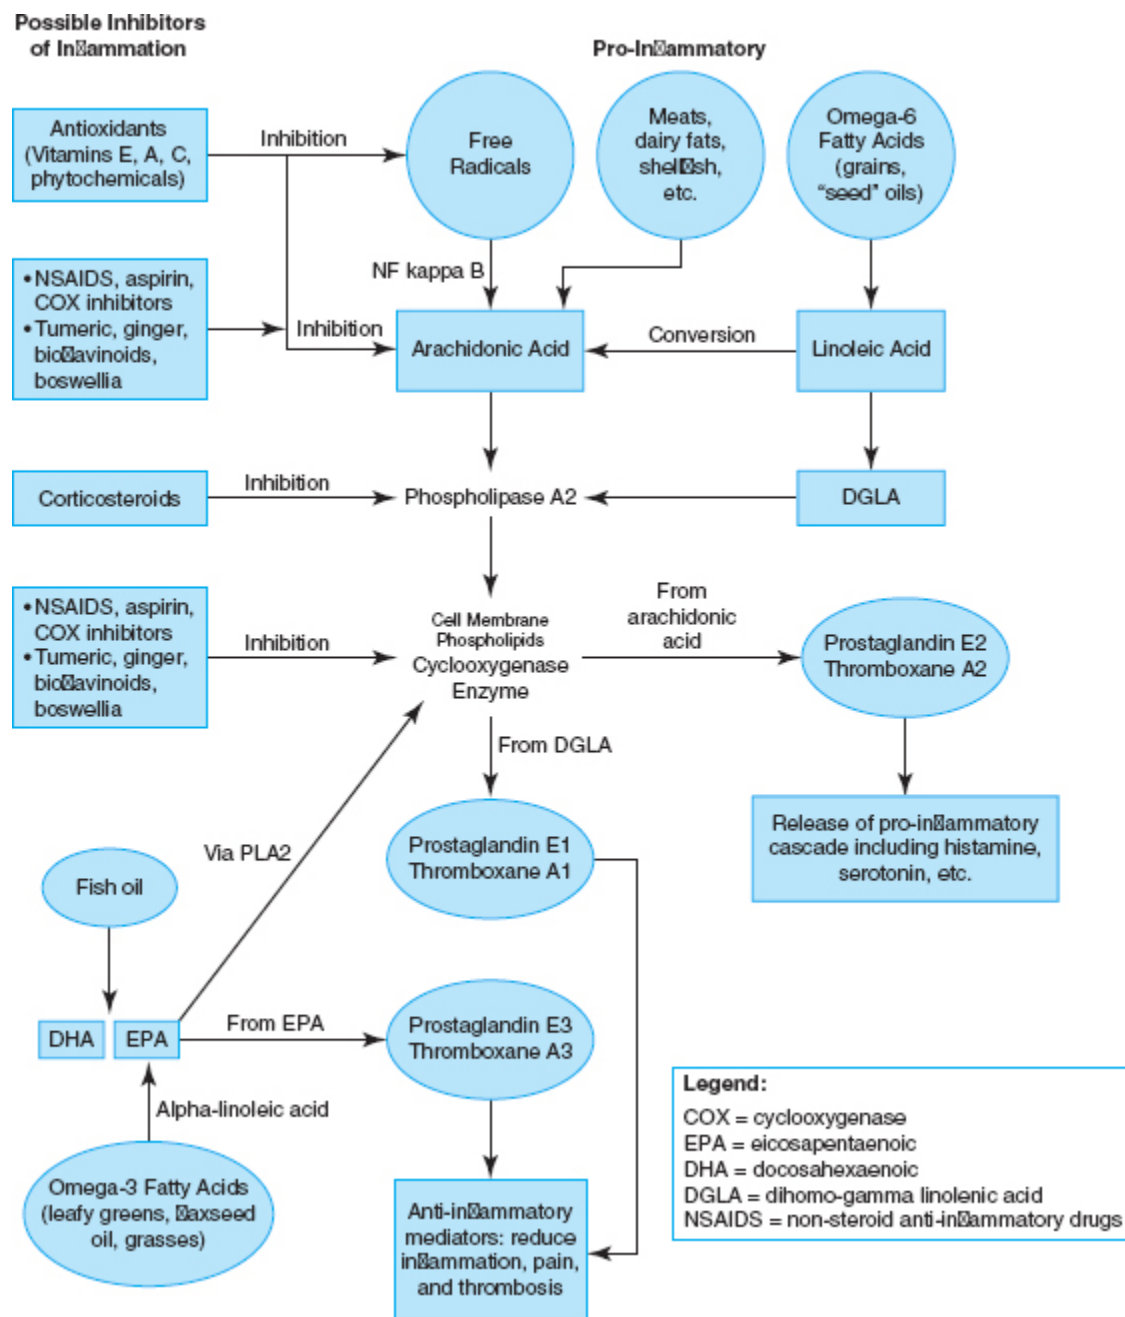

Green tea polyphenols, resveratrol from red wine, vitamins C and E, curcumin, and glutathione reduce the activation of NFκ-B. It is possible that carotenoids and flavonoids also have similar actions. Also, the anti-inflammatory omega-3 fatty acids are found in green vegetables, most fish, wild game, grass-fed meat, and EPA/DHA fish oil.

**Table 1-10** Nutritional Support for Osteoarthritis

Substance	How Might It Work?	Dosage	Special Instructions	Contraindications and Possible Side Effects
Glucosamine sulfate	Stimulates the rebuilding of damaged cartilage	500 mg three times per day	Take with meals Take 6–8 weeks to determine effect	No contraindications May cause some gastrointestinal upset Does not interfere with other anti-inflammatory drugs Some products processed with sodium chloride; use caution with patients who are hypertensive
Boswellia	Decreases inflammation	150 mg three times per day (for example, if extract contains 37.5% boswellic acids, need 400 mg of extract taken three times/day)	Take for 8 to 12 weeks	None at recommended dosage
Horsetail	Decreases inflammation	Taken as a tea at 1–4 g/day; tincture would be taken as 2–6 ml three times per day	Take for 8 to 12 weeks	None at recommended dosage
SAM (S-adenosylmethionine)	Possibly raises levels of dopamine	1600 mg/day	None	Occasional gastrointestinal upset Some caution about patients with manic-depression switching from depression to a manic episode Apparently safe in pregnancy
Vitamin E	Antioxidant	100–300 IU/day	None	None at recommended dosage
Niacinamide	Form of vitamin B3; may relieve symptoms and increase mobility	250 mg of niacinamide or nicotinamide 4–16 times/day	Improvement may take 3–4 months of supplementation	None at recommended dosage Rare liver problems at several thousand milligrams per day
Vitamin C, iron (glycinate), and alpha-ketoglutaric acid	Required for hydroxylation of L-proline to L-hydroxyproline needed for quality collagen production	Vitamin C—3000–6000 mg/day in divided dosages Iron (glycinate)—8–12 mg/day in divided dosages Alpha-ketoglutaric acid—15 mg/day in divided dosages	Improvement may take 3–4 months of supplementation	Use caution with high dosages of vitamin C; it may lead to diarrhea or urinary tract irritation in some people

**Note:** These substances have not been approved by the Food and Drug Administration for the treatment of this disorder.

## Exhibit 1-8 Contributors and Mediators of Inflammation: A Simplified Presentation

Reproduced from Seaman DR. *Clinical Nutrition for Pain, Inflammation, and Tissue Healing*. NutrAnalysis 1998, Hendersonville, North Carolina.

**Table 1-11** presents a general nutritional approach to tendinosis and other soft tissue injury.

**Tables 1-12, 1-13, and 1-14** outline common medications used in the management of musculoskeletal pain and inflammation.

Chondroitin sulfate is occasionally suggested for OA. Probably same effect or less than glucosamine sulfate. If taken, typical level is 400 mg three times per day.

**Table 1-11** General Nutritional Approach to Tendinitis/Tendinosis and Other Soft Tissue Injury

<b>Substance(s)</b>	<b>Recommended Amount</b>
<b>Proteolytic enzymes (trypsin, chymotrypsin, bromelain)</b>	Bromelain at 1200 mg/day of 2400 mcu (milk clotting units) in divided doses in between meals is at the high end of recommended dose. This is for acute inflammatory phase only (for several days only). Contraindicated in patients with bleeding tendencies (or peptic ulcer); systemic infection; or allergy to source product such as pineapple, pork, beef, or papaya.
<b>Bioflavonoids (quercetin, hesperidin, rutin, etc.)</b>	600-1800 mg/day. Often taken at 200 mg every 2 waking hours. Taken before peak of inflammatory phase.
<b>Herbs (boswellia, ginger, turmeric, cayenne)</b>	Boswellia—400 mg, ginger—300 mg, turmeric—200 mg, cayenne—50 mg taken every 2 waking hours during inflammatory phase.

**Table 1-12 Pain Medications**

Drug Class	Examples	General Mechanism	Interactions/Side Effects
NSAIDs	Aspirin (acetylsalicylic acid)	Inhibits the formation of pro-inflammatory prostaglandins. Acts as an anti-inflammatory, antipyretic, and analgesic.	Some individuals are allergic to aspirin and may have a hypersensitivity reaction including an asthma-like response.
	Alka-Seltzer A.S.A. Aspergum Bayer Cosprin Easprin Ecotrin Empirin Entrophen Novasen St. Joseph's Triaphen-10 ZORprin	Also has an antiplatelet effect. Used in the management of pain, fever, and prophylactically for its anticlotting action for prevention of stroke (transient ischemic attack), recurrence of MI, and thrombus formation (such as deep vein thrombosis).	Heartburn and stomach upset may be due to irritation leading to peptic ulcer formation. Anemia may be due to blood loss or hemolytic anemia. Ototoxic effects include tinnitus and hearing loss. High doses may impair renal function.
	Naproxen Naproxen sodium Aleve Anaprox Apo-Naproxen Naprolen Naprosyn	NSAID. Similar to ibuprofen, ketoprofen, etc. Inhibits inflammatory prostaglandin synthesis. Actions include analgesic, anti-inflammatory, and antipyretic. Inhibits platelet aggregation and prolongs bleeding time but does not affect clotting.	May cause headache, drowsiness, dizziness, anorexia, heartburn, nausea, GI bleeding, and rarely agranulocytosis.
	Indomethacin Indameth Indocid Indocin Indocin SR	NSAID used to reduce pain and fever. May reduce activity of PMNs, development of cellular exudates, and vascular permeability when tissue is damaged.	Hypersensitivity possible with rash, dyspnea, asthma syndrome if patient is an aspirin-sensitive asthmatic, edema, hypotension. Also, concern of GI bleeding and rarely an aplastic anemia affect or renal function impairment.

COX-2 inhibitors	Celecoxib	NSAID: cyclooxygenase (COX) 2 inhibitor (does not inhibit COX-1) used primarily for arthritis (osteo, rheumatoid, and rheumatoid variants), acute pain, and menstrual cramps. Reduces fever. Also approved to prevent and reduce the size of polyps in patients with genetic disease.	May cause back pain, peripheral edema, GI problems, dizziness, headache, pharyngitis, and rash.
	Celebrex		
Opioids	Codeine	An opiate derivative from morphine. Antihistamine effect stronger than morphine. Effective for pain relief and cough suppression.	May cause constipation, dizziness, urticaria, anaphylactic reaction, or urinary retention.
	Methylmorphine Paverol		
	Meperidine	An opiate receptor agonist having the effects of analgesia, respiratory depression, and sedation.	May cause dizziness, sedation, nausea, constipation, allergic reaction, respiratory depression, convulsions, cardiovascular collapse.
	Demerol		
	Pethadol		
	Pethidine HCL		
	Pentazocine	A synthetic analgesic, narcotic, CNS depressant used in the management of moderate to severe pain and preoperative sedation.	Not to be used with head injury. Will cause drowsiness, lightheadedness, and sedation. May cause dizziness, nausea/vomiting, constipation, urinary retention, rash, respiratory depression, or shock.
	Talwin Talwin Nx		
	Propoxyphene	Related to methadone; a strong opioid. Used for mild to moderate pain. Also used to manage narcotic withdrawal.	Caution that use with alcohol or high doses may cause death. Also more commonly causes drowsiness, constipation, skin reactions, GI upset, and rarely circulatory collapse or coma.
	Darvon Novopropoxyn		
	Tramadol	Tramadol and its main metabolite bind to opioid receptors. Also reduces uptake of norepinephrine and serotonin. A pain reliever that is similar in action to narcotics with less of a risk for addiction or abuse.	May cause constipation, dizziness, nausea/vomiting, headache, and pruritus.
	Ultram		
Opioid combinations with NSAIDs or acetaminophen	Hydrocodone/acetaminophen	Narcotic pain reliever and cough suppressant similar to codeine (CNS depression). The acetaminophen component is a non-narcotic pain reliever and fever reducer.	May cause dry mouth, nausea, vomiting, lightheadedness, dizziness, euphoria, dysphoria, some respiratory depression, and rash.
	Anexsia Lorcet Lorcet Plus Norco Vicodin Vicodin ES		
	Hydromorphone hydrochloride	Similar to morphine but much stronger analgesic effect. Used for mild to moderate pain and cough suppression.	May cause drowsiness, respiratory depression, euphoria, dizziness, and various GI symptoms.
	Dilaudid Dilaudid-HP		

	<b>Oxycodone</b>  Oxycontin Oxyfast Percolone Roxicodone	Binds to stereo-specific receptors in the CNS having the effects of a potent analgesic; ten times more potent than codeine. Used in the management of pain with fractures, bursitis, dislocations, postsurgery, and postpartum.	May cause sedation, constipation, respiratory depression, or hepatotoxicity.
<b>Non-benzodiazepine muscle relaxants</b>	<b>Cyclobenzaprine</b>  Cycloflex Flexeril	Similar in structure to tricyclic antidepressants, these medications are used as muscle relaxants acting primarily on the CNS specifically at the brainstem. Increases circulating norepinephrine by blocking reuptake. Also has sedative effects and anticholinergic effects.	Drowsiness, dizziness, dry mouth, edema of the tongue, palpitations, chest pain, pruritus, and similar side effects of tricyclic antidepressants. Contraindicated for patients with heart problems.
	<b>Chlorzoxazone</b>  Paraflex Parafon Forte	Used as a "muscle relaxant" due to action of depression of nerve transmission. Has slight sedative action. Used in combination with other medications in the treatment of low back and neck pain associated with muscle spasm.	May cause drowsiness, dizziness, nausea, vomiting, constipation, rash, or jaundice.

**Table 1-13** Rheumatic Drugs Including DMARDs (Biologics and Nonbiologics)

Drug Class	Examples	General Mechanism	Interactions/Side Effects
Disease modifying antirheumatic drugs (DMARD) a.k.a.-Biologics	Abatacept	A disease-modifying antirheumatic drug (DMARD) inhibits T-cell proliferation and inhibits tumor necrosis factor alpha, gamma-interferon and interleukin-2, and decreases anticollagen antibody production. Used in the management of rheumatoid arthritis in patients who have inadequate response to other DMARDs. Used as mono therapy or in combination. Given as IV infusion.	Hypersensitivity reactions, headache, dizziness, hypertension, upper respiratory infection, malignancies, urinary tract infections.
	Orencia		
	Etanercept		
	Enbrel	A recombinant DNA substance that binds to tissue necrosis factor-alpha (TNF) receptors. TNF is a cytokine that induces an inflammatory action through interleukins. Affective in the management of Crohn's disease and inflammatory arthritic disorders such as RA and psoriatic arthritis.	May cause the usual GI disturbances, headache, dizziness, fatigue, loss of hair, pruritus. Rarely cause MI, serious infections, or pancytopenia.
	Adalimumab Humira	A disease-modifying antirheumatic drug (DMARD) is used alone or with methotrexate for the treatment of rheumatoid arthritis and similar disorders. A human monoclonal antibody, it works by blocking tissue necrosis factor (TNF)-alpha, a major protein involved in inflammation.	May cause a local injection response, rash, or increase the risk of serious infection such as tuberculosis, neurologic events, or malignancies. Very expensive.

	<b>Infliximab</b>	An IgG1-K monoclonal antibody that binds to tissue necrosis factor- $\alpha$ (TNF). TNF is a cytokine that induces an inflammatory action through interleukins. Affective in the management of Crohn's disease and inflammatory arthritic disorders such as RA and psoriatic arthritis.	May cause the usual GI disturbances, headache, dizziness, fatigue, lupus-like syndrome, loss of hair, pruritus, and increased liver enzymes.
	<b>Remicade</b>		
<b>Anti-inflammatory</b>	<b>Prednisone</b>	Synthetic oral corticosteroid used to suppress immune system reaction including inflammation. These medications mimic actions of cortisol (hydrocortisone) produced by the adrenal gland. Used in the treatment of inflammatory arthritis, colitis such as Crohn's and ulcerative colitis, asthma, bronchitis, some skin rashes, allergic or inflammatory conditions affecting the nose and eyes.	Long-term use may cause suppression of bone growth, osteopenia and resultant fractures, Cushing's syndrome (osteoporosis, skin atrophy, abnormal glucose tolerance, anemia, behavioral abnormalities, etc.). Increased risk of candida (yeast) infection.
	Dethasone		
	Liquid Pred		
	Medrol		
	Oral Liquid		
	Pediapred		
	Prednisolone		
	<b>Sulfasalazine</b>	A long-acting sulfonamide used in the management of clostridium and <i>E. coli</i> infections, inflammatory bowel disease, and RA. Anti-inflammatory effect may be due to inhibition of prostaglandins, and may have antibacterial effect due to conversion to sulfapyridine and 5-ASA.	May cause nausea, vomiting, bloody diarrhea, anorexia, rash, and allergic reactions.
	Azulfidine		
	Sulfasalazine		
	Salazopyrin		
	S.A.S.-500		
	<b>Methotrexate</b>	An antimetabolite that blocks the metabolism of fast-growing cells. Blocks folate reduction through inhibitory effect on dihydrofolate reductase. Used in the treatment of cancer and rheumatoid-like conditions such as psoriatic arthritis and RA. Cancers include acute lymphocytic leukemia; osteogenic sarcoma; Burkitt's lymphoma; non-Hodgkin's lymphoma; cancers of the brain, head, or neck; and small-cell lung choriocarcinoma. Also used to induce miscarriage (e.g., in ectopic pregnancy).	May cause bone marrow suppression, GI ulcers, nephrotoxicity, hepatotoxicity, nausea, diarrhea, or pulmonary infiltrates.
	Rheumatrex		
	Trexall		
	<b>Sulindac</b>	An indole, prostaglandin inhibitor (similar to indomethacin) used similar to aspirin with fewer GI effects than aspirin. Primarily used for inflammatory arthritis such as RA, ankylosing spondylitis, acute attacks of gout, acute bursitis of the shoulder.	May cause dizziness, headache, abdominal pain, prolonged bleeding time, aplastic anemia, anaphylaxis, toxic epidermal necrosis syndrome.
	Clinoril		
<b>Combination effect</b>	<b>Gold sodium thiomalate</b>	An injectable water-soluble gold compound used in the treatment of rheumatoid arthritis. Appears to have immunosuppressant and anti-inflammatory properties possibly through inhibition of inflammatory prostaglandins.	May cause photosensitivity, dizziness, syncope, proteinuria, stomatitis, GI symptoms, grey to blue discoloration of skin, hypersensitivity and erythema dermatitis.
	Myochrysine		
	<b>Gout Medications</b>	A xanthine oxidase inhibitor used in the treatment of gout. It decreases endogenous uric acid. Inhibiting xanthine oxidase prevents conversion of hypo-xanthine to xanthine and then xanthine to uric acid. Not used for anti-inflammatory effect.	May cause nausea, vomiting, diarrhea, abdominal pain. Concerns over possible hepatotoxicity, renal insufficiency, aplastic anemia, and thrombocytopenia. Check with CBC and liver function tests.
	<b>Allopurinol</b>		
	Alloprin		
	Lopurin		
	Novopurinol		
	Zyloprim		

	Colchicine	Used as an anti-inflammatory agent in the treatment of gout. Sometimes used for sarcoid arthritis and pseudogout.	May cause nausea, vomiting, diarrhea, abdominal pain, steatorrhea, and pancreatitis. Also, a syndrome of muscle weakness may occur with accompanying elevation of serum creatine kinase.
	Novocolchicine		
	Probenecid	A renal tubular blocking agent that prevents the reabsorption of uric acid, thereby, promoting its excretion. Used in the management of chronic hyperuricemia associated with gout.	May cause headache, GI complaints, hemolytic anemia, respiratory depression, and rarely hepatic necrosis.
	Benemid		
	Benuryl		
	Probalan		

**Table 1-14** Neuralgia Drugs

Drug Class	Examples	General Mechanism	Interactions/Side Effects
Calcium channel blocker	Pregabalin  Lyrica	Used in the management of the following: neuropathic pain (diabetic peripheral neuropathy), postherpetic neuralgia, adjunctive therapy for partial seizures, and fibromyalgia. Blocks calcium dependent of pronociceptive neurotransmitter's release.	Dizziness, sleepiness, edema, blurred vision, weight gain, and difficulty with concentration.
Glutamate antagonist	Carbamazepine Carbatrol Tegretol Tegretol-XR	Sodium, potassium, and calcium currents are reduced across neuronal membranes decreasing neuronal transmission. Has an antidiuretic effect. Used in the treatment of seizures and facial neuralgias, also sometimes schizophrenia.	CNS toxicity including sedation, dizziness, imbalance, and nausea/vomiting. Agranulocytosis or aplastic anemia. Also possible cause of birth defects.
GABA agonist	Gabapentin  Neurontin	Related to gamma aminobutyric acid (GABA). Used as an adjunctive treatment of seizures; also used for herpetic neuropathy.	May cause tiredness, ataxia, dizziness, or other CNS effects.

## **CHAPTER 2**

# **Neck and Neck/Arm Complaints**

## **Context**

The cervical spine serves a unique function as a positioner of the head in space. This function requires a proprioceptive integration that results in optimization of head position through reflex setting of muscle tone. Although having the head perched atop the cervical spine allows better appreciation of the surrounding environment, this arrangement creates a potentially damaging lever arm in acute injury events that force the head to move quickly into extremes of flexion, extension, or lateral flexion. In addition to the cervical spine itself, soft tissue and neural structures may be damaged in the extremes of these movements. The lever effect also is operative in a more insidious manner when a forward head position is maintained for prolonged periods, as in a computer work environment. The demands on posterior musculature are dramatically increased by the weight of the head as it moves forward of the body.

The cervical spine is a focus for investigation of complaints that involve the head and upper extremities. The unique association between the upper cervical spinal nerves and the trigeminal nerve is postulated to have effects that result in complaints of headache, facial pain, or ear pain. Upper extremity complaints may be caused or augmented

by cervical spine pathology that affects the spine, nerve roots, or brachial plexus.

Common patient presentations include the following:

- Acute injury neck and/or arm pain (e.g., whiplash, cervical “stingers”)
- Acute, pseudotorticollis (not a true torticollis but a painful limitation of all neck movement)
- Postural pain or stiffness due to poor ergonomics in the work environment
- Osteoarthritis associated stiffness or pain
- Headaches

When arm complaints accompany neck pain, it is essential to make the determination of whether nerve root irritation or a referred phenomenon is the source.

Chiropractors are often faced with patients who, upon examination, demonstrate no objectifiable neurologic deficit in the arm(s) even though numbness/tingling or weakness is part of their complaint. Many of these patients appear to obtain relief from chiropractic procedures, suggesting a referral connection between what is manipulated and what causes the “phantom” symptoms. This is most likely the facet joint. Whether the complaint is local to the neck or referred to the arm, Bogduk<sup>1</sup> states that facet joint pain accounts for the majority of patient complaints. Neck and arm complaints also require a consideration of brachial plexus or peripheral nerve involvement.

The National Board of Chiropractic Examiners (NBCE) Job Analysis 2005<sup>2</sup> estimates that neck pain accounts for approximately 18.7% of all chiropractic visits. In a Canadian study, Cote et al.<sup>3</sup> found that the age-adjusted lifetime prevalence for neck pain was 66.7% and the point prevalence was 22.2%. According to the National Health Interview Survey (NHIS) 13.8% of the population in the United States reported having neck pain in 2004.<sup>4</sup> Data

reported in the Task Force on Neck Pain and Its Associated Disorders provides a range for the 12-month prevalence of 12.1% to 71.5% in the general population and 27.1% to 47.8% in workers (Haldeman). However, the one-year prevalence of disability due to neck pain was between 1.7% and 11.5% in the general population. A more narrow range of only 11% to 14.1% of workers report being limited in their activities during a one-year time frame. Only about 25% of individuals with neck pain seek conventional medical care. However, one to five years after the initial episode of neck pain, 50% to 85% of individuals will again report neck pain. Data from three national surveys indicates that 64% of ambulatory visits for neck pain resulted in a pain diagnosis rather than a pathology diagnosis. In hospitals, 94% of patients with neck pain received a pathology diagnosis with 79% of those patients requiring surgery.

The appropriateness of chiropractic manipulation of the cervical spine for various conditions has been addressed in two major publications: the 1995 scientific monograph of the Quebec Task Force on Whiplash-Associated Disorders<sup>5</sup> entitled “Redefining ‘Whiplash’ and Its Management,” and the 1996 Rand Corporation report<sup>6</sup> entitled *The Appropriateness of Manipulation and Mobilization of the Cervical Spine*. More recently the Bone and Joint Decade 2000–2010 Task Force on Neck Pain and Its Associated Disorders<sup>7</sup> has reviewed the literature and made recommendations regarding evaluation and management. Manipulation is one of the approaches recommended for mechanical neck pain. Although the literature support is not as strong as for the low back, both studies recognize the potential value of manipulation in the management of some cervical spine complaints.

## **General Strategy**

# History

- Screen the patient for “red flags” that indicate the need for either immediate radiographs/special studies or referral to or consultation with a specialist, including severe trauma, direct head trauma with loss of consciousness, nuchal rigidity, bladder dysfunction associated with onset of neck pain, associated dysphasia, associated cranial nerve or central nervous system (CNS) signs/symptoms, onset of a “new” headache, and preexisting conditions such as rheumatoid arthritis, cancer, Down syndrome, alcoholism, drug abuse, or an immunocompromised state.
- If there is a history of trauma, determine the mechanism and severity.
- For patients involved in a motor vehicle accident (MVA), take a thorough history with regard to angle of collision; speed; use of brakes, seat belt, shoulder harness, and air bag; position of the patient in the car; subsequent legal concerns with regard to police reports; and so forth (**Exhibit 2-1**).
- Determine whether the complaint is one of pain, stiffness, weakness, or a combination of complaints.
- Determine whether the complaint is limited to the neck or is radiating to the head or upper extremity unilaterally or bilaterally.
- Determine the level of pain and functional capacity with a questionnaire such as the Neck Disability Index (**Exhibit 2-2**) with a pain scale (e.g., Visual Analog Scale [VAS]).

# Examination

- For patients with nuchal rigidity and/or a positive Brudzinski's or Kernig's sign, refer for medical management.
- For patients with suspected fracture or dislocation (e.g., MVA, compressive or distractive injury to the neck), infection, or cancer, obtain radiographs of the cervical spine.
- For patients with neck pain only, perform a thorough examination of the neck, including inspection, observation of the patient's movements, palpation of soft and bony tissues, motion palpation of the spine, passive and active range of motion (using a goniometer or inclinometer), a functional assessment (e.g., according to Janda<sup>8</sup>), and a brief orthopaedic screening.
- For patients with neck and arm pain, add a thorough orthopaedic/neurologic examination, including compressive and neural stretch maneuvers to the neck in various positions, nerve stretch maneuvers, deep tendon reflex testing, sensation testing (include pain, temperature, light touch, and vibration), and myotome testing.
- Radiographs should be obtained for patients who have radicular findings, including an anteroposterior (AP), AP-open mouth, lateral, and oblique. Flexion-extension views may be added when searching for instability.
- Special imaging, including computed tomography (CT) or magnetic resonance (MR), should be reserved for the differential of radicular or myelopathic cases where there is a need for further distinction among stenosis, tumor, herniated disc, or multiple sclerosis. Electrodiagnostic studies should be reserved for cases where the cause of radicular complaints remains unclear.

## Exhibit 2-1

### Automotive Crash Form

#### Billing Information

Patient name: \_\_\_\_\_

Date of injury: \_\_\_\_\_ Time of injury: \_\_\_\_\_ ☐ AM ☐ PM

City and street where crash occurred: \_\_\_\_\_

What is the estimated damage to your vehicle? \$ \_\_\_\_\_

☐ Yes ☐ No Do you have automobile medical insurance coverage? \_\_\_\_\_

\_\_\_\_\_  
Name/address/phone \_\_\_\_\_

What is your car insurance medical coverage limit? \$ \_\_\_\_\_

What is the claim number? \_\_\_\_\_

☐ Yes ☐ No Do you know the claims adjuster's name? \_\_\_\_\_

☐ Yes ☐ No Have you reported this injury to your car insurance company? \_\_\_\_\_

☐ Yes ☐ No Did the police come to the accident scene and make a report? \_\_\_\_\_

☐ Yes ☐ No Is an attorney representing you? Name/address/phone: \_\_\_\_\_

#### Auto Accident Description

Describe how the crash happened \_\_\_\_\_

\_\_\_\_\_  
\_\_\_\_\_  
\_\_\_\_\_  
\_\_\_\_\_  
\_\_\_\_\_  
\_\_\_\_\_  
\_\_\_\_\_  
\_\_\_\_\_

#### Collision Description

Check all that apply to you:

☐ Single-car crash

☐ Two-vehicle crash

☐ More than three vehicles

☐ Rear-end crash

☐ Side crash

☐ Rollover

☐ Head-on crash

☐ Hit guardrail/tree

☐ Ran off road

#### You were the

☐ Driver

☐ Front passenger

☐ Rear passenger

#### Describe the vehicle you were in

Model year and make: \_\_\_\_\_

☐ Subcompact car

☐ Compact car

☐ Mid-sized car

☐ Full-sized car

☐ Pickup truck

☐ Larger than 1-ton vehicle

#### Describe the other vehicle

☐ Subcompact car

☐ Compact car

☐ Mid-sized car

☐ Full-sized car

☐ Pickup truck

☐ Larger than 1-ton vehicle

#### Estimated crash speeds

Estimate how fast your vehicle was moving at time of crash.

\_\_\_\_\_ mph

Estimate how fast the other vehicle was moving at time of crash

\_\_\_\_\_ mph

**At the time of impact your vehicle was**

- ☐ Slowing down      ☐ Stopped      ☐ Gaining speed      ☐ Moving at steady speed

**At the time of impact the other vehicle was**

- ☐ Slowing down      ☐ Stopped      ☐ Gaining speed      ☐ Moving at steady speed

**During and after the crash, your vehicle**

- ☐ Kept going straight, not hitting anything      ☐ Spun around, not hitting anything  
☐ Kept going straight, hitting car in front      ☐ Spun around, hitting car in front  
☐ Was hit by another vehicle      ☐ Spun around, hitting object other than car

**Describe yourself during the crash**

Check only the areas that apply to you:

- ☐ You were unaware of the impending collision.  
☐ You were aware of the impending crash and braced yourself.  
☐ Your body, torso, and head were facing straight ahead.  
☐ You had your head and/or torso turned at the time of collision:  
    ☐ Turned to left      ☐ Turned to right  
☐ You were intoxicated (alcohol) at the time of crash.  
☐ You were wearing a seat belt.  
    If yes, does your seat belt have a shoulder harness?    ☐ Yes    ☐ No  
☐ You were holding onto the steering wheel at the time of impact.

**Indicate if your body hit something or was hit by any of the following:**

Please draw lines and match the left side to the right side.

Head	Windshield
Face	Steering wheel
Shoulder	Side door
Neck	Dashboard
Chest	Car frame
Hip	Another occupant
Knee	Seat
Foot	Seat belt

**Check if any of the following vehicle parts broke, bent, or were damaged in your car**

- |   |   |                                       |
|---|---|---------------------------------------|
| <input type="checkbox"/> Windshield     | <input type="checkbox"/> Seat frame       | <input type="checkbox"/> Knee bolster |
| <input type="checkbox"/> Steering wheel | <input type="checkbox"/> Side/rear window | <input type="checkbox"/> Other _____  |
| <input type="checkbox"/> Dashboard      | <input type="checkbox"/> Mirror           | <input type="checkbox"/> Other _____  |

**Rear-end collisions only**

Answer this section only if you were hit from the rear.

Does your vehicle have

- ☐ Movable head restraints  
☐ Fixed, nonmovable head restraints  
☐ No head restraints

Please indicate how your head restraint was positioned at the time of crash.\*

- ☐ At the top of the back of your head  
☐ Midway height of the back of your head  
☐ Lower height of the back of your head  
☐ Located at the level of your neck  
☐ Located at the level of your shoulder blades (upper back) below neck

\*Estimate the distance between the back of your head and the front of the head restraints. \_\_\_\_\_ inches

### All types of collisions

Answer this section regardless of the type of crash, indicating those relevant to your case.

Yes No

- ☐ ☐ Did any of the front or side structures, such as the side door, dashboard, or floor board of your car, dent inward during the crash?
- ☐ ☐ Did the side door touch your body during the crash?
- ☐ ☐ Were your hands on the steering wheel or dashboard during the crash?
- ☐ ☐ Did your body slide under the seat belt?
- ☐ ☐ Was a door of your vehicle damaged to the point where you could not open the door?

### Emergency department

Yes No

- ☐ ☐ Did you go to the emergency department after the accident?  
What is name of the emergency department? \_\_\_\_\_  
When did you go (date and time)? \_\_\_\_\_
- ☐ ☐ Did you go to the emergency department in an ambulance?
- ☐ ☐ Did you or another person drive you to the emergency department?
- ☐ ☐ Where you hospitalized overnight?
- ☐ ☐ Did the emergency department doctor take X-rays? Check what was taken:
  - ☐ Skull
  - ☐ Neck
  - ☐ Low back
  - ☐ Arm or leg
- ☐ ☐ Did the emergency department doctor give you pain medications?
- ☐ ☐ Did the emergency department doctor give you muscle relaxants?
- ☐ ☐ Did you have any cuts or lacerations?
- ☐ ☐ Did you require any stitching for cuts?
- ☐ ☐ Were you given a neck collar or back brace to wear?

### When did you first notice any pain after injury?

- ☐ Immediately ☐ \_\_\_\_\_ Hours after injury ☐ \_\_\_\_\_ Days after injury

### If you did not see a doctor for the first time within the first week, indicate why

Check all that apply

- ☐ No pain was noticed ☐ No appointment schedule available
- ☐ No transportation ☐ Work/home schedule conflicts

### If you did not see a doctor for the first time within the first month after injury, indicate why

Check all that apply

- ☐ No pain was noticed ☐ No appointment schedule available
- ☐ No transportation ☐ Work/home schedule conflicts
- ☐ I thought pain would go away ☐ I had no insurance or money
- ☐ I self-treated with over-the-counter drugs ☐ I took hot showers, used ice, heat

### Have you been unable to work since injury?

- ☐ Yes ☐ No If yes, you were off work ☐ partially or ☐ completely

Please list date off work: \_\_\_\_\_ to \_\_\_\_\_.

## Management

- Patients with clinical, radiographic, or laboratory evidence of tumor, infection, fracture, or dislocation

should be sent for medical evaluation and possible management.

- Patients who appear to have a mechanical cause of pain should be managed conservatively for one month; if unresponsive, further testing or referral for a second opinion is suggested.

## **Relevant Anatomy and Biomechanics**

The cervical spine is often discussed as two separate yet interdependent sections: the upper cervical spine (the occiput and C1-C2) and the lower cervical spine (C2-C7/T1). This is due in part to a functional distinction based on the great degree of rotation available at the upper cervical spine, allowed by the unique articulation between the C2 and C1 vertebrae. The dens of C2 acts as a pivotal point for rotation. The intricate musculature support and control in this region are important in substituting for a generally more lax ligamentous system, compared with the thoracic and lumbar regions. Another important difference in the upper cervical region is the lack of intervertebral foramina and discs between the occiput (C0), C1, and C2. From a neurologic perspective, the upper cervical spinal cord has a unique connection with the CNS through the trigeminocervical nucleus, an intermingling of the spinal nucleus of the trigeminal nerve and the dorsal horn of the upper cervical spinal nerves.<sup>9</sup> This connection allows for interactions and misinterpretations postulated to be the cause of headaches, dizziness, and facial pain.

The vertebral arteries enter the transverse foramen at C6 and ascend through the other transverse foramina. At C2 they take sharp turns to run more laterally and horizontally to reach the transverse foramen of C1. At the transverse

foramen of C1 and C2, the vertebral arteries are anchored with fibrous tissue restricting their movement. Continuing upward, the vertebral arteries travel posteromedial to run around the lateral mass of C1. Running through a groove in the posterior arch of C1, the vertebral arteries pass between the atlantooccipital membrane and capsule before entering the dura mater at the foramen magnum. These two sites—C6 and the upper cervical region—are proposed to be tethering or compressive sites leading to occlusion or intimal tearing resulting in vertebrobasilar events (vascular accidents) although studies that evaluate these effects in cadavers have not demonstrated this as likely with maneuvers that simulate cervical manipulation.

Vertebrobasilar events are extremely rare and although they have been associated not only with cervical spine adjustments they also occur with common daily activities such as turning the head while driving and extending the head for a shampoo at the hairstylist as well.<sup>10</sup> When damage does occur it is usually due to trauma to the arterial wall leading to either vasospasm or intimal tearing. Intimal tears may occur in isolation or be complicated by embolic formation or dissection of the arterial wall.<sup>11</sup> The dorsolateral medullary syndrome (Wallenberg's) and the locked-in syndrome or cerebromedullospinal disconnection syndrome are two possible consequences of vertebrobasilar injury. Wallenberg's syndrome usually involves occlusion of the posterior inferior cerebellar artery with resulting problems of vertigo, diplopia, and dysarthria. Most patients regain a significant degree of neurologic function. The locked-in syndrome is much more serious, leaving the patient conscious but paralyzed.

## **The Discs**

Like all intervertebral discs, the cervical disc is composed of a central nucleus pulposus and an outer annulus. However, by age 40 years the nucleus pulposus is essentially nonexistent, having changed to a ligamentous-like, dry material.<sup>12</sup> Herniation is therefore theoretically not possible in the older patient unless small hyaline pieces become free. The cervical discs have much less weight to bear than the lumbar discs for two reasons: (1) only the head plus gravity is borne and (2) the distribution of load is approximately equal among the disc and the two facet joints (i.e., each bears one-third the load). Like the other regions of the spine, the outer annulus fibrosus is innervated by the sinuvertebral nerves as are the vertebral bodies. **Exhibit 2-3** illustrates the innervations of deep spinal structures.

In a recent study<sup>13</sup> examining the discs of rats, researchers demonstrated that the C5/C6 disc was innervated multisegmentally from the dorsal root ganglions of C2-C8. In addition, there was innervation sympathetically from the stellate ganglion and parasympathetically from the nodose ganglion (vagus). Seventy-nine percent of the nerve fibers innervating the IVD were sensory nerves and 20.4% were autonomic nerves. Specifically, 23.9% of the nerve fibers innervating the IVD were afferent sensory pain-related nerves, 8.9% were efferent sympathetic nerves, and 11.5% were efferent parasympathetic nerves. Given the varied and unusual clinical signs and symptoms related to cervical disc injury, this finding of autonomic innervation may partially explain why. Potentiating the effect and extent of sympathetically mediated pain is a structure named “Terminal Dogiel’s nests,” described as bundles of sprouting sympathetic axons in the dorsal root ganglia that seem to form after injury.<sup>14</sup>

## **Exhibit 2-2 Neck Disability Index**

This questionnaire has been designed to give the doctor information as to how your neck pain has affected your ability to manage in everyday life. Please answer every section and mark in each section only the *one* box that applies to you. We realize you may consider that two of the statements in any one section relate to you, but please just mark the box that most closely describes your problem.

***Section 1—Pain Intensity***

- ☐ I have no pain at the moment.
- ☐ The pain is very mild at the moment.
- ☐ The pain is moderate at the moment.
- ☐ The pain is fairly severe at the moment.
- ☐ The pain is the worst imaginable at the moment.

***Section 2—Personal Care (Washing, Dressing, etc.)***

- ☐ I can look after myself normally without causing extra pain.
- ☐ I can look after myself normally but it causes extra pain.
- ☐ It is painful to look after myself and I am slow and careful.
- ☐ I need some help but manage most of my personal care.
- ☐ I do not get dressed, I wash with difficulty and stay in bed.

***Section 3—Lifting***

- ☐ I can lift heavy weights without extra pain.
- ☐ I can lift heavy weights but it gives extra pain.
- ☐ Pain prevents me from lifting heavy weights off the floor, but I can manage if they are conveniently positioned, for example, on a table.
- ☐ Pain prevents me from lifting heavy weights, but I can manage light to medium weights if they are conveniently positioned. I can lift very light weights.
- ☐ I cannot lift or carry anything at all.

***Section 4—Reading***

- ☐ I can read as much as I want to with no pain in my neck.
- ☐ I can read as much as I want to with slight pain in my neck.
- ☐ I can read as much as I want with moderate pain in my neck.
- ☐ I can't read as much as I want because of moderate pain in my neck.
- ☐ I can hardly read at all because of severe pain in my neck.
- ☐ I cannot read at all.

***Section 5—Headaches***

- ☐ I have no headaches at all.
- ☐ I have slight headaches that come infrequently.
- ☐ I have moderate headaches that come infrequently. I have moderate headaches that come frequently.
- ☐ I have severe headaches that come frequently.
- ☐ I have headaches almost all the time.

### **Section 6—Concentration**

- ☐ I can concentrate fully when I want to with no difficulty.
- ☐ I can concentrate fully when I want to with slight difficulty.
- ☐ I have a fair degree of difficulty in concentrating when I want to.
- ☐ I have a lot of difficulty in concentrating when I want to.
- ☐ I have a great deal of difficulty in concentrating when I want to.
- ☐ I cannot concentrate at all.

### **Section 7—Work**

- ☐ I can do as much work as I want to.
- ☐ I can only do my usual work, but no more.
- ☐ I can do most of my usual work, but no more. I cannot do my usual work.
- ☐ I can hardly do any work at all.
- ☐ I can't do any work at all.

### **Section 8—Driving**

- ☐ I can drive my car without any neck pain.
- ☐ I can drive my car as long as I want with slight pain in my neck.
- ☐ I can drive my car as long as I want with moderate pain in my neck.
- ☐ I can't drive my car as long as I want because of moderate pain in my neck.
- ☐ I can hardly drive at all because of severe pain in my neck.
- ☐ I can't drive my car at all.

### **Section 9—Sleeping**

- ☐ I have no trouble sleeping.
- ☐ My sleep is slightly disturbed (less than 1 hr. sleepless). My sleep is mildly disturbed (1–2 hrs. sleepless).
- ☐ My sleep is moderately disturbed (2–3 hrs. sleepless). My sleep is greatly disturbed (3–5 hrs. sleepless).
- ☐ My sleep is completely disturbed (5–7 hrs. sleepless.)

### **Section 10—Recreation**

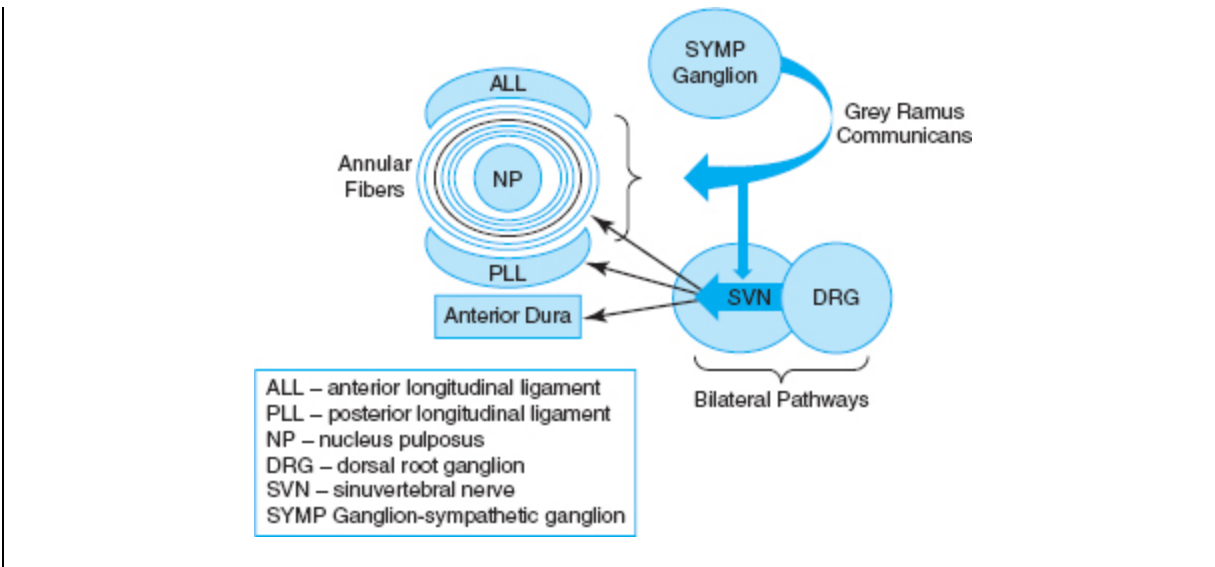

- ☐ I am able to engage in all my recreation activities with no neck pain at all.
- ☐ I am able to engage in all my recreation activities with some pain in my neck.
- ☐ I am able to engage in most, but not all, of my usual recreation activities because of pain in my neck.
- ☐ I can hardly do any recreation activities because of pain in my neck.
- ☐ I can't do any recreation activities at all.

## **Exhibit 2-3 Innervation of deep spinal structures**

## The Facets

The facets of the upper cervical spine are angled approximately  $35^\circ$  to the horizontal plane, whereas the lower cervical spine facets are oriented at approximately a  $65^\circ$  angle.<sup>15</sup> The facets (zygapophyseal) joints are surrounded by a joint capsule that is generally looser in the cervical region than in the thoracic and lumbar regions, allowing for more range of motion. The capsule is lined with synovium on the upper and lower aspects. There are often inclusions of fat-filled synovial folds and meniscoids that extend between the facets. Although they are believed primarily to be shock absorbers, these inclusions can become trapped, causing a mechanical lock.<sup>16, 17</sup> It is unlikely, however, that they are the primary cause of vertebral fixation given that meniscoids are not always present in fixed joints and that patients with rheumatoid arthritis have a higher incidence of meniscoids yet no higher incidence of fixation.<sup>18</sup> However, in children and in those who develop sudden neck pain without significant trauma that is relieved with manipulation, a synovial entrapment or extrapment (caught outside the joint) is likely the cause.

Histological studies of facet joints demonstrate the existence of substance P reactive fibers suggesting a potential role in mediating pain.<sup>19</sup> Facet-joint capsules contain low-threshold mechanoreceptors, mechanically sensitive nociceptors, and silent nociceptors. The speed at which mechanoreceptors are stimulated may affect their role in pain. Low stretch levels activate proprioceptors in the facet-joint capsule whereas sudden severe capsular stretch activates nociceptors, which may lead to prolonged discharge and damage to the capsule and to axons in the capsule.<sup>20</sup>

The facet joints are innervated by the medial branch of the posterior primary rami. Recent evidence from rat research<sup>21</sup> indicates that sensory nerve fibers of cervical C5-C6 facet joints are derived from the dorsal root ganglia (DRG) of multisegmental levels, from C3 to T3. This likely explains common referral patterns from the facets including neck and head pain from the C2-C3 joints and neck and shoulder pain from the C5-C6 joints. Also, this multisegmental innervation may determine more global neurological reactions to pain generated at a local segment.

The DRG themselves are at risk due to a peculiar vascular structure.<sup>22</sup> Primarily internal arterialization coupled with a superficial venous drainage places the DRG at risk for ischemic damage from external pressure (e.g., degenerative osteophytes) or from internal edematous pressure leading to a form of “compartment syndrome.”

Although it might be assumed that all spinal levels have contributions to the DRG, a study by Tubbs et al.<sup>23</sup> indicates that at the C1 level there is substantial variation with potential clinical results. The researchers found that in all specimens there were C1 and C2 spinal nerves, but only 46.6% of specimens had C1 dorsal rootlets and of these, only 28.5% had an associated dorsal root ganglion. In 50% of specimens, the spinal accessory nerve joined with dorsal

rootlets of C1. When the spinal accessory nerve combined with the dorsal rootlets of C1, there was no C1 DRG.

Calcitonin gene-related peptide (CGRP) immunoreactive dorsal root ganglion neurons innervate the cervical facets and are affected by trauma. One study<sup>24</sup> indicated that although the number of CGRP cells decreased after trauma, there was a phenotypical switch to larger cells.

## Ligaments and Muscles

The upper cervical spine has an intricate system of ligaments and muscles to stabilize and control fine head movements. In addition, the muscles serve a function of providing important proprioceptive input integrated into the reflex control of the head and neck and posture in general. Studies have demonstrated that injections into the upper cervical spine area result in various symptoms, including vertigo.<sup>25</sup>

Three ligaments help stabilize the dens of C2 to the anterior arch of C1. These include the alar ligament, cruciform (cruciate) ligament, and tectorial membrane. These continue down as the posterior longitudinal ligament. A prominent section of the cruciate ligament is the transverse ligament. This ligament is the primary stabilizer of the dens. Deterioration of the transverse ligament, usually through rheumatoid processes, will allow abnormal movement between C2 and C1. The posterior longitudinal ligament (PLL) is broad in the cervical spine, providing more protection against lateral disc herniation than found in the lumbar region. Also, the joints of Luschka provide some bony protection to nerve root impingement from disc herniation. The ligamentum flavum is posterior to the PLL, attaching to the laminae forming the anterior support for the facet joint capsules and protecting the spinal cord. A recent study indicates that contrary to accepted knowledge,

the ligamentum flavum does not connect the posterior arch of the atlas to the laminae of the axis 15a. Bogduk<sup>1</sup> emphasizes that the interspinous ligament is nonexistent in the cervical region and that the sagittal and superficial component of the ligamentum nuchae are simply extensions of other structures.

The muscles of the cervical spine are often divided into posterior and anterior with subdivisions of superficial and deep sections. The more superficial muscles are involved with upper extremity movement and respiration. The deeper muscles are involved more with posture and head/neck movement. The posterior muscles, including the semispinalis, spinalis, and splenius, are essential as antigravity/postural muscles, often being called upon to fire eccentrically during flexion of the neck/head, and are chronically strained during forward head positions. The four suboccipital muscles (obliquus capitis inferior and superior and the rectus capitis posterior major and minor) plus the deep “shunt” muscles of the middle and lower cervical spine, such as the interspinales, multifidus, rotatores, intertransversarii, and longus cervicis, are important for intersegmental movement. In addition, they play a major role in providing afferent proprioceptive input to the spinal cord used both for gross postural control and spinal segmental (involuntary) positioning. This is due to the high density of muscle spindles in this region.<sup>26</sup>

## **Thoracic Outlet**

The thoracic outlet is the path taken by the brachial plexus and associated vasculature into the arm from the neck. Thoracic outlet syndrome (TOS) is an overdiagnosed condition. It is purported to be caused by neurologic or neurovascular compromise of the brachial plexus and/or subclavian-axillary vessels. The potential sites of

entrapment or compression include: at the cervical ribs (elongated C7 transverse processes), the scalene muscles, the costoclavicular interval, and the subcoracoid loop involving the pectoralis minor. When TOS is present it is most common to have involvement of the lower brachial plexus (C7-T1) with related medial arm and hand complaints. Factors that have been suggested as causes include trauma, posture (rounded shoulders), tight scalenes or pectoralis minor, and cervical ribs. Leffert<sup>27</sup> states, however, that patients who have had stabilizing surgery for the shoulder have had accompanying TOS symptoms resolved.

## **Biomechanics**

The various motion patterns available to the cervical spine are determined by both active and passive elements. The passive elements include the facets, discs, ligaments, and bone. The various components of functional patterns that may be affected include range of motion (ROM), coupling patterns, the instantaneous axis of rotation (IAR), and the neutral zone. Many of the biomechanical studies have focused on how the various static components contribute to movement and ROM, and therefore must be considered cautiously when extrapolated to patients. Many of the manipulative maneuvers used by chiropractors and others, however, require elimination of muscular participation; therefore, the studies may have some clinical validity.

The cervical spine flexes, extends, rotates, and bends laterally. Flexion and extension occur mainly at three areas: (1) the atlantooccipital joint, (2) the C1-C2 level, and (3) between C4 and C6. Each accounts for about 20° of flexion/extension. The other segments contribute between 10° and 20°. Flexion at the atlantooccipital joint is accompanied by a coupled movement of slight anterior translation of the occiput relative to C1.

The facet orientation in the cervical spine allows for a large degree of motion. Approximately 50% to 60% of axial rotation occurs between C1 and C2.<sup>28</sup> It is in large part due to the pivot-shaped articulation between these segments. On the other hand, axial rotation is minimal (0° to 5°) at the atlantooccipital articulation. Lateral bending between segments increases from the upper to the lower cervical spine. In the upper cervical spine only about 5° is available; in the middle and lower cervical spine 5° to 10° is available. With lateral bending in the middle and lower cervical regions, the spinous processes rotate to the opposite side (i.e., left lateral bending causes the spinous processes to move to the right). This coupling occurs most at C2-C3 and decreases in the lower segments. With rotation, C2-C3 and segments above bend laterally in the opposite direction of rotation (i.e., right rotation causes left lateral bending). Below this level, however, the cervical spine generally bends to the same side as head rotation. Another coupled pattern with rotation is flexion and extension. Above the C4-C5 level, extension accompanies rotation; below this level, flexion occurs with rotation. These coupling patterns change with the beginning head position.<sup>29</sup> For example, if the head rotates while in full flexion, lateral flexion coupled with axial rotation decreases compared to neutral. These coupled patterns may be important factors for planning positioning and force application with manipulative procedures.

Because acceleration/deceleration injury to the cervical spine is a common mechanism of injury in patients seeking chiropractic care, a brief overview of the biomechanics of whiplash is presented. There is considerable research to indicate a “typical” sequence of events following a rear-end collision. They are divided into phases by Croft:<sup>30</sup>

- *Phase One*—When a vehicle is rear-ended, the patient’s torso is forced back into the seat and at the same time moves upward. This upward movement is

accompanied by straightening of the cervical spine as it is being compressed axially. The head and neck then begin to extend.

- *Phase Two*—As the head and neck are extending, the vehicle has reached its peak acceleration. Energy stored in the seat from the backward movement of the body into the seat may add more acceleration to the torso as a “diving board” effect. The upward (vertical) movement of the torso may allow ramping over the headrest, adding an element of extension. If the driver’s foot is taken off the brake, acceleration may be prolonged.
- *Phase Three*—Acceleration diminishes while the head and torso are thrown forward. It may be accentuated if the driver’s foot is reapplied to the brakes.
- *Phase Four*—As the body moves forward, a seat belt and shoulder harness (if applicable) will restrain the torso, allowing the head to decelerate forward.

The older model of hyperextension/hyperflexion injury associated with a “whiplash” or rear-end collision is not always the case. In fact, in recent studies the global neck motion did not extend beyond the normal range of motion.<sup>31</sup> Although global hyperextension does not always occur, intersegmental hyperextension does appear to occur and may be the most prominent injury mechanism. Recent evidence suggests that low-speed rearimpact collisions (LOSRIC) result in a distinct s-shaped curvature with the lower cervical segments hyperextending and the upper cervical segments flexing.<sup>32</sup> As a result of the injury sequence, the instantaneous axis of rotation changes in the lower cervical segments placing more compressive forces on the facet joints and discs in a rapid manner (within 100 msec), particularly at C5-C6.

## Evaluation

### History

The first line of business is to attempt to rule out “serious” causes of neck or neck and arm pain. It is important to consider the possibility of meningitis when there is accompanying fever and a complaint of neck stiffness. Although neck stiffness may be a common complaint with the flu, the severity of pain and the response to passive flexion of the head are usually less remarkable. When neck pain is associated with a severe headache that is “new” or worse than any headache previously experienced, a red flag should be raised for infection, tumor, or vascular causes.

When patients have a complaint of neck and arm pain, clues to the cause may be evident from the history ([Table 2-1](#)). If the complaint is of a strip of pain connecting the neck or shoulder to the hand and this strip overlaps several dermatomes or in the hand is rather diffuse, nerve root compression is unlikely. Patients with this presentation often have a referred pain that is unrelated to nerve root compression. These patients rarely complain of weakness in the arm (or if they do it is usually not objectifiable). Patients with nerve root compression will have complaints not only of pain (often localized to a dermatome) but also of eventual motor weakness that can be objectified on the physical examination.

---

### Traumatic/Overuse Injury

When there is direct trauma to the head or neck, it is important to gauge the degree of injury, the mechanism of injury, and whether there was loss of consciousness. There are some classic patterns of injury with respect to specific

types of fractures (**Table 2-2**). When these mechanisms are evident from the history, radiographic evaluation can be more focused. In addition to the well-known Ottawa Knee and Ankle Rules, Canadian Cervical Spine Rules<sup>33</sup> have been developed in an attempt to determine who does or does not need radiographic examination following trauma to rule out fracture. Developed a number of years ago, these rules have stood the test of time and comparison to other approaches, and have proven very sensitive for detecting patients in need of radiographic evaluation following trauma.<sup>34, 35</sup> The rules are a set of questions:

- Are there any high-risk factors involved (i.e., age greater than or equal to 65 years, work with dangerous mechanisms, or paresthesias in extremities)? If the answer is yes, then x-rays are indicated.
- Are there any low-risk factors that allow safe assessment of range of motion (i.e., simple rearend collision, sitting in emergency department or ambulatory since injury, delayed onset neck pain, or absence of midline cervical spine tenderness)? If not, x-rays are indicated. If so, move on to the next question.
- Is the patient able to actively rotate neck 45° right and left? X-rays are indicated if the answer is no.

These rules are intended only to detect those individuals who might have a cervical spine fracture.

Similarly the National Emergency X-Radiography Utilization Study (NEXUS)<sup>36</sup> rules state that, for patients with neck trauma no radiographs are needed if all of the following are true:

- No posterior or central cervical spine tenderness
- No evidence of intoxication
- A normal level of alertness

- No focal neurologic deficit
- No painful distracting injuries

If the patient was involved in an MVA, it is important to acquire detail such as type of vehicle, angle of collision, and damage to the vehicle(s) (see Exhibit 2-1). Information to be elicited from the patient includes his or her position in the car, whether a seat belt and shoulder harness were worn, whether an air bag was triggered, and whether the head or other body parts made contact with the windshield, steering wheel, or dashboard.

Lateral flexion injury to the neck is common in sports and MVAs. When a patient reports having his or her neck snapped to the side, compression injury on the side of head/neck movement and stretch injury on the side opposite are likely. When the brachial plexus is stretched, the upper section is most often involved. The patient will report a sudden onset of weakness in the arm, often with a burning or tingling pain down the outside of the arm to the hand. This type of injury is often referred to in sports as a “burner” or a “stinger.” Most injuries are transient; however, some cases may need further evaluation with electrodiagnostic studies. When a lateral flexion injury is reported, it is a caution to the chiropractor not to take the head/neck into the position of injury when adjusting the neck.

When forced flexion is the mechanism, in addition to fractures of the vertebral bodies, myelopathy from a stenotic spinal canal must be considered when the patient has arm or leg complaints. If the patient has accompanying complaints of urinary dysfunction, myelopathy must be suspected and investigated further via physical examination and radiographs.

**Table 2-1** History Questions for Cervical Spine Injuries

Primary Question	What Are you Thinking?	Secondary Questions	What Are You Thinking?
Were you involved in an accident?	Sprain/strain, subluxation, dislocation, fracture, disc lesion	Was your head forced forward?	Sprain/strain of posterior neck muscles/ligaments, fracture of vertebral body, facet dislocation, disc lesion
		Was your head forced back?	Sprain/strain of anterior neck muscles/ligaments, facet compression, hangman's or teardrop fracture at C2-C3
		Was your head turned and flexed?	Facet subluxation or dislocation, sprain/strain
		Was your head stretched to the side?	Brachial plexus stretch lesion, facet fracture, nerve root compression on side of head flexion
		Was your head turned and extended?	Facet compression, articular pillar fracture, sprain/strain
Does the pain radiate to your arm(s)?	Disc lesion, nerve root entrapment, referred pain, myelopathy, brachial plexus damage, double crush	Did you hit the top of your head?	Possible Jefferson fracture
		Is there isolated weakness or numbness?	Nerve root involvement
		Was there associated numbness/tingling or weakness that resolved over a few minutes?	Burner or stinger if involved with a lateral flexion injury
		Is there associated difficulty with walking or urinary dysfunction?	Myelopathy possible
		Is there more numbness and tingling in a diffuse or ill-defined pattern?	Referred pain from facet or trigger points
Are you unable to move your head in a specific direction?	"Torticollis," osteoarthritis, fracture/dislocation, meningitis	Did you simply wake up with this?	Acute "pseudotorticollis" due to global muscle spasm
		Is there associated fever? Is it worse with flexion?	Possible meningitis if flexion pain is severe
		Was there a gradual onset? (in an older patient)	Likely osteoarthritis
		Did this occur after head or neck trauma?	Consider fracture or dislocation
Do you have chronic pain or stiffness?	Osteoarthritis, postural syndrome, subluxation	Does work involve a forward head posture or lateral flexion while on the phone?	Postural syndrome
		Is there local pain with specific movement?	Subluxation

Overuse injury is in most instances postural "injury." A line of questioning regarding occupational mechanical stresses is particularly important for patients with chronic neck pain. Questions should be asked regarding workstations (i.e., height of chair, desk, and computer

monitor) and how the telephone is answered and for how long during a one-day period. For those patients whose employment requires less sitting and more lifting, it is important to determine the degree of overhead lifting, which often requires a degree of hyperextension of the neck. Dentists, mechanics, plumbers, electricians, and others represent a unique population who often work in awkward positions. It is important to have the patient give a detailed explanation of common prolonged positions or any single position that causes pain. From this description, a relationship regarding which anatomic structures are stretched and which are compressed can be appreciated.

**Table 2-2** Fractures of the Cervical Spine

Mechanism	Fracture	Best Radiographic View	Stable/Unstable?
Hyperflexion	Wedge fracture of vertebral body	AP and lateral views; loss of anterior body height	Generally stable; based on neurologic signs or potential risk
	Clay shoveler's [C6-T1 spinous process]	Lateral; may need swimmer's view	Generally stable; however, may require several weeks in a hard collar or in rare cases surgical excision
	Teardrop	Lateral view	Unstable; may be associated with anterior cord injury
	Burst fracture	Lateral view	Generally stable; however, requires close monitoring for neurologic compromise
Flexion/rotation	Bilateral facet dislocation	Lateral view demonstrates instability	Unstable
	Unilateral facet dislocation	Lateral view may demonstrate anterior body translation or a dysrelationship of the normal overlap of facets	May be unstable
Hyperextension	Extension teardrop fracture of anteroinferior body of C2	Lateral view	Relatively stable in flexion; unstable in extension
	Hangman's: bilateral pedicle fracture of C2	Lateral view	Highly unstable, requiring halo traction immobilization
Hyperextension/rotation	Articular pillar	Lateral view may show a double outline; AP may show a disruption of the smooth cortical line; oblique or pillar views may be necessary; if found, CT is suggested	Generally stable; however, swelling may produce some radicular signs
Hyperextension/lateral flexion	Facet fracture	Obliques	Usually neurologically stable; however, must be assessed for stability after healing
Compression	Jefferson burst fracture of C1	Visible on AP open mouth; on lateral view increase in retropharyngeal space	Highly unstable, requiring halo traction immobilization

Key: AP, anteroposterior; CT, computed tomography.

## Stiffness/Restricted Motion

For many patients, the biggest concern is stiffness or restricted ROM; they complain that looking over the shoulder is not possible. In an acute setting, the patient often will present with an insidious onset that began upon waking. He or she will complain of difficulty moving the head in any direction with accompanying pain. Often this

acute “torticollis” is not a torticollis at all, because all ranges are affected and the patient’s head is held in neutral and not cocked to one side. Although there is no known cause, the global muscle-splinting effect makes this a painful but benign condition in the majority of cases.

## Instability

Instability is a concern with trauma to the head or neck. The type of fracture often suggests the mechanism of injury ([Table 2-2](#)). Fracture should always be considered with compressive or distractive injury to the neck. Instability is always a concern with patients who have signs or symptoms or a previous diagnosis of rheumatoid arthritis, seronegative arthritides (i.e., ankylosis spondylitis, Reiter’s syndrome, or psoriatic arthritis), or Down syndrome.

## Examination

Inspection, palpation, and ROM testing are the clinical approach taken when neck pain or stiffness is the primary complaint. A recent study evaluated the intrarater and interrater reliability of visual assessment of cervical and lumbar lordosis (without the use of a measurement instrument).<sup>37</sup> This study included chiropractors, physical therapists, physiatrists, rheumatologists, and orthopaedic surgeons. Subjects were divided into those with back pain and those without. Raters were asked to rate photographs placed in a PowerPoint presentation. Lateral views of relaxed individuals’ cervical and lumbar curves were rated as normal, increased, or decreased. Interestingly, there was no difference in rating between those with or without back pain. The intrarater reliability was statistically fair ( $\kappa = 0.50$ ) and the interrater reliability was poor ( $\kappa = 0.16$ ). When the

complaint involves radiation into the back or extremities, specific orthopaedic and neurologic tests are added. The primary intention of orthopaedic tests is to compress or stretch pain-producing structures such as facets and nerve roots. The standard battery of orthopaedic tests includes various forms of cervical compression, cervical distraction, shoulder depression, the brachial plexus stretch test, Soto-Hall test, and Lhermitte's test. Cervical compression also referred to as Spurling's test (**Figure 2-1**) is usually axially applied with the patient's head in neutral and then in all positions of lateral flexion, flexion, extension, and rotation. Local pain felt more on extension and/or rotation indicates facet involvement, while radiating pain down the arm indicates nerve root involvement. Cervical distraction is an attempt to reduce local or radiating complaints. If the maneuver is more painful, muscle splinting is likely. There are very few orthopaedic tests for the cervical spine. Most of these tests are provocative or relief tests for cervical radiculopathy. Recently, a study evaluating the sensitivity and specificity of Spurling's test determined that although not very sensitive, Spurling's test is a specific test for cervical radiculopathy.<sup>38</sup> Therefore, the test is not useful in screening, but is useful in confirming a cervical radiculopathy diagnosis. Shoulder depression can cause nerve root or brachial plexus stretching on the side opposite head deviation, or nerve root compression on the side of lateral flexion; however, there is no evidence for the value of this test. Shoulder depression, in fact, is imbedded in the upper limb tension test and does not need to be performed separately. Cervical distraction too is part of the upper limb tension group of testing maneuvers and will be discussed later (**Figure 2-2**). Soto-Hall and Lhermitte's tests involve passive flexion of the patient's neck. Electric shock sensations down the arm or arms is a positive Lhermitte's response and is occasionally found with multiple sclerosis or cervical myelopathy.

**Figure 2-1** Spurling's test.

**Figure 2-2** Distraction.

Vikari-Juntura and colleagues<sup>39, 40</sup> evaluated the interexaminer reliability and validity of some common clinical evaluation procedures for the cervical spine. Inspection of atrophy of small muscles of the hand, sensitivity tests for touch and pain, and the cervical compression and distraction tests were considered reliable. Muscle strength testing and an estimation of ROM were considered fairly reliable. Palpation for trigger points, the brachial plexus stretch test, and the shoulder abduction relief test (relief of arm pain when holding the arm above shoulder level), however, were considered poor. When 43

patients with known cervical disc disease were tested with cervical compression, distraction, and shoulder depression the specificity was high; however, the sensitivity was low (25% to 50%). Therefore, patients with cervical disc disease did not consistently have pain provoked or relieved by these maneuvers. When the test was positive, however, it was fairly specific to a disc lesion. Adding neurologic and radiographic information raised the sensitivity to between 40% and 64%. A recent study<sup>41</sup> suggests that the addition of cervical nonorganic signs to assess abnormal illness behavior may be helpful.

A more recent and high-level review by Wainner et al.<sup>42</sup> on the diagnostic accuracy of the clinical examination and patient self-report for cervical radiculopathy indicates that there may be some value in clusters of findings. The upper limb tension test (ULTT), sometimes referred to as the brachial plexus stretch test, was found to be a very good screening to rule out cervical radiculopathy. As with the lumbar spine examination, the neurological examination for dermatome, myotome, and deep-tendon reflex abnormalities is relatively specific but not sensitive (i.e., the patient may have nerve-root involvement and not have neurological evidence upon examination). The recommended cluster of test findings was:

- The ULTT
- Cervical rotation of less than 60°
- The distraction test (i.e., relief of radicular symptoms)
- Spurling's "A" test

**Exhibit 2-4** provides a graphical example of how the likelihood of cervical radiculopathy is estimated using this approach. It was estimated that if three out of these four tests were positive, the probability of having cervical radiculopathy increased to 65%. If all four were positive, the probability increased to 90%. (For a description of how to

perform these tests see **Table 2-3** and **Figure 2-3**.) The authors caution the clinician in applying the cluster in practice. They indicate that the 95% confidence intervals (CI) for diagnostic accuracy for individual examination tests, and the test cluster, were wide due to the limited sample size and low prevalence of radiculopathy in their study. Another review by Rubinstein et al.<sup>43</sup> concurs with this caution stating that more high-quality studies are needed.

Nordin et al.<sup>44</sup> have made recommendations as the Task Force on Neck Pain and Its Associated Disorders committee addressing assessment. The committee came to similar conclusions in other studies. Specifically, they found that the interexaminer reliability was quite variable for muscle strength testing and sensitivity to touch. There was better reliability for increased versus decreased sensation. For radiculopathy, they concluded that a specific portion of the ULTT was highly sensitive and potentially specific. This position was a contralateral rotation of the head and extension of the arm and fingers. For nonemergency neck pain, the evidence does not support the diagnostic validity of provocation discography, anesthetic facet or medial branch blocks, surface electromyography, dermatomal somatosensory evoked responses, or quantitative sensory testing for radiculopathy. It is important to note that facet or medial branch blocks are also used as treatment, and this group did not address this use given that their focus was on diagnosis.

Other tests with acceptable diagnostic accuracy included cervical flexion less than 55°, a decrease in biceps reflex and muscle strength, the Valsalva test, a variation of Spurling's (test A), shoulder abduction weakness, C5 dermatome involvement, and two history questions: "Where are your symptoms most bothersome?" and "Do your symptoms improve with moving or positioning of your neck?"

The standard neurologic examination attempts to differentiate the cause of associated arm pain, numbness and tingling, or weakness. This process attempts to rule in or rule out nerve root compression, peripheral nerve entrapment, referred pain, brachial plexus injury, and spinal cord injury. This is accomplished by determining whether regions specific to a nerve root or peripheral nerve have sensory or motor deficits (see **Figure 2-4**). Larger, more diffuse patterns of sensory or motor loss require a search for brachial plexus or spinal cord involvement. Bilateral patterns suggest systemic polyneuropathies or spinal cord involvement.

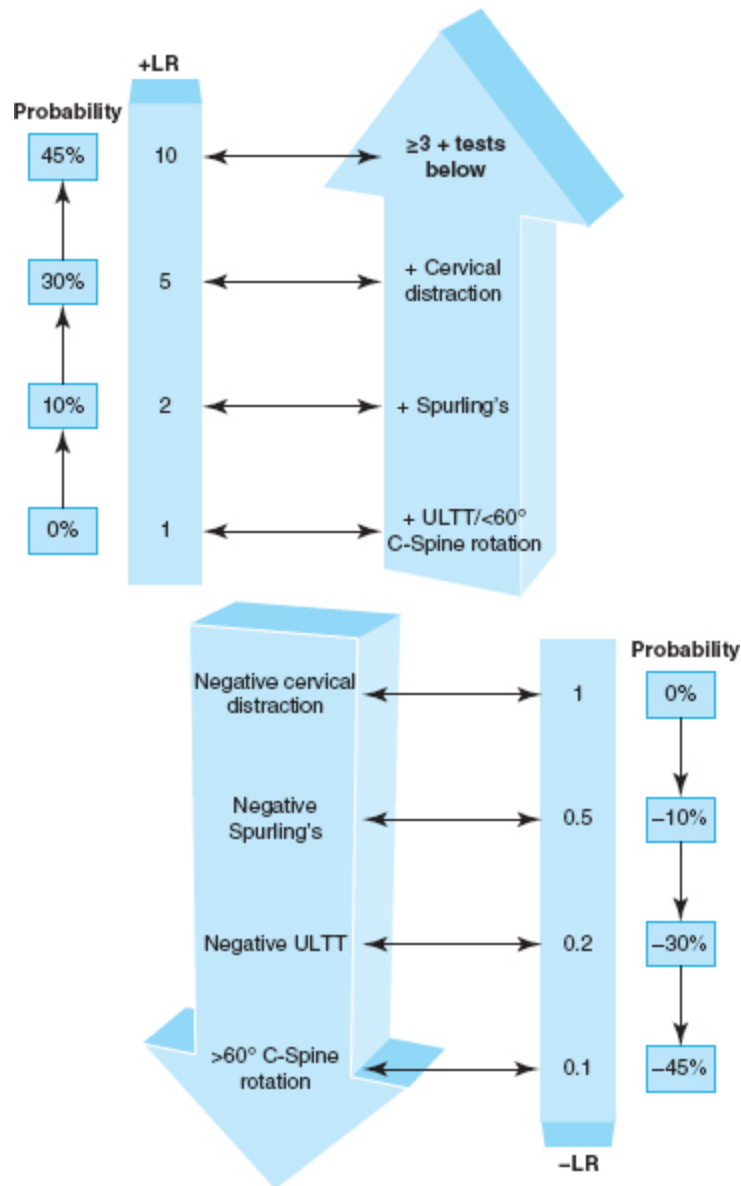

It is important to note that weakness found on physical examination is actually more common than subjective weakness. Of patients with radiculopathy, 64% to 75% demonstrate weakness upon examination while only 15% to 34% complain of weakness. Deep tendon reflex involvement is found in 84% of patients with radiculopathy and dermatome sensory changes in only 33%.

The most commonly involved nerve root is C7 followed by C6. The standard muscle test for C7 is elbow extension. For C6, the standard muscle test used is wrist extension. A recent study<sup>45</sup> evaluated the value of adding forearm pronation to these muscle tests. Their results indicated that with C6 radiculopathies, forearm pronation was weak in 72% of patients, twice the number of patients demonstrating weak wrist extension. For C7, elbow extension and forearm pronation were weak in 23% of patients but in 10% of patients the only weakness found was in the forearm.

### **Exhibit 2-4 Likelihood Patient Has a Cervical Radiculopathy Approximating Probability**

The likelihood ratios (LRs) in this graphical representation represent estimates of probability based on the aggregate of multiple reviews of each test finding. They are only approximations and only reliable indicators of a change in the context of a patient having an intermediate pre-test probability

of between 20% to 80%. If the pre-test probability is very high or very low, the LR has little effect on changing the probability.

**Table 2-3** Tests as Described and Performed in the Wainner et al.<sup>1</sup> Study

Name of Test	How to Perform	Positive Test
--------------	----------------	---------------

		<b>Finding</b>
Spurling's test A	With the patient seated, the neck is passively laterally bent toward the symptomatic side and the examiner applies over-pressure.	Symptom reproduction
Spurling's test B	With the patient seated, the neck is passively placed in a combination of laterally bending, coupled with rotation and extension toward the symptomatic side and the examiner applies over-pressure.	Symptom reproduction
Neck distraction	The patient is tested supine. The examiner's contact is under the chin and occiput. The patient's neck is then flexed to a position of comfort. Gradual distraction is then applied up to 14 kg.	Symptom decrease or elimination
Upper limb tension (Part A)	The patient is supine. The patient is positioned sequentially through six positions. The first five gradually increase stretch to the nerves and therefore may create a positive reproduction of arm symptoms. Scapular depression is followed by shoulder abduction (with scapular stabilization), then forearm supination coupled with wrist and finger extension. Next, shoulder external rotation, then elbow extension is added followed by contralateral cervical side-bending. The final position is movement of the head to ipsilateral cervical side-bending. This final position should provide relief of arm symptoms if positive.	In addition to reproduction of the patient's complaints with any of the first five maneuvers, or relief of symptoms with ipsilateral side-bending of the neck, side-to-side differences of $>10^\circ$ in elbow extension are also considered a positive.
Cervical rotation	The patient is seated and asked to perform two repetitions in each direction and then a single measure with a long-arm goniometer is performed.	Cervical rotation $<60^\circ$

Cervical flexion	The patient is seated and asked to perform two repetitions. A single inclinometer is used to measure.	Cervical flexion <55°
------------------	---	-----------------------

1. Data from Wainner RS, Fritz JM, Irrgang JJ, Boninger ML, Delitto A, Alison S. Reliability and diagnostic accuracy of the clinical examination and patient self-report measures for cervical radiculopathy. *Spine*. 2003;28(1):52-62.

The basic approach to detecting nerve root involvement is a search for corresponding deficits in sensory, motor, and reflex function. Following is a basic pattern for spinal levels C5-T1 (patterns may vary depending on the source due to root overlap):

- C5—motor supply to the deltoid (shoulder abduction) and biceps (elbow flexion/supination), biceps reflex, and sensory supply to outer shoulder (axillary nerve)
- C6—motor supply to the biceps (elbow flexion/supination) and wrist extension, brachioradialis reflex, and sensory supply to the outer forearm
- C7—motor supply to the triceps (elbow extension), finger extensors and wrist flexors, triceps reflex, and sensory supply to the middle finger
- C8—motor supply to the finger flexors, no reflex, and sensory supply to the little and ring fingers
- T1—motor supply to the interosseous muscles of the hand (abduction/adduction of fingers), no reflex, and sensory supply to the medial arm

It is interesting to note though that in a study by Murphy et al.<sup>46</sup> patients with radiculopathy do not seem to indicate a dermatomal pattern to their radiating pain. Only 30.3% of patients with cervical radiculopathy reported a dermatomal pattern to their radiating pain (69.7% reported a nondermatomal pattern) with the exception of C4 where 60% of patients reported a dermatomal pattern. Given C4 is not often involved in radiculopathy, the majority of patients then describe a nondermatomal pattern.

**Figure 2-4** Neck complaints. Dermatomes of the upper extremity and the cutaneous innervation of the arm by the peripheral sensory nerves.

Part of the neurologic examination includes evaluation of grip strength. The most common device used is a Jamar dynamometer (Bissell Healthcare Corporation, Bolingbrook, Illinois). This device has been shown to be accurate, and the interrater reliability is high. There are, however, positional and postural effects on readings:<sup>47</sup>

- The wrist can be between 15° of palmar flexion and 30° of extension without an effect on strength; grip is stronger in supination, weaker in pronation; use neutral as the standard forearm position.
- The maximum readings are found with the second- and third-handle positions of a Jamar dynamometer.
- The first and second attempts are the strongest.

- Hand dominance may cause a 10% to 15% higher reading on that side.
- Test and retest reliability is best with the mean of three trials (attempts) (0.80).
- The patient should be tested in a seated position with the elbow flexed 90° at the patient's side.
- Patients test stronger in the standing position.
- If there is any question as to patient participation, it may be helpful to have the patient test with each handle position; a bell curve should appear even with neurologic weakness (i.e., strongest in the middle handle positions, weakest in the shortened and lengthened positions).

Common muscle imbalances at or affecting the cervical spine include tightness of the sternocleidomastoids (SCMs); short, deep neck extensors; upper trapezius; levator scapulae; and the pectoralis major and minor. Muscles that tend to be inhibited include the deep neck flexors and the lower stabilizers of the scapulae, including the lower and middle trapezius and the rhomboids. Taken together, these imbalances often lead to a rounded shoulder, forward head position. Functional testing as described by Janda<sup>8</sup> includes the spine-chin tuck test. The supine patient is instructed to tuck the chin in as much as possible and then raise the head 1 cm off the table. If the chin pokes or juts forward or if the head shifts up or down, Janda considers this an indication of substitution by the SCMs for the deep neck flexors.

TOS is often considered in the differential diagnosis of patients with arm complaints. Unfortunately, much of this testing is associated with a high level of false-positive and false-negative responses. These maneuvers are designed to compress the brachial plexus by specific structures in the hope of reproducing the patient's arm complaint. If a diminished pulse is used as a positive, however, a false-positive rate of 50% occurs.<sup>48</sup> Tests include Adson's,

Halstead's, Wright's, and Roos' hyperabduction test. Adson's and Halstead's tests attempt to isolate the anterior or middle scalenes, respectively, as compression sites. The patient's arm is passively abducted while the patient turns his or her head to one side and then the other. The examiner palpates the radial pulse for a decrease; however, a true positive is reproduction of the patient's arm complaints. Wright's hyperabduction test is similar; however, the arm is abducted and extended back. The Roos' test is a functional assessment. The patient is asked to hold the hand up above the head and repeatedly grip and release for 20 to 60 seconds in an attempt to reproduce the arm complaint(s).

Although numerous factors have been implicated as potential predispositions to vascular injury, none has been demonstrated to be significant for vertebrobasilar risk.<sup>49</sup> Analysis of the literature published before 1993 that reported vertebrobasilar artery dissection and occlusion leading to brainstem and cerebellar ischemia and infarction totaled 367 case reports.<sup>51</sup> Of these, 160 cases were of spontaneous onset with no association to manipulation, whereas 115 cases were of onset after spinal manipulation, 58 cases were associated with trivial trauma, and 37 cases were caused by major trauma. An analysis of possible causative head positions or specific manipulative procedures failed to identify any consistent pattern. In a review article by Haldeman et al., data from 64 cases of CVA associated with cervical spine manipulation did not reveal any inherent predictors in the history or physical examination that would assist in determining which patients are at risk.<sup>52</sup>

Routine radiography of the cervical spine is considered unnecessary unless it can potentially change the management of a case. Conditions that might warrant routine radiography include trauma, infection, gross instability, fracture/dislocation, and cancer. Another possible

indication is radiating pain or numbness/tingling into the arm/hand. The decision is based on a thorough history and examination, however. Routine radiographs to evaluate degenerative changes are considered of limited value.<sup>53</sup> Radiographic examination of the cervical spine begins with a standard three-shot series including an AP, an AP open-mouth, and a lateral. Based on what is viewed on these basic films, a decision to complement the evaluation with oblique, flexion/extension, swimmer's, or pillar view can be made. Oblique views are valuable for visualizing the intervertebral foraminae (IVF) in search of foraminal encroachment due to osteophytes or dislocation. A bilateral or unilateral pillar view may be helpful when concerned about a possible hidden fracture of the posterior elements.<sup>54</sup> The unilateral view is safest with the patient's head turned 45° and slightly flexed. There is a 30° to 35° caudad tube tilt based on the degree of cervical lordosis. When segmental instability is suspected, the lateral view will provide sufficient evidence for the middle and lower cervical spine. The criteria that are used include the following:

- fanning of adjacent spinouses
- a kyphotic angulation greater than 11°
- greater than 3 mm anterior displacement between the inferior posterior border of the superior vertebra and the superior posterior border of the adjacent inferior vertebra

Medical evaluation of instability may involve a radiographic traction stretch test.<sup>55</sup>

For the upper cervical spine, instability is often the result of rheumatoid or congenital disorders, although trauma is a possible cause. In patients with rheumatoid arthritis, the seronegative arthropathies, or Down syndrome, an evaluation of the atlantodental interspace is warranted. It is measured on a lateral view; most evident in flexion on a

flexion/extension series. A measurement of the distance between the posterior margin of the anterior tubercle of C1 and the anterior surface of the odontoid is referred to as the atlantodental interspace (ADI), and it is an indirect measure of the integrity of the transverse ligament of the atlas. For adults the normal ADI measurement is between 1 and 3 mm; in children, it is between 1 and 5 mm.

Intersegmental hypermobility has been suggested as a biomechanical factor worth investigating; however, examiners have not been able to establish either the criteria or the ability to detect this entity.<sup>56</sup> The standard approach is to use flexion/extension lateral views to observe or to mark intersegmental movement not visible on a neutral lateral view.

A measure of the spaciousness of the spinal canal can be estimated on the lateral cervical view. The distance is measured with a line drawn from the posterior surface of the vertebral body extending to the same-level spinolaminar junction. The diameter varies based on the segmental level and the age of the patient (i.e., adults versus children); however, a canal less than 12 mm is considered stenotic. Another approach is to take the ratio of the sagittal diameter (same as above) to the vertebral body sagittal diameter. A ratio of less than 0.82 is considered evidence of stenosis (Pavlov or Torg ratio).<sup>57</sup>

With regard to TOS, many doctors will assume that the presence of cervical ribs is diagnostic. Yet less than 1% of the population have cervical ribs; of these individuals, less than 10% will have symptoms. Also, the more common cause of TOS is fibrous bands not visible on a radiograph.<sup>58</sup> Three spaces can be measured if a soft tissue mass is believed to be anterior to the cervical vertebrae: the retropharyngeal (at C2-C3), retrolaryngeal (at C4-C5), and retrotracheal (at C5-C7) spaces. Normal values on the neutral are 5 mm at C2, 7 mm at C3-C4, and 20 mm at C5-C7.<sup>59</sup>

When ordering special studies, it is always important to consider which imaging tool best evaluates what type of tissue. It also is extremely important to correlate clinical findings with special study findings due to the significant number of abnormal findings in asymptomatic patients. CT scans and MR imaging are valuable only when radiographs fail to determine the exact cause of a complaint of radiation of symptoms into the arms or back. Even then, it is probably worth a conservative trial prior to using these expensive tools. If stenosis is suspected, a CT scan is quite valuable. If disc herniation, multiple sclerosis, tumor, infection, or cancer is suspected, MR imaging is probably more valuable in most cases.

Electrodiagnostic studies occasionally are needed in the differentiation of neck and arm pain. Electromyography (EMG) and nerve conduction velocity (NCV) tests are valuable in differentiating nerve root compression from peripheral neuropathies. Somatosensory-evoked potentials (SEPs) and dermatomal somatosensory-evoked potentials (DSEPs) may be helpful in evaluating the patient suspected of having cervical myelopathy and determining the degree of involvement.

## Management

The Neck Pain Task Force (Guzman et al.<sup>60</sup>) recommends a triage approach. They have devised four grades with associated recommendations:

- Grade I—Neck pain with no signs of serious pathology and little or no difference with daily activities. No further work-up is necessary; reassurance and self-care should be emphasized.
- Grade II—Neck pain with no signs of serious pathology but interference with daily activities. Assess factors

and advise about methods that may help decrease interference in daily activities; discuss options for short-term relief.

- Grade III—Neck pain with neurologic signs of nerve compression. Monitor if deficits are stable and minor; consider MRI and referral if deficits are major or progress; an EMG might be needed.
- Grade IV—Neck pain with signs of major structural pathology. Investigate according to the suspected condition.

Recommendations regarding options for short-term relief include exercise training and mobilization for those with neck pain after a traffic collision. For those with no trauma the task force recommends exercise training, manipulation, mobilization, acupuncture, analgesics, and low-level laser treatment. **Table 2-4** is a summary of all of the conclusions and recommendations of The Bone and Joint Decade 2000–2010 Task Force on Neck Pain and Its Associated Disorders.

The Mercy Guidelines<sup>61</sup> and other sources suggest that approximately six weeks of care is usually all that is needed in most “uncomplicated” cases. Initial high-frequency treatment ranging from three to five treatments for one to two weeks is considered appropriate. Treatment past this point is gradually decreased if the patient is responding; if not, a second two-week trial using a different form of treatment is suggested. If unsuccessful, then special studies or referrals for medical consultation are suggested. It is suggested that a questionnaire such as the Neck Disability Index (Exhibit 2-2) be used as a baseline measurement of patient status. This tool has been demonstrated to be a reliable indicator of the patient’s functional improvement.<sup>62</sup>

The Bone and Joint Decade 2000–2010 Task Force on Neck Pain and Its Associated Disorders (Haldeman et al.<sup>63</sup>) provides a list of modifiable risk and protective factors, which include smoking, exposure to environmental tobacco,

and participation in physical activity. Although they found insufficient evidence of the effectiveness of workplace interventions, they did find that high quantitative work demand, low social support at work, repetitive work, precision work, and sedentary work position all increased the risk of neck pain. Poor prognosis was associated with:

- poor health
- prior neck pain episodes
- poor psychological health
- worrying
- becoming angry or frustrated in response to neck pain

Indicators of a good prognosis included a coping style that involved self-assurance, optimism, and less need to socialize. Recovery appeared to be unrelated to a specific workplace or physical work demands with those patients who included general exercise or sports as part of their lifestyle.

**Table 2-4** Conclusions and Recommendations from the Task Force on Neck Pain and Its Associated Disorders

<b>Intervention</b>	<b>Recommendations</b>
<b>Nonsurgical Intervention<sup>1</sup></b> <b>Whiplash-Associated Disorders</b>	
Education or advice	<ul style="list-style-type: none"> <li>• Evidence that an educational pamphlet was not associated with recovery in patients with acute WAD.</li> <li>• Some evidence that an educational video in combination with usual urgent or</li> </ul>

	emergency care is associated with lower pain ratings at six months with acute WAD compared to usual care alone.
Exercise	<ul style="list-style-type: none"> <li>• Some evidence that using an exercise component was positively associated with more favorable results in short- and long-term outcomes with acute or subacute WAD when compared to passive interventions including education.</li> <li>• Supervised and home exercise have marginal effects over advice but not in the long term.</li> </ul>
Medications	<ul style="list-style-type: none"> <li>• Cervical facet injections were not associated with greater pain reduction at three months.</li> <li>• Infusion of methylprednisolone was not associated with greater pain relief in the short term for acute WAD.</li> </ul>
Manual therapies	<ul style="list-style-type: none"> <li>• Mobilization was associated with greater pain relief in the short term for acute WAD as compared to passive modalities or general advice.</li> <li>• No advantage for a rigid collar for two weeks and mobilization over usual care at 12 months follow-up.</li> </ul>
Physical modalities	<ul style="list-style-type: none"> <li>• No advantage for passive modalities (TENS, ultrasound, diathermy) alone or in combination with mobilization in the short term compared to exercise and manual therapy for acute or subacute WAD.</li> </ul>
Collars	<ul style="list-style-type: none"> <li>• No advantage for soft or rigid collars compared to other approaches for acute WAD.</li> </ul>
Combined approaches	<ul style="list-style-type: none"> <li>• Evidence that multidisciplinary management was associated with quicker claim closure for WAD compared to usual care.</li> <li>• Evidence that fitness training or in- or outpatient rehabilitation plus usual care may increase recovery time for acute WAD.</li> </ul>
<b>“Nonspecific” Neck Pain</b>	
Education or advice	<ul style="list-style-type: none"> <li>• No evidence of advantage in education or advice over other interventions.</li> </ul>

Exercise	<ul style="list-style-type: none"> <li>• Evidence that a neck exercise program alone or in combination with spinal manipulation decreases pain and disability in the short term when compared to manipulation alone, TENS, or usual GP care.</li> <li>• Evidence that manual therapy or pulsed diathermy with neck exercise and coping advice were not associated with improvement compared to exercise and advice alone.</li> <li>• Compared to endurance exercise, strengthening exercise was not associated with a better outcome in the short and long term with female workers.</li> </ul>
Medications	<ul style="list-style-type: none"> <li>• No advantage to botulinum toxin A.</li> <li>• No advantage of piroxicam over indomethacin in the short term.</li> <li>• Some evidence that orphenadrine and paracetamol are associated with greater pain relief in the short term.</li> <li>• Some evidence that manipulation with advice and salicylates is more effective in the short term compared to salicylates with advice, massage electrical stimulation, or traction.</li> </ul>
Manual therapies	<ul style="list-style-type: none"> <li>• Evidence that cervical spine manipulation along or with advice and home exercise was not associated with either pain or disability outcomes in the short or long term compared to mobilization with or without exercise, strengthening exercise, or instrumental manipulation.</li> <li>• Mobilization or exercise alone or in combination with medications was associated with better pain and functional outcomes in the short term compared with usual CP care, pain medication, or advice to stay active.</li> <li>• Evidence that manipulation or mobilization was not associated with better pain or disability outcome for subacute or chronic neck pain as compared to exercise alone or to exercise with massage or passive modalities.</li> </ul>
Physical modalities	<ul style="list-style-type: none"> <li>• Consistent evidence that passive modalities alone or in combination with other passive</li> </ul>

	<p>treatments or modalities have no advantage in the short or long term compared to usual CP, other modalities, or sham interventions.</p> <ul style="list-style-type: none"> <li>• Percutaneous neuromodulation therapy was associated with better intermediate post-treatment measure of pain, improved sleep, and more physical activity after three weeks with cervical disc disease causing chronic pain.</li> </ul>
Acupuncture	<ul style="list-style-type: none"> <li>• Inconsistent evidence of effectiveness.</li> <li>• Some evidence that acupuncture was better in the short term when compared to massage in the short term for patients with chronic pain.</li> <li>• Evidence that acupuncture was not better than mobilization or traction in the short term.</li> </ul>
Laser therapy and magnetic therapy	<ul style="list-style-type: none"> <li>• Evidence that low-level laser therapy was associated with improvements in pain and function in the short term for patients with subacute or chronic neck or shoulder pain.</li> <li>• Evidence that magnetic stimulation had better pain and disability outcome in the short term for myofascial pain compared to TENS or placebo.</li> </ul>
Combined approaches	<ul style="list-style-type: none"> <li>• Combinations of exercise, manual therapy, and advice were positively associated with decreased pain and disability and decreased time for sick leave compared to usual PCP care, surgery, cervical collar, or advice to stay active.</li> </ul>
Workplace or employee interventions	<ul style="list-style-type: none"> <li>• Evidence that any of the following were not associated with better outcomes: ergonomic interventions, relaxation or behavioral support, software-simulated work breaks which included rest or exercise, and physical training and stress management programs.</li> <li>• Evidence that endurance or strength training in combination with dynamic exercise involving the upper and lower extremities was associated with better one-year pain and disability outcomes in female office workers with chronic or recurrent</li> </ul>

	neck pain compared to advice to perform exercises.
<b>Invasive Interventions<sup>2</sup></b>	
Cervical injections for neck pain and radiculopathy	<ul style="list-style-type: none"> <li>• There is evidence that treatment using a short course of epidural or selective root injections with corticosteroids gives short-term relief for radicular symptoms in patients involved in litigation. No evidence that multiple injections offer a benefit beyond one to three injections.</li> <li>• No evidence that cervical root or epidural injections in seriously symptomatic individuals reduce the need for surgery.</li> </ul>
Cervical injection or radiofrequency neurotomy for neck pain without radiculopathy	<ul style="list-style-type: none"> <li>• Evidence that intra-articular steroid injection is not effective for facet joint pain as compared to other anesthetic blockage protocols.</li> <li>• No evidence to support the use of radiofrequency neurotomy for facet pain.</li> </ul>
Open surgical treatment of cervical radiculopathy	<ul style="list-style-type: none"> <li>• No evidence for long-term benefit of surgery for radiculopathy; however, evidence for substantial short-term decrease of pain and impairment.</li> <li>• Evidence that anterior plating in one- and two-level fusions reduces kyphosis progression after surgery.</li> <li>• No evidence that complex approaches (fusion, case, plates, or fusion augmentation with bone) have an advantage over cervical decompression alone.</li> </ul>
Open surgical treatment for neck pain without radiculopathy	<ul style="list-style-type: none"> <li>• No support for the use of anterior cervical fusion or cervical disc arthroplasty for neck pain without radiculopathy.</li> <li>• No evidence to support surgical intervention for suspected upper cervical ligamentous injury following whiplash as determined by spinal change within these ligaments on MRI.</li> </ul>
Complications with surgery	<ul style="list-style-type: none"> <li>• With cervical foraminal or epidural injections—minor adverse effects in 15% to 20% of patients; serious events in &lt; 1%.</li> <li>• Cervical open surgical procedures—serious complications in 4% of patients (higher in older patients and those with surgery for</li> </ul>

	myelopathy); minor complications such as dysphagia, hoarseness, and donor site pain are frequently reported but resolved in most cases.
--	---

*WAD = whiplash-associated disorder.*

Data from: 1. Hurwitz EL, Carragee EJ, van der Velde G, et al. Treatment of neck pain: noninvasive interventions: results of the Bone and Joint Decade 2000–2010 Task Force on Neck Pain and Its Associated Disorders. *Spine*. 2008;33(4 Suppl):S123–152; 2. Carragee EJ, Hurwitz EL, Cheng I, et al. Treatment of neck pain: injections and surgical interventions: results of the Bone and Joint Decade 2000–2010 Task Force on Neck Pain and Its Associated Disorders. *Spine*. 2008;33(4 Suppl):S153–169.

Following are a list of some of the side effects or complications with various treatment approaches (Guzman et al.<sup>63</sup>):

- Anti-inflammatory medication—dyspepsia (heartburn), GI bleeding in up to 2% of individuals with chronic use, heart attacks, hypertension
- Muscle relaxants or narcotics—drowsiness in one out of three individuals
- Exercise—transitory increases in pain
- Manipulation or manual medicine—transitory increase in pain in up to 30% of individuals; less common with mobilization
- Injections—transient increases in pain, numbness, and dizziness in up to 16% of individuals; major complications in less than 1%
- Surgery—transitory hoarseness and difficulty swallowing, rarely permanent hoarseness, nerve or spinal cord injury, or stroke

The recent Thiel et al.<sup>64</sup> prospective national survey involved more than 28,000 treatment consultations and over 50,000 cervical spine manipulations. There were no serious adverse events reported. Minor side effects with possible neurologic involvement were most common, with

the highest risk occurring immediately after treatment for fainting, dizziness, or light-headedness (approximately 16 per 1,000 treatment consultations). For up to seven days post-treatment, the risks were headache (at most approximately 4 per 100), numbness or tingling in the upper limbs (approximately 15 per 1,000), and fainting, dizziness, or light-headedness (approximately 13 per 1,000).

Rubinstein et al.,<sup>65</sup> in a prospective, multicenter, cohort study, have also demonstrated that although adverse effects are relatively common (56%), they are short-lived and rarely severe in intensity (13%). Patients were initially treated three times. Symptoms such as tiredness, dizziness, nausea, or ringing in the ears were uncommon (less than 8%). At 12 months, 1% of patients reported being worse. Of patients who returned for a fourth visit, about 50% reported recovery.

Ernst<sup>66, 67</sup> is commonly critical of cervical manipulation and its associated risk (as evident in several publications). Bronfort et al.<sup>68</sup> clearly point out the methodological flaws in Ernst's arguments.

The strongest study to date by Cassidy et al.<sup>69</sup> evaluated vertebrobasilar (VBA) stroke and chiropractic care. This very large population-based, case-control, and case-crossover study evaluated over 100 million person-years and found there were 818 VBA stroke patients who were hospitalized. Individuals younger than 45 years were three times more likely to see a chiropractor or a primary care practitioner (PCP) before their stroke as compared to controls. There was no increased association between VBA stroke and chiropractic visits in those older than 45 years. However, there was an association between VBA stroke and patients of all ages visiting a PCP prior to stroke. Those billed for headache or neck complaints were highly associated with subsequent VBA stroke. The conclusions that are drawn are:

- A VBA stroke is extremely rare.

- Given there is at least an equal association between chiropractic visits and PCP visits and stroke, it is unlikely that there is something unique to the chiropractic treatment that would contribute as a cause of the stroke.
- Given that patients who subsequently had a stroke had complaints of headache and/or neck complaints, it is likely that dissection (intimal tearing) was occurring at the time of presentation and not due to an intervention in the PCP's or chiropractor's office.

Another revealing report by Boyle et al.<sup>70</sup> reviewed the statistics for VBA stroke in Saskatchewan (over eleven years) and Ontario (over nine years) covering more than 100,000 person-years in each province. It appears that the incidence for VBA in Saskatchewan was 0.855 per 100,000 person-years and 0.750 per 100,000 person-years in Ontario. The study revealed that there was an increase of 300% of cases in Saskatchewan in 2000 and only a 38% increase in Ontario in the same year. Correspondingly, there was only a small increase in chiropractic utilization in Saskatchewan and an actual decrease in chiropractic utilization in Ontario during this year. This data would seem to suggest that there is no association between the increase in VBA stroke and chiropractic utilization.

Finally, a number of basic science investigations into the effect on vertebral artery blood flow by manipulation or positioning for manipulation have been conducted on cadavers and live participants. A 2014 publication<sup>71</sup> confirmed what other studies have found. In this study using phase-contrast magnetic resonance imaging on asymptomatic volunteers, physiologic measures of VA blood flow and velocity at the C1-C2 spinal level were obtained after three different head positions and a chiropractic upper cervical spinal manipulation. There were no significant

changes in blood flow or velocity in the vertebral arteries with any positions or with manipulation.

Prior to the use of manipulation for the cervical spine, it has often been suggested that the patient be informed of the very rare yet potential risk of a vertebrobasilar accident. As mentioned earlier, there is no sensitive or reliable screening test, and it is not enough to rely on a past history of uncomplicated manipulation treatment.<sup>49</sup> It must be accepted that the risk is small but real, and there is no known clinical test to identify those who will have an accident. The patient should be informed of this rare complication, given the potential for neurologic compromise.

Postural advice regarding work and everyday posture is considered an important adjunct by many chiropractors. The focus should be to maintain a neutral head position. This often involves a focus on stretching of the short spinal extensors with strengthening of the deep neck flexors. Supportive to this attempt is correction of the factors contributing to a hyperlordotic lumbar spine or hyperkyphotic thoracic spine when possible. Exercises should include stretching of the upper trapezius/levator scapulae, pectorals, lumbar extensors, and hip flexors, followed by strengthening of the middle/lower trapezius, abdominals, and gluteals. Ergonomically, workstations should be oriented to provide a straight-ahead view of a computer screen, shoulder support or a headpiece for long-term telephone usage, and arm supports on the chair.

The sequence of prescribed exercises usually begins with mild isometrics, progressing to a more functional approach. Minimal contractions into all six movement patterns of flexion, extension, lateral bending, and rotation are initiated as soon as pain restriction permits.

## **Mechanical Traction**

Although traction is often utilized for neck pain, there are few studies to substantiate effect. One study<sup>50</sup> in 2009 attempted to predict improvement with mechanical traction for mechanical neck pain by evaluating the effect of several variables. A clinical prediction rule utilizing five variables was created based on patient response which included: (1) patient reported peripheralization with lower cervical spine (C4-7) mobility testing; (2) positive shoulder abduction test; (3) age  $\geq$  55; (4) positive upper limb tension test A; and (5) positive neck distraction test. The prediction for success with mechanical traction when three out of five predictors were present resulted in a + LR equal to 4.81 (95% CI = 2.17-11.4). This increased the likelihood of success with cervical traction from 44% to 79.2%. But dramatically increasing the effect was if four out of five variables were present. Then the LR was equal to 23.1 (2.5-227.9), increasing the post-test probability of having improvement with cervical traction to 94.8%. The protocol for application included:

- Intermittent traction was applied to a supine patient with 24° flexion.
- If full flexion was not possible, the angle was reduced to 15°.
- The application was one minute on; 20 seconds off. During the off-phase, 50% of the traction pull was maintained.
- Starting pull was 10-12 pounds and was increased in an attempt to reduce symptoms.
- Traction time was 15 minutes.
- There were a total of six sessions at two to three per week for three weeks.

## Exercise

Most systematic reviews (including Cochrane) have concluded that exercise is an integral part of management for neck pain patients.<sup>72-74</sup> There is strong evidence for the incorporation of deep neck flexor strengthening either alone or in combination with mobilization or manipulation. There are several approaches to strengthening the neck flexors, yet it appears that the most commonly used are generally equal in effect.<sup>75</sup> The most common approaches are:

- Instruct the supine patient to lift the head and tuck the chin while maintaining the craniocervical area in neutral for a goal of three sets of 12 repetitions. The patient initially uses head weight against gravity. If unable to perform the 12 repetitions, the table is tilted to reduce the effect of gravity until the patient reaches the 12 repetitions goal. After three sets of 12 repetitions is reached, 0.5 kg are added with the goal of 12 repetitions always as the target. Eventually, over a four-week program, the goal is three sets of 20 repetitions.
- Using a pressure biofeedback device, patients are instructed to focus on the craniocervical junction to deemphasize the superficial neck flexors. The patient's head rests on a pressure-sensitive device to a level of 22-30 mm/hg and holds for 10 seconds. The goal is 10 repetitions with small rest periods in between.

An interesting study by Chiu et al.<sup>76</sup> randomized patients with chronic neck pain into either an infrared irradiation and neck care advice group, or a group that added an active exercise program that strengthened deep neck flexors for six weeks. There was a benefit at six weeks for those in the active exercise group; however, this appears to be lost at six-month follow-up when compared to the infrared irradiation plus neck care advice only group.

Two studies published in 2012 compared manipulation with exercise. The first study by Evans et al.<sup>77</sup> compared three groups: (1) supervised exercise with manipulation, (2) supervised exercise alone, and (3) home exercise. Both supervised exercise groups demonstrated similar success; better than the home exercise group. The second study by Bronfort et al.<sup>78</sup> was designed to compare manipulation, medication, and home exercise as a treatment approach for acute, and subacute neck pain. This randomized controlled trial compared these groups for benefit at three, six, and twelve months. There was no real difference between the manipulation and home exercise groups, although there was a significant advantage for manipulation compared with medication, especially at the one-year follow-up.

Fitz-Ritson<sup>79</sup> suggests exercises that are based on reflex mechanisms similar to the work of Feldenkrais and Alexander. His study indicated a marked improvement in pain and in disability index rating compared with a group using standard (stretching/isometric/isokinetic) exercises. This approach is based on influencing the vestibulo-ocular reflex (VOR), which involves a quick (phasic) coordination of the eye, head, and neck through integration and processing of vestibular, visual, and proprioceptive input.

## Manipulation

The effectiveness of chiropractic manipulation for chronic neck pain is supported in the recent literature;<sup>80-84</sup> however, more randomized trials must be performed. In the study by Giles and Muller,<sup>80</sup> a comparison of manipulation to acupuncture and a nonsteroidal anti-inflammatory drug indicated a significant improvement in pain and disability for the manipulated patients as compared with patients undergoing other treatment approaches. Hurwitz et al.<sup>83</sup> published a study as part of the clinical outcomes section of

the UCLA Neck-Pain study. The researchers randomized patients with neck pain who were part of a health maintenance organization (HMO) into manipulation with or without heat, manipulation with or without electrical muscle stimulation, mobilization with or without heat, and mobilization with or without electrical muscle stimulation. Cervical spine manipulation and mobilization provided similar clinical outcomes with neither demonstrating an advantage at six months. Giles and Muller<sup>84</sup> conducted a randomized clinical trial on patients with chronic spinal pain presenting to a sports clinic in Australia. They compared treatment results using data from patients randomized to medication, acupuncture, or spinal manipulation. The results indicate greater short-term improvement with manipulation. The largest number of patients who were asymptomatic the earliest were those who were treated with manipulation (27.3%), followed next by acupuncture (9.4%), and then medication (5%). A systematic review<sup>85</sup> published in 2014 concluded that after review of 51 randomized controlled trials, manipulation or mobilization and exercise in combination were effective for management of adults with chronic neck pain.

The management of cervical disc herniation is controversial. An interesting study by Croft<sup>86</sup> demonstrated a “standard” of adjusting (manipulating) patients with known cervical disc herniation among the doctors polled. This finding is interesting given that chiropractors can be accused of causing disc herniation. The majority of chiropractors, however, would not adjust the affected level. There are published case studies<sup>82-88</sup> indicating that chiropractic management of cervical disc herniation may be successful.

Although controversial, manipulation under anesthesia (MUA) for chronic spinal pain has some published support. An early study by West et al.<sup>89</sup> for cervical spine pain indicated good results. Almost all patients were back to

work after six months and use of medication dropped significantly. Since then, there have been no large studies using a control group.

## Whiplash

A recent report by the Task Force on Neck Pain and Its Associated Disorders (Carroll et al.<sup>90</sup>) noted that approximately 50% of those with whiplash associated disorder (WAD) report neck pain symptoms one year following the initial injury. Some predictors for prolonged recovery appear to be more symptoms, greater initial pain, and greater initial disability. Also prognostic for prolonged recovery were depressed mood, fear of movement, and a passive coping style. Interestingly, factors related to the actual collision such as direction, position, headrest type, and so on, were not found to be prognostic. It is proposed, though, that the number of WAD patients has been decreased by a seat design that has been changed over the last decade. Softer seats that absorb the body's backward movement prevent some ramping, while also bringing the head/neck to the head restraint sooner.

In a study by Cassidy et al.<sup>91</sup> patients who were involved in a whiplash injury were divided into four groups determined by their follow-up care:

- 1.** Fitness training at a health club
- 2.** Outpatient rehabilitation
- 3.** Inpatient rehabilitation
- 4.** Standard care

Those receiving fitness training or outpatient rehabilitation had slower recovery times than patients in the other two groups. Patients in the inpatient rehabilitation group did not differ in outcome as compared to those assigned to

standard care. Another study by Cassidy et al. reflects a similar finding when a patient is returned to work too quickly following a WAD.

For massage, a systematic review published in 2007 by Ezzo et al.<sup>92</sup> concluded that no recommendations could be made based on the existing literature regarding the contribution, type, frequency, multimodal application, or effect on patients with mechanical neck disorders. They recommend better research designed to determine the role of massage therapy.

There have been some small studies<sup>93, 94</sup> with patients suffering from myofascial chronic neck pain that suggest that low-level laser treatment (830 nm or 904 nm) may be effective alone or in combination with other treatment as compared to a sham laser treatment. Although a 2009 review<sup>95</sup> in Lancet concluded that LLLT reduces pain immediately after treatment for acute neck pain and for patients with chronic pain up to 32 weeks after treatment with LLLT, there were limitations to the strength of these conclusions. Three of the studies quoted and utilized in the review that had the largest reported mean differences in favor of LLLT had limitations or errors.

- Two studies had significant baseline differences in favor of the active treatment
- A typing error indicated a significant mean difference when in the original study, there was no significant difference
- Pooling of data for nonspecific neck pain, myofascial pain syndrome, and cervical osteoarthritis may be inappropriate because each may represent a different set of patient types and clinical responses

A more recent study<sup>96</sup> published in 2011 was a small RCT that compared patients randomized to CMT, CMT with LLLT, or a group with both therapies combined concluded that the

combination therapy demonstrated better results. However, this was a small group and the effect differences were minimal. More studies need to be conducted with a larger group of participants.

The Quebec Task Force on Whiplash-Associated Disorders<sup>5</sup> concluded that there is little or no evidence for the efficacy of soft cervical collars, corticosteroid injections of the facet joints, pulsed electromagnetic treatment, magnetic necklace, and subcutaneous sterile water injection. Use of soft collars beyond the initial 72 hours postinjury will probably prolong disability. The task force also found that the literature did not support the use of cervical pillows, postural alignment training, acupuncture, spray and stretch, heat, ice, massage, muscle relaxation techniques, epidural or intrathecal injections, psychological interventions, ultrasound, laser, or short-wave diathermy. It is important to note that lack of literature support often means that no significant research has been performed to evaluate efficacy, even though many of these approaches are commonly used. In other words, it does not mean that they are ineffective; more often they are simply untested. Often this is due to the complacent attitude of, “if it works, why question it?”

The contribution of zygapophyseal joint pain to chronic neck pain following whiplash injury was evaluated in a study by Barnsley et al.<sup>97</sup> Fifty consecutive patients with chronic neck pain following whiplash were studied using a double-blind controlled approach incorporating local anesthetic blocks of cervical zygapophyseal joints. Joint blockade injections provided relief to 54% of patients.

In addition to pain, it appears that other reflex abnormalities may occur and persist as a result of cervical spine afferent activation. The question is whether these “late effects” are the result of damage at the time of injury, chronic pain, or cervical afferent activation. These effects include:

- abnormal neuropsychological test results<sup>98</sup>
- vestibular hyperreactivity and abnormalities of the vestibulo-ocular reflex<sup>99</sup>
- cervicocephalic kinesthetic sensibility decreases (ability to return to a neutral cervical position after movement)<sup>100</sup>
- reduction of smooth pursuit ability with neck torsion (ability to smoothly track a moving object)<sup>101</sup>

Results from another study<sup>102</sup> implied a possible positive association between a history of neck injury in an MVA and headaches, disabling neck pain, and a perception of lower general health compared to those with no history of neck injury. Although interesting, it is important to realize that these results do not imply a cause-and-effect relationship between the injury and these subsequent complaints. Low-speed rear-impact collisions (LOSRIIC) account for as many as 80% of rear-impact collisions. The range of speed in these LOSRIICs is between 6 and 12 mph.

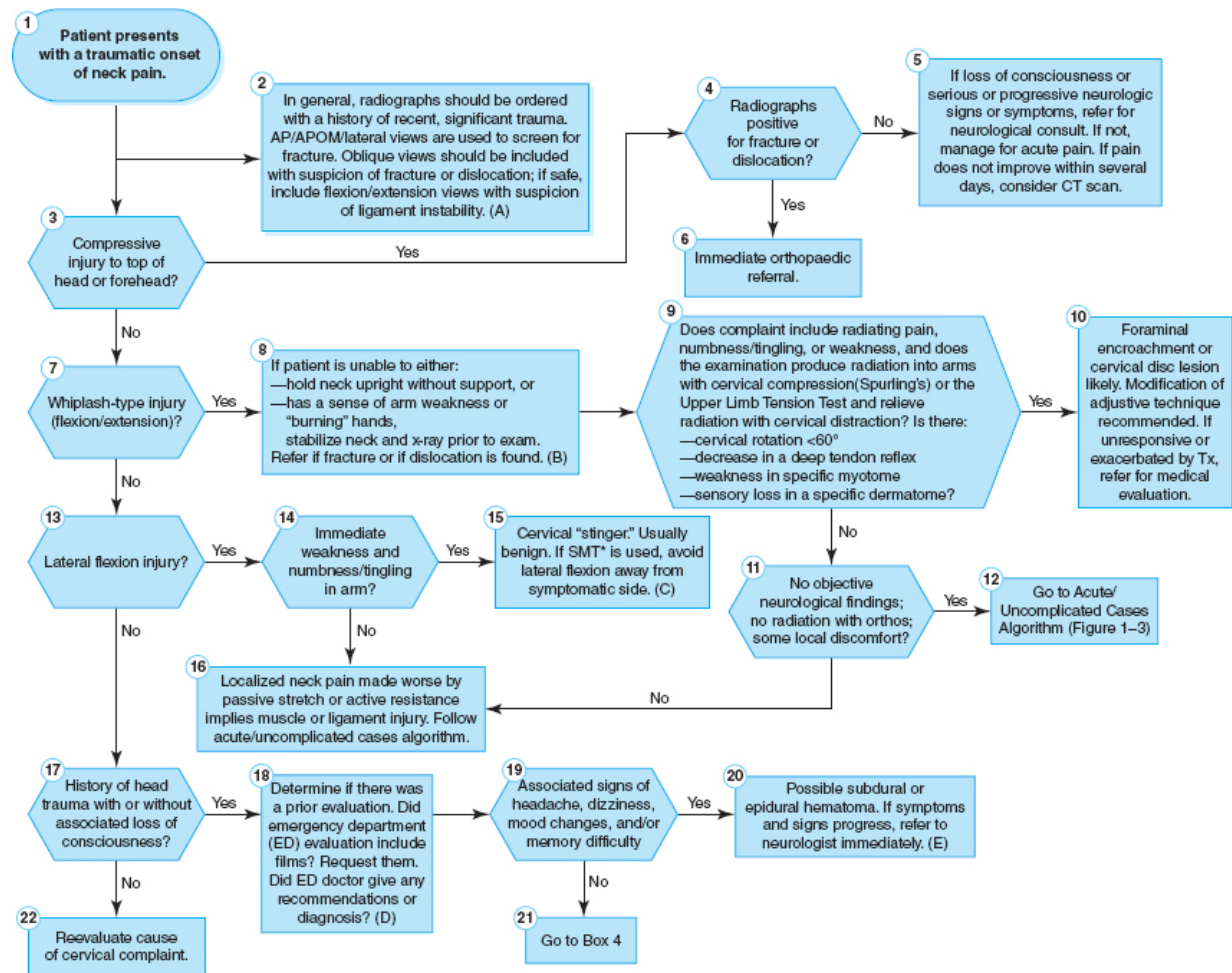

Recent, encouraging research<sup>103, 104</sup> indicates that patients with symptoms of chronic whiplash injury respond well to chiropractic management. Interestingly, one of these studies<sup>103</sup> identified a subgroup of patients who did not respond well to most therapies. These patients include those with severe neck pain, yet with a full range of motion and no neurologic symptoms/signs specific to a myotome or dermatome. These patients often complained of other symptoms and signs such as blackouts, visual disturbances, nausea and vomiting, chest pain, and a nondermatomal pattern of pain.

## Algorithms

Algorithms for traumatic neck pain, nontraumatic neck and arm pain, nontraumatic neck pain with no radiation, and

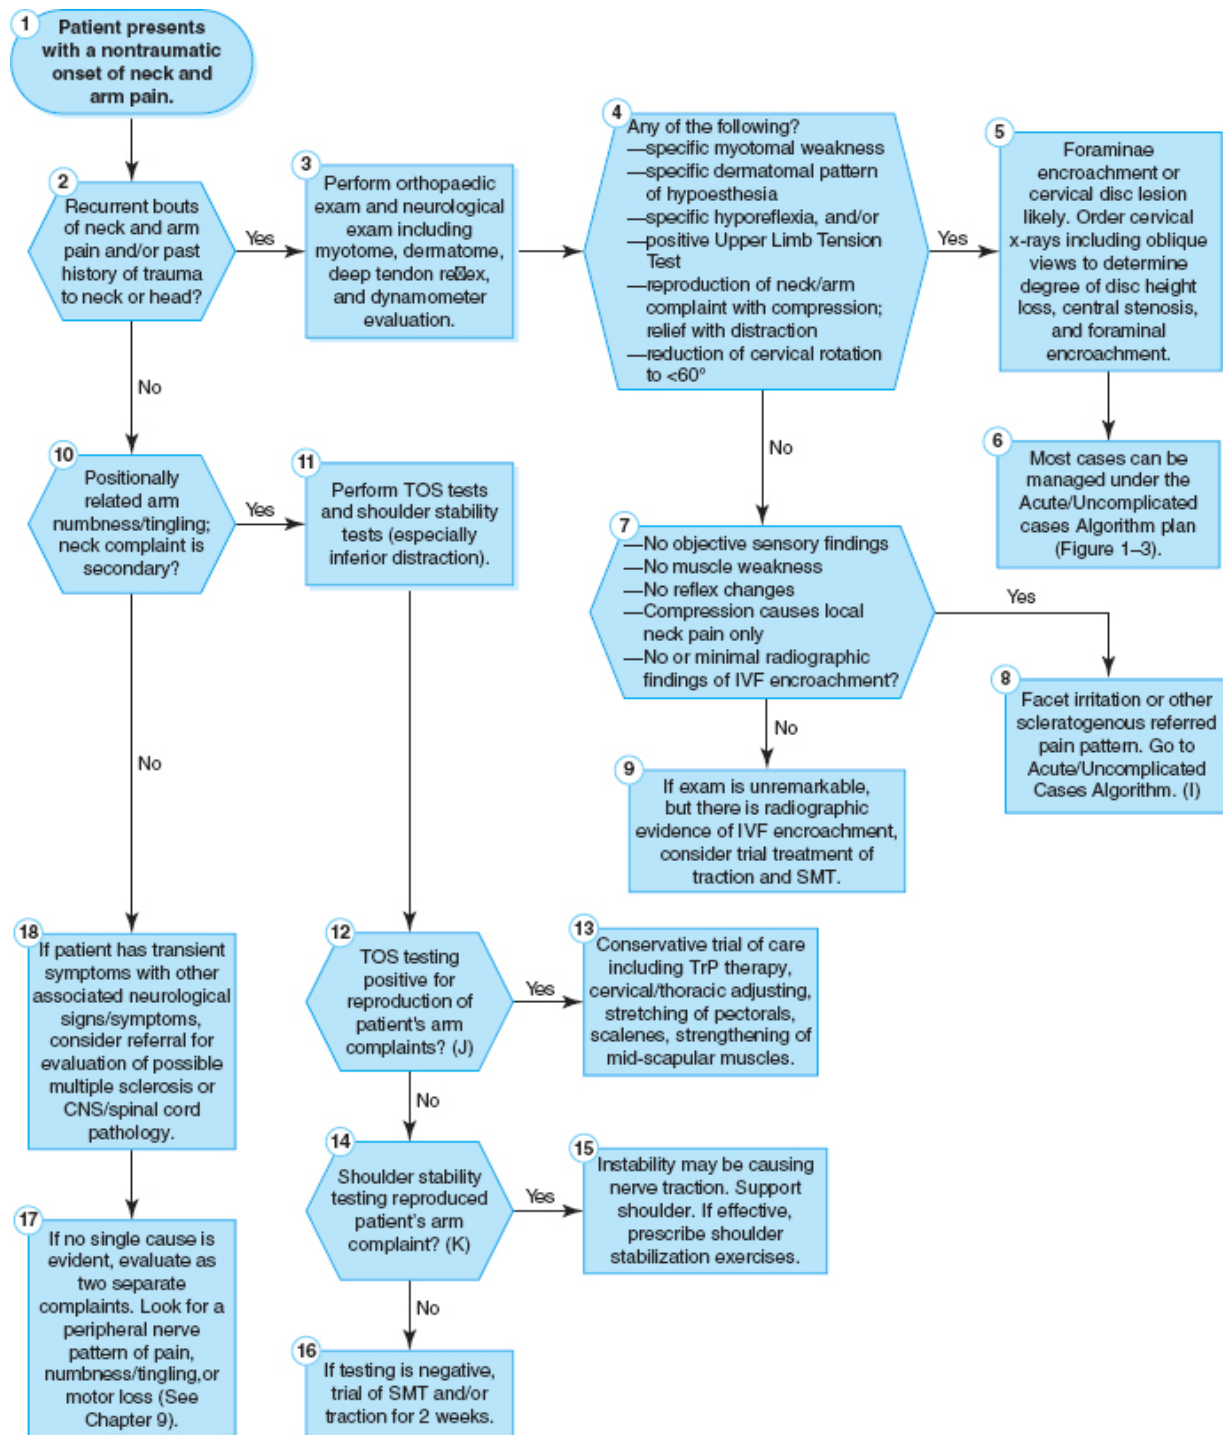

annotations are presented in **Figures 2-5** through **2-8**.

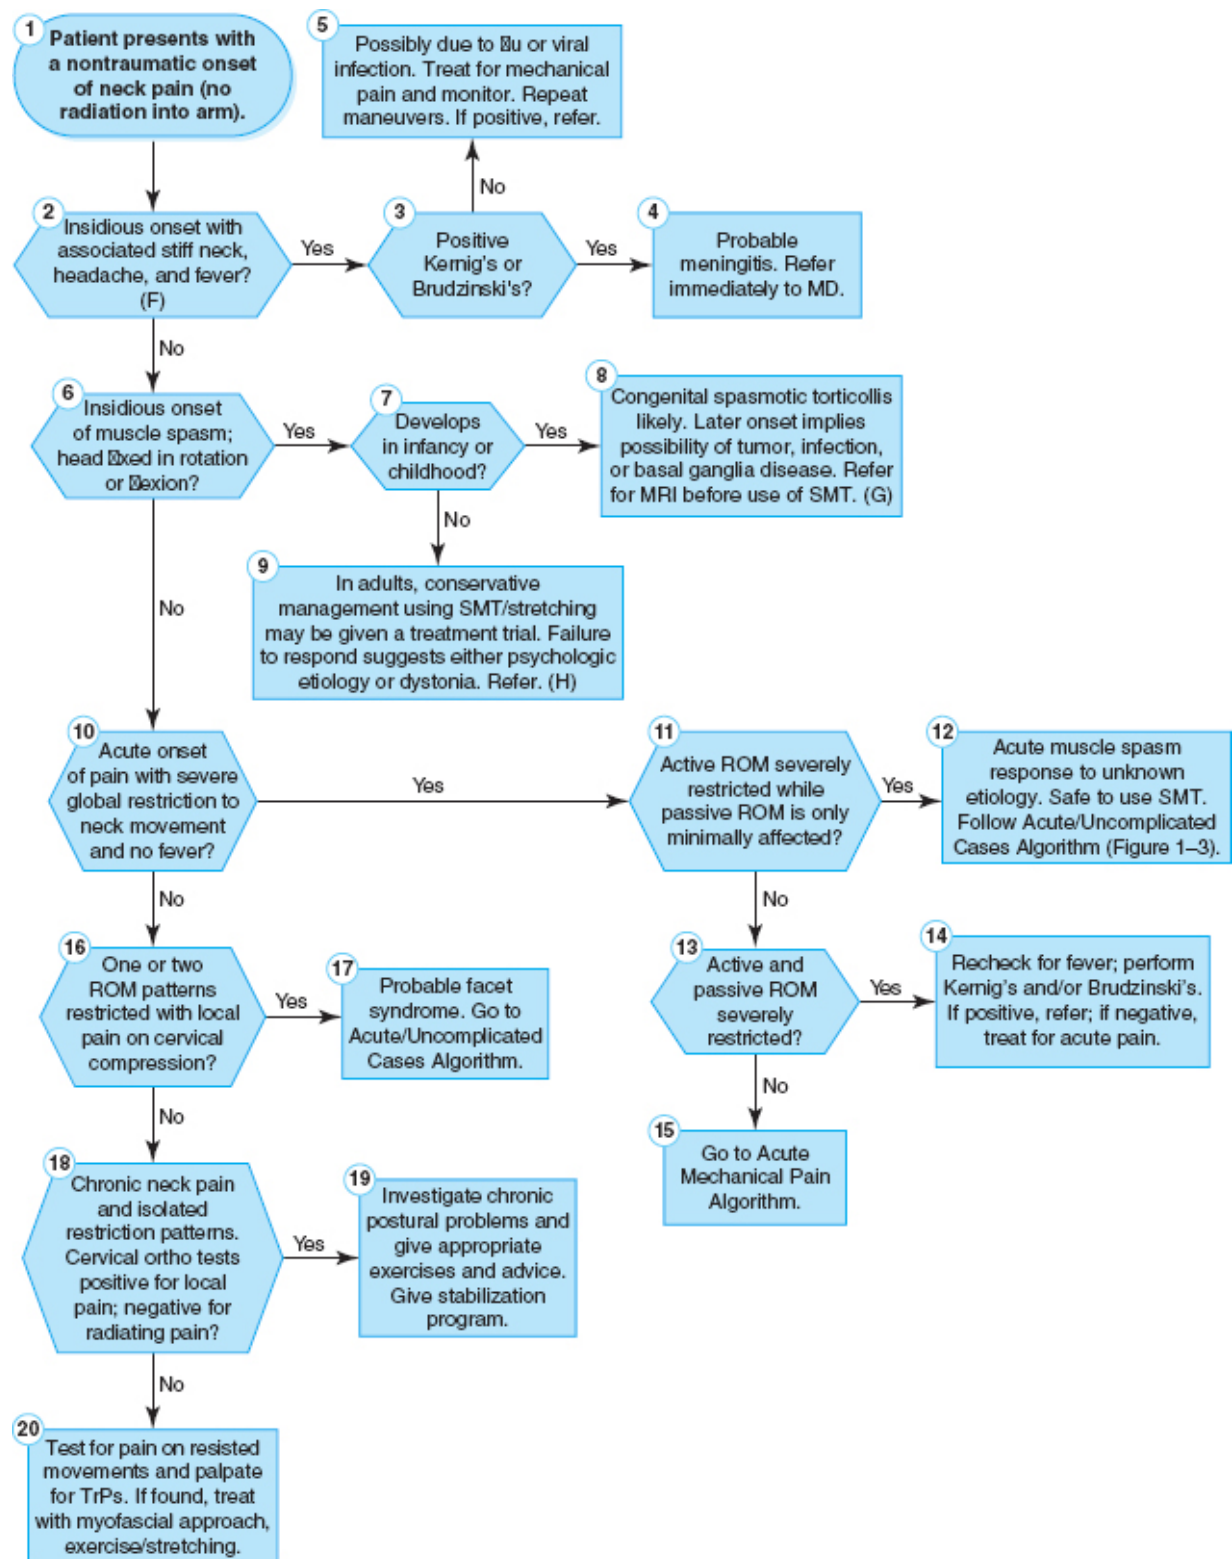

**Figure 2-5** Traumatic Neck Pain—Algorithm

**Figure 2-6** Nontraumatic Neck and Arm Pain—Algorithm

**Figure 2-7** Nontraumatic Neck Pain (No Radiation)—Algorithm

- A. If trauma is significant or patient is unable to move their neck without significant discomfort, stabilize neck and shoot x-rays prior to orthopaedic examination.
- B. Burning-hands syndrome represents spinal cord injury due to stenosis or fracture. Radiographs to determine fracture and degree of stenosis should also include lateral flexion/extension views to determine any contributory instability. Most cases of burning-hands syndrome are self-resolving; however, prolonged recovery is not uncommon.
- C. A "stinger" usually involves a traction injury of either the nerve root or plexus. Most are brief occurrences representing a neuropraxia, however, with more severe trauma an axonotmesis can occur requiring referral to a neurologist.
- D. It is extremely important to get information regarding any evaluation at another facility. Often films are available and a previous diagnosis and/or patient instructions have been given including some contraindications to manipulation.
- E. Any patient with a Hx of head trauma should be monitored for several weeks. Usually due to a torn vein, pressure may develop slowly resulting in very subtle neuro signs/symptoms. With patients who do not seem "quite right," referral to neurologist is warranted. Epidural hematomas usually involve a temporal bone fracture and bleeding from an artery usually resulting in a more rapid onset of neuro signs.
- F. Subarachnoid hemorrhage is essentially a brain bruise. It may result from trauma or a ruptured aneurysm or AVM. With vessel rupture, the onset is sudden and there is no associated fever. This may help distinguish the presentation from meningitis. Immediate referral is necessary.
- G. Spastic torticollis (wryneck) may be congenital and is self-resolving or is correctable within the first few months. Other causes may include basal ganglion disorders, infection, tumors, and psychiatric disorders. A thorough evaluation is needed prior to application of CMT. Note that the restriction is limited to one side.
- H. Dystonia may first present with torticollis and an accompanying distortion of another body part such as the feet. It is rare yet progressive resulting in sustained abnormal postures.
- I. Sclerogenous pain patterns are less distinct than dermatomal or peripheral nerve patterns. Additionally, reflexes, sensory testing, and muscle strength are normal.
- J. TOS tests may produce frequent false positives. It is not enough to obtain a diminished pulse. The test must reproduce the patient's complaint of arm pain/numbness/tingling.
- K. Shoulder instability has been shown to produce similar symptoms as TOS due to tractioning of the plexus.

**Figure 2-8** Annotations for neck pain—Algorithm

# Selected Causes of Cervical Spine Pain

## Cervical Radiculopathy

### Classic Presentation

The patient complains of neck and arm pain. Onset often follows neck injury; however, it may be insidious. There is often a past history of multiple bouts of neck pain following minor injuries. The patient also complains of some weakness in the hand. The pain is described as a deep ache. Some patients report some relief with the hand held behind the head.

### Cause

Unlike the lumbar spine, herniation of the nucleus pulposus accounts for only 20% to 25% of cases in the cervical spine. The clear difference is the natural history of the intervertebral disc of the cervical spine, which dehydrates to the point of almost a ligamentous structure by the age of 40 to 50 years. In fact, the peak incidence occurs at approximately 50 to 54 years old when the disc can no longer herniate, and a history of trauma is found in only about 15% of cases. The prevalence is quite low compared to the lumbar spine: only 0.8 to 3.5 per 100,000 patients.<sup>105</sup> Seventy percent to seventy-five percent of cases are due to foraminal encroachment due to degeneration, including decreased disc height, uncovertebral joint arthrosis, and facet joint arthrosis.

### Evaluation

The patient often will have a painful restriction in active and passive ROM, often more on one side. Orthopaedic testing with cervical compression ([Figure 2-1](#)) may reproduce the neck and arm pain. Radiation into the medial scapular area also is possible. Cervical distraction ([Figure 2-2](#)) may relieve the arm pain. All of these orthopaedic tests are relatively insensitive but moderately specific.<sup>106</sup> Some patients report some relief of the arm pain by putting the hand behind the head, thereby decreasing any traction effect. Neurologic testing should reveal a decreased corresponding deep tendon reflex, weakness in a related myotome, and sensory abnormality in a related

dermatome. Radiographic evaluation of the neck should include oblique views to determine the degree of bony foraminal encroachment. MR imaging or CT scans are reserved for patients with severe pain or those unresponsive to nonsurgical management. Electrodiagnostic studies may be helpful three to four weeks after the onset of symptoms if a specific cause has not yet been identified or the patient is unresponsive to care.

## Management

The natural history appears favorable.<sup>107</sup> Conservative treatment is used for approximately 74% of cases. Ninety percent of patients fully recover or have only mild residual dysfunction. A small prospective study<sup>108</sup> published in 2013 evaluated the short-term effectiveness of manipulation for patients with MRI-confirmed radiculopathy caused by disc herniation. There was no comparative group for natural history or other treatment approach, yet, the improvement rates were, at two weeks 55.3%, at one month 68.9%, and at three months 85.7%. Given there was no comparative control group, it is important to note that for subacute and chronic patients, 76.2% were improved at three months. No adverse events related to manipulation were reported in this previously-assumed high-risk group of patients.

A prospective study<sup>109</sup> published in *Spine* in 2013 compared the results of a structured physiotherapy approach versus anterior decompression surgery and physiotherapy for patients with cervical radiculopathy and followed patients over two years. At a one-year follow-up, 87% of the patients in the surgical group rated their symptoms as “better/much better” versus 62% in the nonsurgical group. At two years, the percentage for improvement using the above rating was 81% in the surgical group versus 69% in the structured physiotherapy group. Improvement was more rapid in the surgical group; however, at two years, there were significant reductions in the Neck Disability Index, in neck pain, and with arm pain compared with baseline in both groups.

Cervical manipulation at sites other than the herniation is used by many chiropractors.<sup>86</sup> If osseous adjusting is to be used, it should be applied with a trial of mild mobilization impulses at the involved level to determine patient response. The degree of force application should be the least possible. It should always be kept in mind that if the patient has hard neurologic evidence of nerve root compression, the chiropractor is at risk of irritating the nerve and being accused of causing the herniation. Nonosseous techniques may be attempted for a short course to determine therapeutic effect.

A first-time randomized controlled trial<sup>87</sup> examined the management of cervical radiculopathy with either a semihard cervical collar or physiotherapist-direct exercise versus rest during the first six weeks of onset. Although the use of a cervical collar for neck pain has decreased significantly based on evidence that it does not seem to make a difference for whiplash patients, there was no evidence for or against the use of a cervical collar for patients with cervical radiculopathy.

Reduction in arm pain at six weeks in the wait-and-see group was approximately 19 points on a 100-point scale. Comparatively, the semirigid collar group experienced on average a reduction of 31 points on a 100-point scale at six weeks. Reduction in neck pain at six weeks in the wait-and-see group was only 5 points, whereas the reduction in the semirigid collar group was an additional 9–12 points.

Consider using a semihard cervical collar for patients with recent onset cervical radiculopathy, in particular, if there is concern by you or the patient regarding manipulation. Instruct the patient to wear the brace during the day. To avoid complications, wean the patient off of the brace over a period of six weeks. The results of this study also support the opposite approach; have patients perform mild exercising and stretching of the neck during the first six weeks of onset with caution if symptoms are increased by the exercise.

Cervical traction and physical therapy may also be incorporated. Home traction for 15 minutes twice a day will be of benefit to some patients. The response is usually evident within a few days.<sup>110</sup> Patients who are unresponsive or are simply in too much pain should be referred for medical comanagement.

## **Myelopathy**

# **Classic Presentation**

Patient presentation may differ depending on the type and degree of compression. Classically, a patient presents with complaints of bilateral symptoms of clumsiness of the hands, difficulty walking, possible urinary dysfunction, and possible shooting pains into the arms.

## **Cause**

Cervical spine myelopathy is present in 90% of individuals older than 70 years of age and is the most common cause of spinal cord dysfunction in individuals older than 55 years of age. It is more common in males and in Asians.

There are numerous causes of spinal cord compression (myelopathy), including tumor, herniated disc, and spondylotic sources. Depending on which portion of the spinal cord or whether nerve roots are also involved, the signs and symptoms will vary. Direct pressure on the posterior columns often occurs with spondylotic myelopathy, causing disturbances in vibration perception and proprioception. If compression of nerve roots also occurs, signs of a lower motor neuron problem will surface.

## **Evaluation**

If the anterior cord is involved, then pain, pathological reflexes and/or hyperactive deep tendon reflexes or motor weakness may be evident. If the posterior cord is involved, then loss of dexterity, gait abnormalities, poor coordination, clumsiness, or sensory loss may be the dominant signs and symptoms. Overlap may occur so that headache, neck stiffness, shoulder pain, paresthesia in one or both arms or hands, or other radiculopathic signs may also be present.

Long tract signs, such as Hoffmann's, Babinski sign, clonus, the crossed-abductor sign, the inverted supinator sign, or hand withdrawal reflex testing, reflect the disinhibition of the primitive afferent or efferent (pyramidal) spinal cord pathways that are normally suppressed or modulated in the adult. Mixed findings of UMNL and LMNL signs may occur. At the level of involvement, LMNL signs may be present and below the level of involvement, UMNL signs. Mixed findings may be found including LMNL signs in the upper extremity with UMNL signs in the lower extremity. Sensory loss may include both numbness and vibration loss bilaterally, or if unilateral involvement is present it may cause contralateral numbness with unilateral vibration loss. There is a dynamic component where extension of the cervical spine may add compression through buckling of the ligamentum flavum or with flexion compression from the posterior longitudinal ligament, especially if calcified.

Cook et al.<sup>111</sup> conducted a systematic review and through classifying exam findings into gait abnormalities, pathological signs, and deep tendon reflex changes, they determined the following:

- Gait or balance—Both abnormal gait (ataxia, wide-based gait, or spastic gait) and a positive static or dynamic Romberg sign were very specific but not sensitive for cervical spine myelopathy.
- Pathological signs—Hoffmann sign, Babinski sign, and clonus were very specific but not very sensitive for cervical spine myelopathy.
- DTR changes—Hyperreflexia was very specific but not very sensitive for cervical myelopathy.

In other words, most tests for cervical myelopathy are specific but not sensitive, meaning that finding a positive is relatively good at ruling-in myelopathy but not finding positive tests is not very good at ruling-out myelopathy. The inverted supinator sign is probably the most sensitive test. It is similar to the brachioradialis reflex test with the patient's forearm placed in slight pronation on the examiner's knee. A few quick strikes with a percussion hammer near the radial styloid process with a pathological response of slight finger flexion or elbow extension.

The researchers combined the following to develop a clinical prediction rule.<sup>112</sup> The Babinski sign, inverted supinator sign, Hoffmann sign, and gait dysfunction (spastic, wide-based gait, or ataxia) and age older than 45 years. If only 1 of 5 tests was positive (4 tests are negative) the sensitivity was 0.94 with a – LR of 0.18 (rule-out). If there were 3 of 5 positive tests, the + LR was 30.9 (rule-in) (95% CI = 5.5-181.8) with a posttest probability of 94%.

The most common finding in patients with myelopathy identified on MRI is gait abnormality found in 91% of patients. Babinski's was found positive in only about 44% of myelopathic patients.<sup>113</sup> Hyperreflexia was more common

in the lower extremity (81%) compared to the upper extremity (67%). Eighty-four percent of patients had a positive clinical examination.

Radiographic measurement of spinal canal diameter may be accomplished on the lateral view of the cervical spine. The width is measured from the posterior vertebral body to the lamina-pedicle junction. Anything less than 13 mm should warrant concern. Anything less than 10 to 11 mm is an indication of absolute stenosis. The Torg (or Pavlov) ratio uses the spinal canal width over the anterior to posterior width of the vertebral body. A ratio less than 0.82 is considered stenotic.<sup>114</sup> If there are myelopathic findings on exam or absolute stenosis evident on radiographs, order MRI (or CT). Evidence of myelopathy is primarily seen on sagittal images. Evidence of spinal cord compression on MRI is indicated by an indentation on the spinal cord parenchyma. More significant involvement is indicated by a T2 signal abnormality in the spinal cord, which is indicated by the presence of a hyperintense signal within the spinal cord parenchyma.<sup>115</sup> This finding should be confirmed on axial images to avoid an artifact effect causing a false positive.

MRI has been shown to be 79–95% sensitive and 82–88% specific with a positive likelihood ratio (LR) of 4.39–7.92 and a negative likelihood ratio (LR) of 0.06–0.27 for identifying selected abnormalities such as space-occupying tumors, disk herniation, and ligamentous ossification. Although special imaging is the “gold standard,” in some individuals the presence of radiographic spinal cord compression is seen without clinical symptoms or physical signs of cervical myelopathy. Findings are seen in 16% of asymptomatic patients younger than 64 years of age, increasing to 26% of those older than 64 years of age.

Electrodiagnostic studies may be helpful in estimating the degree of involvement and perhaps the level. The most valuable tests are SEPs and DSEPs because they may determine latency of signal transmission through the spinal cord.<sup>116</sup>

## Management

Surgery is often recommended in cases where there are “hard” lesions such as spondylosis or ossification of the posterior longitudinal ligament because of the possibility of permanent neurologic damage. “Soft” lesions such as disc lesions may resolve over time. Decompression surgery for spondylotic myelopathy has variable results between 33% and 74%.<sup>117</sup> In 2002, a Cochrane review of surgery for cervical spondylotic radiculomyelopathy determined that although the short-term effects of surgery were superior to conservative management for pain, weakness, or sensory loss, the effect was lost at one year where there was no significant difference between the two groups.<sup>118</sup> For those with a mild functional deficit associated with cervical myelopathy, there were no significant differences two years following treatment. A follow-up Cochrane review<sup>119</sup> in 2010 still maintained that there

was lack of evidence for surgery's having a superior long-term effect. Recommendations should be based on the severity of functional impairment and failure of conservative management.

Murphy et al.<sup>120</sup> published a case-series report on patients with early and mild myelopathy managed chiropractically. Seventy percent of patients, on average, improved although there was a wide range of 0–100%. No neurological signs developed and no major complications occurred. A management approach to the patient with cervical myelopathy based on this study is:

- If there are mild myelopathic signs/symptoms or MRI evidence of compression with *no* T2 changes, consider an initial trial of HVLA adjusting using premanipulative positioning (i.e., setting up without thrusting) to determine if peripheralization occurs or not. It is important to find a position that does not peripheralize prior to adjusting. Make this clinical decision for treatment with patient education, input, and approval.
- If there are advanced or severe clinical findings of myelopathy or T2 hyperintense signal changes on MRI, surgical consult or a trial of nonmanipulative approaches is suggested.

Comanagement is recommended for patients who show no improvement after one to two weeks.

## **Burner/Stinger**

# **Classic Presentation**

The patient reports a sudden onset of burning pain and/or numbness along the lateral arm with associated arm weakness following a lateral flexion injury of the neck/head (e.g., lateral “whiplash”). The symptoms usually last only a couple of minutes.

## **Cause**

“Burner” or “stinger” are the names given to injury of the brachial plexus or nerve roots caused by a lateral flexion injury. This is a common injury in sports and has a high percentage of underreporting (70%) because of the transient symptoms.<sup>121</sup> In general, lateral flexion of the head away from the involved side with accompanying shoulder distraction (depression) on the involved side causes a brachial plexopathy. Compression on the side with lateral flexion is more likely to result in nerve root compression. When the brachial plexus is involved, the upper trunk (C5–C6) is most often affected. Varying degrees of injury may occur; however, the majority of injuries are mild, with transient symptoms.

# Evaluation

The most common physical finding is weakness of shoulder abduction, external rotation, and arm flexion. Both muscle weakness and sensory findings may be delayed; therefore, it is important to reexamine patients within about one week postinjury. Persistent symptoms require a radiographic evaluation for instability, including flexion and extension views. If arm weakness is persistent after three weeks, an EMG study may be helpful.<sup>122</sup> If a nerve root problem is suspected, an MRI may be of help. Otherwise, most cases require no special testing evaluation.

# Management

It is important to avoid reproduction of the injury with a lateral-flexion type of adjustment. Given that recurrence of the injury is common in sports, athletes are encouraged to strengthen their neck muscles and wear protective gear when appropriate. Repeated episodes may lead to more damage requiring neurologic consultation.

## Thoracic Outlet Syndrome

# Classic Presentation

The patient presents with diffuse arm symptoms, including numbness and tingling. Often the patient will describe a path down the inside of his or her arm to the little and ring fingers. This is often made worse by overhead activity.

# Cause

The brachial plexus and/or subclavian/axillary arteries can be compressed at various sites as they travel downward into the arm. Several common sites are possible, including an elongated C7 transverse process (cervical rib), the scalene muscles, the costoclavicular area, and the subcoracoid area (between the coracoid and the pectoralis minor). Muscular compression at the scalenes or with the pectoralis minor is believed to be due to tight muscles and/or posturally induced (forward head and rounded shoulder habit). Leffert<sup>123</sup> reports that in 40% of cases there is a report of inciting trauma. It is important to recognize that only 1% of the population has cervical ribs, and only 10% of those individuals have symptoms.<sup>124</sup> A fibrous band connecting the cervical rib to the first rib also may be the culprit in some cases.

# Evaluation

Although a number of provocative tests are used, there are often false positives and false negatives. The intent of the tests is to reproduce symptoms in the arm. If the positive is based on simply a reduction of the radial pulse, many false positives will be found. When the scalenes are being tested, the patient is asked to look either toward (Adson's test) or away (Halstead's test) from the involved side with the arm held in slight abduction. When the pectoralis minor is tested, the arm is lifted into abduction and horizontal abduction (Wright's test). A functional test is to have the patient raise the arms above head level and repeatedly grip and release the hands for 20 to 60 seconds (Roos' test) in an attempt to reproduce arm symptoms or weakness. It is always important to perform a neurologic evaluation in an attempt to differentiate TOS from lower brachial plexus, nerve root, or peripheral entrapment problems.

# Management

Generally, management is conservative with an approach based on postural correction, stretching of tightened muscles, and strengthening of weakened muscles. This includes strengthening of the middle and lower trapezius and rhomboids, and stretching of the pectorals and scalenes. Trigger-point therapy is also advocated by Travell and Simons.<sup>125</sup> Taping or bracing may help with a proprioceptive training program for postural correction. There is also a belief that a first rib subluxation may cause the signs and symptoms of TOS. Several investigators have suggested manipulation of the first rib in an attempt to correct this problem.<sup>126-128</sup> Surgery is suggested for a minority of patients (approximately 24%) who do not respond to conservative management.<sup>129</sup>

## Facet/Referred

# Classic Presentation

The patient often will report a minor (e.g., sudden turning of the head) to moderate (e.g., motor vehicle accident) traumatic onset of neck and arm pain. In some patients the onset can be insidious with no recent trauma. The patient often will draw a line of pain down the outer arm to the hand. The arm and hand pain do not often fit a specific dermatome.

## Cause

Irritation of the facet joints or deep cervical muscles causes a referred pain down the arm. The most common location is down the outer arm to the hand. This location often implicates segmentally related facet joints of C5-C7.

## Evaluation

It is assumed that what chiropractors affect are facet joints, yet there have been no studies to correlate findings of facet involvement with facet injections for pain relief. A recent study by King et al.<sup>130</sup> evaluated patients who were diagnosed by physical therapists as having facet joint dysfunction. The patients who were willing to participate then had controlled diagnostic blocks performed to determine which facets, in fact, were involved. The manual examination was sensitive, but not specific, for facet involvement.

A standard orthopaedic and neurologic examination of the neck and upper extremity should be performed. With referred pain, there is rarely any hard neurologic evidence. Deep tendon reflexes are normal, muscle strength is normal or weakness does not fit a specific myotome, and numbness is often subjective with no objective sensory findings. Local pain may be reproduced with cervical compression ([Figure 2-1](#)) with the neck in extension and rotation to the involved side. A search for trigger-point referral should be made, including supraspinatus or infraspinatus involvement. Radiographic evaluation may be performed to detect any foraminal encroachment on the oblique views. Patients with mild foraminal encroachment, however, may still have referred pain as opposed to nerve root impingement if the neurologic examination is normal.

## Management

Manipulation of the neck is the treatment of choice. If unsuccessful, cervical traction may be of benefit. Any myofascial contribution may be addressed with stretch-and-spray techniques, trigger-point therapy, or myofascial release.

### Torticollis

## Classic Presentation

There may be several presentations of torticollis based on age and cause. In congenital torticollis, the infant will have a fixed asymmetry of the head that is seen within hours (or sometimes weeks) of delivery. In the adult version, a patient presents with painful spasm of the SCM, causing the head to be held in rotation and sometimes slight flexion. In pseudotorticollis, the patient

presents with the inability to move the head in any direction without pain. The patient reports having awakened with the condition; there is no trauma or obvious cause. The head is held in neutral.

## Cause

The congenital cause of torticollis is probably birth trauma, often breech delivery. Damage to the SCM causes it to become fibrous. The adult version may be due to a number of causes, including CNS infection, tumor, basal ganglion disease, or psychiatric disease. Pseudotorticollis has no known cause. It differs from classic torticollis in that all movements are painful and there is no deviation of the head.

## Evaluation

It is important to determine whether there is a moderate to high fever, which would be suggestive of meningitis. Kernig's or Brudzinski's signs would be positive, causing severe pain and/or flexion of the lower limbs on passive flexion of the neck. Palpation of the SCMs and the anterior neck for masses is important. Patients with pseudotorticollis often have markedly increased passive ROM when examined carefully in the supine position. The amount of passive ROM is used as the gauge as to whether or not manipulation is appropriate. A neurologic check for upper motor and lower motor neuron dysfunction will reveal any medically referable causes. Radiographs are usually not necessary. MR imaging or CT scans may be needed when CNS disease is suspected.

## Management

---

The congenital type of torticollis may respond to physical therapy attempts to lengthen the SCM; however, the therapy must be consistent and often takes up to one year. For the adult who has no known cause, attempts at neck manipulation and physical therapy may help, or the condition may self-resolve. With pseudotorticollis, manipulation should be applied cautiously as soon as possible in an attempt to decrease the global muscle spasm. Failure to resolve warrants a referral for medical evaluation.

# **The Evidence—Cervical Spine**

## **Translation into Practice Summary (TIPS)**

Directed by the patient presentation, the evaluation for cervical spine fracture, instability, and radiculopathy are important specific focuses of the examination. The history and examination together are good at determining the need for radiography in the evaluation of fracture and instability. The history is poor but the examination good at ruling-in cervical radiculopathy. There is no evidence for the value of the clinical examination to screen for risk of vertebrobasilar accidents.

## **The Literature-Based Clinical Core**

- The clinical examination together with specific historical indicators is sensitive for cervical spine fracture. Both the NEXUS and Canadian Spine Rule are very good at ruling-out (but not ruling-in) fracture of the cervical spine.
- The Sharp-Purser test may be valuable in ruling-in cervical spine instability.
- The patient history is not helpful in ruling-in or ruling-out cervical radiculopathy.
- The biceps and brachioradialis DTRs are good at ruling-in (but not ruling-out) C5 and C6 nerve root involvement. However, the triceps DTR is only fair at ruling-in, but bad at ruling-out C7 nerve root involvement.
- Although the specificity for myotome and dermatome testing for radiculopathy is good, the overall performance based on LR is poor. Adding resisted pronation testing may increase the sensitivity of detecting a C6 or C7 nerve root involvement.

- Patients are less likely to report weakness compared to the finding of weakness by the examiner so that strength testing should always be performed with patients complaining of radiating pain.
- It is less common for patients to describe a dermatomal pattern when a radiculopathy is present; therefore, any radiation warrants the application of the clinical prediction rule stated below.
- The combination of the upper limb tension test (ULTT), Spurling's, cervical distraction, and ROM less than 60° together are very good at ruling-in cervical radiculopathy
- The ICCs are good for ROM testing and cervical strength and endurance testing.
- The kappa values are poor for assessing pain with palpation and intervertebral motion testing. Palpation of cervical facets posteriorly has a good -LR and a fair +LR.
- With the exception of a forward flexed head, the kappa values for postural assessment and muscle length assessment of the cervical spine area are good.
- There is no evidence for the reliability or validity of any tests for thoracic outlet syndrome (TOS) when evaluating for the medically defined entity of TOS.

### **The Expert-Opinion-Based Clinical Core**

- When all neurological findings are negative including the upper limb tension test, it is likely that a patient's radiating pain is not, in fact, radicular and more likely scleratogenous with the main sources coming from internal disc disruption and cervical facet joints.
- Mapping of a patient's description of radiation should always include a scleratogenous and trigger point comparison.

- Use of TOS testing may have some value when determining a myofascial component of radiating complaints of numbness, tingling, or pain.
- Screening tests for vertebrobasilar accidents (ischemia) are of no value and may introduce false positives that compromise clinical decision making. None of the tests from George's or deKleyn's are of value in screening for VBA.
- Older patients should always be screened for myelopathy especially with gait problems or with neurological symptoms or radiating complaints (especially bilaterally).
- Older patients with diffuse symptoms in both arms/hands should also be evaluated for T4 syndrome.

## APPENDIX 2-2

# Neck Diagnosis Table

Diagnosis	Comments	History Findings	Positive Examination Findings	Radiography/Special Studies	Treatment Options
<b>Segmental Dysfunction of Cervical Spine Joints</b>	<ul style="list-style-type: none"> <li>Should be used when chiropractic manipulation is used as Tx for any cervical spine problem/Dx.</li> <li>Can be primary Dx if patient is asymptomatic or patient has tenderness and no pain.</li> <li>Must indicate chiropractic exam findings to support Dx.</li> </ul>	<i>Nonspecific</i>	<i>Palpation</i> —Local tenderness or other signs of subluxation <i>Ortho</i> —None <i>Neuro</i> —None <i>Active ROM</i> —Variable restriction <i>Passive ROM</i> —Endrange restriction <i>Motion palpation</i> —Specific vertebral segmental restriction or symptoms produced on endrange	<ul style="list-style-type: none"> <li>Radiography not required for the diagnosis of subluxation.</li> <li>Radiographic biomechanical analysis may assist in treatment decisions.</li> <li>For specifics see radiographic guidelines.</li> </ul>	<ul style="list-style-type: none"> <li>Chiropractic adjustive technique.</li> <li>Decisions regarding specifically which technique(s) is/are applied and modifications to the given approach will be directed by the primary Dx and patient's ability to tolerate pre-adjustment stresses.</li> </ul>
<b>Cervical Sprain/Strain</b>	<ul style="list-style-type: none"> <li>Should be reserved for acute traumatic sprain/strain.</li> </ul>	<i>Trauma</i> —Overstretch or over-contraction Hx as acute event <i>Radiation of pain</i> —Possible (referred) <i>Pain radiation with Valsalva-type activities</i> —No <i>Worse with Specific ROM</i> —Contraction of muscle or stretch of muscle or joint	<i>Ortho</i> —None <i>Neuro</i> —None <i>Active ROM</i> —Pain on active ROM that contracts involved muscles <i>Passive ROM</i> —Pain on endrange stretch of involved muscle or ligament	<ul style="list-style-type: none"> <li>Radiography not required for diagnosis.</li> <li>With significant trauma or for med/legal purposes, radiographs may be required.</li> <li>For specifics see radiographic guidelines.</li> </ul>	<ul style="list-style-type: none"> <li>Myofascial therapy.</li> <li>Limited orthotic support.</li> <li>Ergonomic advice.</li> <li>Preventive exercises and stretches (e.g., spinal stabilization exercises).</li> </ul>
<b>Neuritis or Radiculitis Due to Disc</b>	<ul style="list-style-type: none"> <li>Requires hard neurological evidence of nerve root dysfunction.</li> <li>Requires special imaging confirmation.</li> </ul>	<i>Trauma</i> —Often Hx of similar events with resolution; major or minor trauma possible <i>Radiation of pain</i> —Often into arm/hand <i>Pain radiation with Valsalva-type activities</i> —Possible <i>Worse with Specific ROM</i> —Variable; may be related to disc protrusion	<i>Ortho</i> —Nerve compression or stretch tests positive (e.g., upper limb tension test) <i>Neuro</i> —Deficit in corresponding dermatome, myotome, and DTR <i>Active ROM</i> —Variable; weakness more in related upper limb muscle(s) <i>Passive ROM</i> —Variable	<ul style="list-style-type: none"> <li>Radiography may help initially in differentiating stenosis and disc.</li> <li>MRI or electrodiagnostic studies may be needed after one month without resolution or if progressive.</li> </ul>	<ul style="list-style-type: none"> <li>Emphasis may be placed more on "soft" techniques such as activator or traction.</li> <li>Limited orthotic support.</li> <li>When subacute, begin spinal stabilization.</li> </ul>

Diagnosis	Comments	History Findings	Positive Examination Findings	Radiography/Special Studies	Treatment Options
<b>Non-Specific Cervical Spine Pain</b>	<ul style="list-style-type: none"> <li>Used for patients with evidence of a myofascial cause.</li> <li>Also used for patients without Hx of recent trauma.</li> <li>May be used for unspecified neck pain.</li> </ul>	<p><i>Trauma</i>—Not recent</p> <p><i>Radiation of pain</i>—May radiate into shoulder or arm to hand</p> <p><i>Pain radiation with Valsalva-type activities</i>—No</p> <p><i>Worse with Specific ROM</i>—Variable</p>	<p><i>Ortho</i>—None positive, however, may reproduce local symptoms</p> <p><i>Neuro</i>—None (although patient may have neurological complaints such as numbness)</p> <p><i>Active ROM</i>—Variable</p> <p><i>Passive ROM</i>—Variable</p>	<ul style="list-style-type: none"> <li>Radiography not necessary.</li> <li>May be used to access biomechanical status or predisposition.</li> <li>See PCCW Radiographic Guidelines.</li> </ul>	<ul style="list-style-type: none"> <li>Myofascial therapy</li> <li>Limited orthotic support</li> <li>Ergonomic advice</li> <li>Preventive exercises and stretches (e.g., spinal stabilization exercises)</li> </ul>
<b>Neuritis or Radiculitis Unspecified</b>	<ul style="list-style-type: none"> <li>Used in cases where there are radicular signs/symptoms. However, not enough evidence to pinpoint disc vs other causes.</li> <li>Used with radicular signs/symptoms where no specific nerve root is clearly involved.</li> </ul>	<p><i>Trauma</i>—Variable presentation</p> <p><i>Radiation of pain</i>—May radiate down shoulder and arm</p> <p><i>Pain radiation with Valsalva-type activities</i>—Possible</p> <p><i>Worse with specific ROM</i>—Variable</p>	<p><i>Ortho</i>—Nerve compression or stretch tests positive (e.g., upper limb tension test)</p> <p><i>Neuro</i>—Deficit in corresponding dermatome, myotome, and DTR</p> <p><i>Active ROM</i>—Variable weakness</p> <p><i>Passive ROM</i>—Variable</p>	<ul style="list-style-type: none"> <li>Radiography may help in differentiating stenosis and disc.</li> <li>MRI or electrodiagnostic studies may be needed after one month without resolution or if progressive.</li> </ul>	<ul style="list-style-type: none"> <li>Limited orthotic support</li> <li>Myofascial therapy</li> <li>When subacute, begin deep flexor strengthening</li> </ul>

## **CHAPTER 3**

# **Temporomandibular Complaints**

## **Context**

Although often viewed as the domain of the specialist, many temporomandibular joint (TMJ) disorders may be sufficiently screened and managed by the chiropractor. If the TMJ is conceptually approached like any other synovial joint, most common problems can be detected. These problems include synovitis, capsulitis, disc (meniscal) derangement, tendinitis, arthritis, and associated myofascial involvement. The complexity arises when multiple factors with regard to dentition occur. Comprehensive, yet cumbersome, approaches such as the craniomandibular index (74 separate items) generally are impractical and are not weighted toward items of most importance. Screening procedures are sufficient and can provide a baseline determination of the degree of involvement without sacrificing thoroughness.

Ambiguous terminology has always hampered discussions of TMJ disorders. In general, it is important to view (no matter what the terminology) TMJ conditions as intraarticular and extraarticular. Extraarticular involvement may range from cervical spine involvement (myofascial, postural, subluxation-related dysfunction) to dental abnormalities or pathologies. Some practitioners refer to the

dysfunctional cervical spine-TMJ relationship as a TMJ syndrome. Intraarticular disorders center around familiar problems such as synovitis and capsulitis with a focus on the articular disc, which is often displaced or degenerated.

One study suggests that 85% to 90% of individuals will develop some TMJ-related symptom in their lifetime.<sup>1</sup> It appears that women are affected more commonly than men. Using a temporomandibular disorder (TMD) questionnaire, Nornura et al.<sup>2</sup> found that in a group of students, 53% showed some level of TMD, 36% had mild TMD, 12% had moderate, and 5.5% had severe TMD. In evaluating the severe responders, women were about nine times more affected than men. Interestingly, many showing any level of TMD considered themselves tense people, clenched or ground their teeth, and reported clicking of the TMJ. Sixty-five percent reported frequent headaches and 61% had neck pain. Unfortunately, studies have shown a poor response to TMJ management, in the range of only 4% to 36%. An interesting subgroup of patients are professional violin and viola players who seem to have a higher than average predisposition toward TMJ problems.<sup>3</sup> Although osteoarthritis of the TMJ obviously is more prevalent in the elderly population, signs and symptoms of craniomandibular disorders tend to decrease in the elderly.<sup>4</sup> Although the TMJ may be the source of local pain, it has been accused of being a primary referral source for both neck and ear pain.<sup>5</sup>

Some additional complaints related to TMJ dysfunction include:

- Headache
- Ear pain
- Ipsilateral face pain
- TMJ pain on opening and closing the mouth
- Joint sounds
- Mandibular excursion restrictions
- Tinnitus/congestion/vertigo

- Neck stiffness
- Sinus congestion

Chronic headache unresponsive to treatment is a difficult scenario. First on the list of possibilities should be temporomandibular joint (TMJ) disorders.<sup>6-8</sup> Overlap with clinical indicators of tension-like headache is common. Some differentials include tenderness of the pterygoids, tenderness of the TMJ, clicking in the TMJ, and abnormal mandibular movement patterns on opening and closing.<sup>6</sup>

## General Strategy

### History

- Determine whether the patient's complaint is one of pain, clicking/popping, crepitus, inability to open fully, or fatigue with chewing.
- Determine whether there is any history of direct trauma, episodes of jaw locking, whiplash injuries, past diagnoses of an arthritis, or significant dental pathology.
- Determine whether there are other signs or symptoms suggestive of an underlying arthritis.
- Attempt to distinguish between an intraarticular and extraarticular problem.

### Evaluation

- Determine dental status.
- Measure all aspects of mandibular gait.
- Perform provocative maneuvers of stretch (capsulitis), compression (synovitis), and contraction (myofascial).

- Palpate common tender areas indicating sites for specific, commonly involved structures.
- Radiographs are not helpful; magnetic resonance imaging (MRI) may be of benefit; however, it should be reserved for patients who have severe pain or are not responsive to several months of conservative care.

## Management

- Management is multifactorial. Address myofascial issues with trigger-point massage, and muscle hyperactivity or hypertonicity with myofascial release techniques. Address compressive retrodiscal problems with a splint or stretching and breaking up adhesions with short-amplitude thrusts (except in those cases listed below).
- Refer patients to a dentist who specializes in TMJ problems if dental involvement is significant, an acute lock cannot be reduced, or treatment for chronic pain is unsuccessful. Refer to a medical doctor if fracture is suspected.

## Relevant Anatomy and Biomechanics

The TMJ is best visualized by using both anterior-to-posterior and lateral-to-medial perspectives (**Figures 3-1** and **3-2**). These perspectives will assist when conceptualizing function and dysfunction. It is easiest to view the TMJ as a two-joint compartment. The superior compartment is bordered by the articular surface of the eminence of the temporal bone superiorly and the articular disc inferiorly. The superior compartment's function is to allow and govern linear

movement or translation. The inferior compartment is bordered by the inferior surface of the articular disc and the superior surface of the condyle. The inferior compartment permits full rotary (open and closing) motion of the mandibular condyle if the condyle is seated under the articular disc. The articular disc, separating the TMJ into the superior and inferior compartments, is a necessary component for smooth jaw movement. If the disc is either degenerated or displaced (or both), limitation or popping/clicking of jaw movement will occur. The posterior attachment to the disc is the retrodiscal tissue. Although these two structures are connected, their composition and function are quite different. The disc is a biconcave structure consisting of dense fibrous connective tissue and, as such, is not vascularized or pain sensitive. The retrodiscal tissue, however, is mainly a large venous plexus covered with synovial membrane. It is well innervated and therefore a likely source of some TMJ pain. When irritated, the retrodiscal tissue is capable of producing synovial effusion.

**Figure 3-1** Frontal view of the TMJ showing the ligaments that tether the disc atop the condyle, dividing the TMJ space into two parts.

**Figure 3-2** Lateral view of the TMJ.

The TMJ has a rich arterial supply arising from the branches of the anterior tympanic artery, the deep temporal artery, the auricular posterior artery, the transverse facial artery, the middle meningeal artery, and the maxillary artery. Of note is that the superficial temporal artery and the maxillary artery run along the lateral and medial sides of the condylar neck and may be at risk from soft tissue procedures or surgery for the TMJ.<sup>9</sup>

The disc is connected and stabilized by the collateral discal ligaments. Together with the capsular ligaments, they are important in guaranteeing combined movement of the disc and condyle during jaw movement. Elongation or damage disengages this coupling and may allow anterior displacement of the disc.

A discussion of normal opening and closing of the jaw will illustrate the need for a balance among several structures to accomplish smooth and painless movement. As the mouth opens, there is relaxation of the closing muscles (mainly temporalis and masseters). After about 1 cm of opening, the inferior head of the external pterygoid muscle pulls on both the disc and the condyle. With the hyoid bone stabilized by the supra- and infrahyoid muscles, the digastric muscle helps pull the mandible downward and backward toward the end of opening. Rotation occurs primarily in the first third of

opening. This movement occurs primarily between the inferior articular disc surface and the condylar head. Rotational movement is limited by tautness of the outer oblique band of the temporomandibular ligament. Further opening results in translation down the slope of the articular eminence to the point at which the condyle is slightly past the center of the eminence. During closing, the inferior head remains silent while the superior head of the pterygoid muscle stabilizes the disc and condyle as they translate posteriorly. The muscles that are primarily involved are the temporalis and masseter. Limitation of posterior movement of the condyle is provided, in part, by the inner horizontal band of the temporomandibular ligament.

Lateral movement of the mandible is caused by contraction of the ipsilateral temporalis and masseter muscles and contralateral contraction of the medial and lateral pterygoid muscles. Protrusion is the result of forward movement of the condyles through contraction of the lateral pterygoid muscle combined with forward mandible movement caused by contraction of the masseter and medial pterygoid muscles.

Abnormal movement may be asymptomatic or result in pain, popping/clicking, or crepitus. One of the most common functional problems with the TMJ is anterior displacement of the articular disc. When this occurs, the condylar head is positioned behind the posterior band of the disc. When viewed from the side, the articular disc looks like a stretched-out red blood cell. There is a thicker anterior band, a thin intermediate band, and a thickened posterior band. Normally, the condylar head rests in between the anterior and posterior bands in the depression formed by the intermediate area. This position is maintained from a closed-mouth to an open-mouth position. With anterior displacement, the condyle's starting position is behind the posterior band. With opening, if the condyle can override the posterior band to reach the intermediate area, a pop is

often heard. When the pop is heard or felt close to full opening, marked anterior displacement and posterior ligament deterioration are suggested.<sup>11</sup> This characteristic pop is an indicator of anterior disc displacement with reduction. The condyle retains its normal position until full closing, when often it is again pulled back behind the posterior band of the disc. This may cause a pop or click, referred to as a reciprocal click. When the condylar head cannot reduce into the intermediate disc depression on opening, no pop is heard. This functional derangement is referred to as a closed lock. This unreduced displacement is referred to as a *lock* because condylar translation is limited by the disc-condyle relationship, preventing full opening. An open lock may occur when the condylar head extends far past the articular eminence and is not able to return posteriorly.

Although injury may be acute, many of the TMJ's problems are the result of chronic biomechanical dysrelationships. These may be complex, involving abnormalities of bone development or occlusal problems, yet many complaints are, at least in part, due to the indirect effects of soft tissue problems. As in any other joint, the capsule and ligaments are susceptible to acute or chronic stretching to the point that they no longer provide stability. In acute-stretch scenarios, further stretch often increases pain. One of the most common causes of overstretching of the capsule and ligaments is a distended joint. If this is a chronic process, the capsule and ligaments may be left in a poorly functioning overstretched position leading to hypermobility of the TMJ.

The pain-sensitive retrodiscal area is susceptible to compression. Both the compression itself and the resulting synovial fluid reaction that increases pressure in the joint may cause pain. Externally applied compression often increases the pain in this scenario. Compression of the

retrodiscal tissue may be due to a number of reasons; however, there are some common culprits, as follows:

- Condylar compression due to anterior disc displacement, which forces the condyle posteriorly.
- A hypertonic temporalis muscle (posterior fibers) may pull the condyle back posteriorly.
- The vertical height of the teeth, when diminished (loss of teeth or attrition), causes the condyle to be displaced up and back into the retrodiscal material.
- A blow (or an overly aggressive adjustment) to the mandible in a superior/posterior direction may jam the condyle into the retrodiscal tissue.

## Evaluation

## History

It is important to determine any direct or indirect trauma to the TMJ (**Table 3-1**). Direct blows to the jaw can stretch or compress the same-side TMJ. A blow to the front of the jaw driving the jaw directly back will cause more of a compressive injury with a reactive synovitis. A blow to the lateral jaw may stretch the joint capsule, resulting in a capsulitis or disc derangement. Microtrauma may occur as a result of bruxism. Bruxism may be evident to the patient if he or she notices it during the day; however, if bruxism occurs at night, the patient may be unaware of grinding the teeth. A sleep partner may provide the answer.

If the patient has had a diagnosis of an inflammatory arthritis, such as rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, Reiter's syndrome, or lupus erythematosus, it is likely that the TMJ pain is due to an inflammatory process. Patients with local infections such as

measles, mumps, or infectious mononucleosis are similarly affected.

Asking about provocative maneuvers may help narrow the list:

- Clicking and popping—If the jaw clicks on opening, a disc displacement with reduction is often the cause; this occurs as the translating condyle slips into its normal position under the posterior edge of the disc; a closing click indicates that a weakened posterior ligament is failing to retract the disc.
- Locking—There are two general types of lock: (1) If the patient simply cannot open fully (closed lock), the disc is probably anterior to the condyle during jaw opening (recapture not possible). (2) If the patient is unable to close the mouth (open lock), the anterior condyle has dislocated; this may occur as the result of excessive joint laxity or blunt trauma.
- Pain with excessive opening—This is the hallmark of a capsulitis; additional accompanying complaints are pain with contralateral chewing and protrusion or lateral excursion of the mandible.
- Pain with chewing—The first possibility is a dental disorder; when the TMJ is involved, a synovitis is likely; this may be due to atypical chewing habits, chronic gum chewing, or any impact injury; the patient may notice that he or she cannot close fully on the involved side so that the teeth touch.

**Table 3-1 History Questions for Temporomandibular Joint Disorders**

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Was there a direct blow to the jaw?	Fracture, disc derangement, synovitis, capsulitis	Did you have a blow to the front of the jaw (directly back)? Did you have a blow to the outside of the jaw?	Fracture, synovitis, disc derangement Same-side capsulitis; opposite-side synovitis
Does your jaw lock?	Closed lock, acute open lock	Is the lock felt as a block to full opening? Does the jaw lock in full opening?	Closed lock (recapture of condyle to disc not possible) Anterior dislocation of condyle (often due to hypermobility of TMJ)
Is the complaint more one of popping or clicking?	Disc displacement, adhesions	Is there an opening and closing pop? Is there grinding or popping throughout opening or closing?	Disc displacement Adhesions
Is the pain worse when opening the mouth wide?	Capsulitis, hypermobility of TMJ	Did you have either a whiplash injury or a prolonged dental procedure? Do you often yawn widely?	Sudden or prolonged stretching of capsule leading to capsulitis Possible chronic stretching of capsule leading to hypermobility of TMJ
Is the pain worse with chewing?	Dental pathology, TMJ synovitis	Is the pain worse with cold, hot, or sweet foods? Is it worse when biting down on one side?	Dental pathology Same-side synovitis (ask about chronic gum chewing, grinding teeth at night, or habit of chewing on one side)
Are there other joints that hurt?	Referral from cervical spine, rheumatoid arthritis (RA), rheumatoid variants, connective tissue disease	Do you have cervical spine pain or headaches? Have you had a past diagnosis of another arthritis? Do your fingers or knees also hurt? Does your low back hurt (point to sacroiliac joint) or do your heels hurt?	Possible referral to TMJ (check for forward head position) More common with inflammatory arthritides Possible RA Reiter's syndrome, ankylosing spondylitis
Are there current signs of local or systemic infection?	Acute otitis media, measles, mumps, or mononucleosis	Do you have associated ear pain? Do you have sore throat and fatigue? Do you have swelling of the outer cheeks?	Ear infection Possible mononucleosis Mumps

Questioning the individual regarding associated neck pain, postural habits with regard to work and sleep, and any previous neck injuries may help establish a more myofascial or referred cause in those patients without specific complaints of clicking, popping, locking, or pain with chewing.

## Examination

Examination of the TMJ focuses on two main bodies of information: (1) mandibular “gait” analysis with auscultation, and (2) palpation combined with provocative maneuvers including compressive, stretch, and contractile challenge. Secondary evaluation focuses on possible involvement of dental and cervical spine contributions.

The degree of opening is measured in two ways. One is measurement with a ruler (in millimeters). The other approach is to use the patient’s own knuckles as a patient-specific (accounts for patient size) approach. The general rule of thumb is that if the patient can open two or two and a half knuckles’ width, range of motion is considered normal. Less than two knuckles suggests hypomobility; an opening of three or more knuckles suggests hypermobility. It must be remembered that a hypermobile joint may be the result of posterior ligament stretching over a prolonged period of time.<sup>12</sup>

Mandibular gait analysis attempts to document visual range of motion on a cross-hair diagram. Measurement is made with a transparent straight-edge ruler in millimeters. With the horizontal line as an x-axis, laterotrusion (lateral movement to the left and right) from a starting position of neutral with the mouth closed may be documented. The vertical or y-axis line is used to document both maximum opening distance and deviation upon opening. An X placed next to the vertical line indicates a point at which clicking, crepitus, or pain occurs. Small notes indicating whether the clicking is on opening or variable should be added. The vertical line above the intersection point on the diagram represents the z-axis and is used to document the degree of protrusion of the jaw.

Muscle/tendon involvement is determined through the traditional approaches of palpation and contraction. There are distinct areas of tenderness that may correlate with involved structures. The masseter muscle may house several tender areas. The tendinous area is palpated under

the zygomatic arch. Posterior to this are the deep vertical fibers of the masseter. The belly of the masseter is palpated just above the angle of the jaw. Cautious palpation should be used over the posterolateral aspect of the masseter because of the overlying parotid gland. Temporalis trigger points are not uncommon and often are found in a halo array above the ear in the belly of the muscle.

General testing of jaw opening and closing may give clues to muscle involvement due to an increased pain response. Resisting the patient's attempt at opening may cause pain when the inferior heads of the pterygoid muscles are involved. Resisted closing is accomplished by using a padded gauze contact over the incisors. Pain production implicates either the temporalis or masseter muscle.

Palpation of the TMJ should be performed both anterior and posterior to the tragus. Anterior to the tragus, a small depression is formed with jaw opening. Using a finger to palpate this depression, the examiner asks the patient to open and close the mouth. What may be appreciated is whether there is too much or too little condyle translation. Tenderness in the pretragus depression is an indicator of inflammation. Guided by the external auditory meatus to gain access to the posterior aspect of the TMJ, the examiner inserts a gloved fifth finger with the fingernail facing posteriorly. The patient is then asked to open and close slowly. The examiner may appreciate clicking or popping. If clicking or popping is felt, the examiner focuses on the involved joint and asks the patient to repeat opening until a pop or click is appreciated. Before closing, a tongue blade is placed between the teeth. The opening and closing sequence is repeated to determine whether the clicking or popping can be eliminated. If so, the disc has been recaptured, suggesting a mechanical cause of anterior disc displacement that may respond to a dental appliance. Tenderness on full closure suggests an inflamed posterior

joint. Tongue blades placed posteriorly may reduce this tenderness.

One study by Kobs et al.<sup>13</sup> indicated that diagnosing anterior disc displacement clinically is not always possible. Special imaging is needed. This conflicts with an earlier study by Usumez et al.<sup>14</sup> In their study, MRI was used as the gold standard. The diagnostic accuracy overall was 83% for determining a normal disc-condyle relationship, 72% for diagnosing anterior disc displacement with reduction, and 81% for diagnosing anterior disc displacement without reduction. They conclude that not all patients with TMD symptoms require MRI.

Stretch testing is used to determine whether capsular irritation is present (**Figure 3-3**). An intraoral contact may be used to distract the mandible down and forward. An increase in pain is suggestive of capsular irritation. Compression testing is used to provoke pain when synovitis is present (**Figure 3-4**). Pressure on the mandible in a superior posterior direction is likely to increase pain when the retrodiscal tissue is inflamed or a synovitis is present.

**Figure 3-3** Stretch testing for capsular irritation.

**Figure 3-4** Compression testing for synovitis.

Postural evaluation is an important component of TMJ evaluation. The most common postural abnormality is a forward head position with a compensatory extension of the head to correct for visual requirements. Although the initial flexion component of the forward head position causes the mandible to translate down and forward, the compensatory extension forces the mandible posteriorly, potentially irritating the retrodiscal tissue.

Radiographic evaluation of TMJ disorders may be valuable when TMJ tomograms are employed. Standard radiography of the joint rarely provides any additional information. However, two studies indicate that the addition of tomogram findings had a significant effect on clinical decision making. The most common findings that influenced either diagnosis or treatment decisions were unanticipated osseous changes and unexpected condylar position.<sup>15, 16</sup>

## Management

Several recent publications have demonstrated that some TMJ complaints can be successfully managed through a myofascial approach. One randomized study<sup>17</sup> evaluated in a private-practice setting the value of intraoral myofascial

therapy or myofascial therapy plus exercise and advice for patients with TMJ pain. This research study utilized a standardized approach that included intraoral therapy to the pterygoids, temporalis, and a technique called the sphenopalatine ganglion technique. Home exercises were also standardized and added to the management of half of the patients. The results indicate that intraoral myofascial therapy or intraoral myofascial therapy plus exercise and advice are superior to a control wait-and-see group. At a one-year follow-up, the groups with combined therapy of myofascial therapy plus exercise/advice had more success. Specific protocols are illustrated in the full-text article.

Osteopathic manual therapy was compared to standard conventional care of TMJ problems in a small randomized controlled trial.<sup>18</sup> Although patients in both groups improved, the group receiving osteopathic manual therapy required significantly less medication (nonsteroidal medication and muscle relaxants).

In a small randomized control trial,<sup>19</sup> researchers concluded that myofascial therapy to the muscles of mastication combined with the use of an occlusal splint led to an increase in mandibular ROM similar to a comparison asymptomatic group of patients.

One of the key distinctions in the determination of the appropriateness of TMJ adjustment (manipulation) is whether the joint is inflamed or whether there are adhesions. Compressive adjustments to an inflamed joint may provoke more pain. Adhesions are likely when the patient has opening clicks. The adjustment suggested by Curl and Saghafi<sup>20</sup> is to have the patient open to the point of the click. At this point the examiner loads the TMJ with a superior/anterior compression. A quick, small-amplitude thrust is then delivered parallel to the slope of the articular eminence. When the patient has an acute closed lock (not able to open fully, however, no joint clicking or popping) a distraction or gapping maneuver is used. The force is

applied 90° to the slope of the articular eminence in an inferior posterior direction.

Splints are one form of conservative treatment with TMJ disorders. Splints should be considered as adjunctive therapy for TMJ disorders, given the observation that they are often no better than placebo.<sup>21</sup> There is a vast array of simple and complex splint products. In general, they are divided into hard and soft splints. The two types of hard splints are full occlusion or pivotal. Hard, full-occlusion splints are used for repositioning or stabilization. Repositioning splints attempt to alter the condylar position whereas stabilization splints do not alter dental alignment. Sato et al.<sup>22</sup> demonstrated in a small study group that 42% of patients with nonreducing TMJ disc displacement who opted for no treatment had resolution. Those treated with a stabilization splint had a 55% success rate. Those patients who did not have resolution naturally or respond to stabilization splinting after 19 months benefited most from surgery, with a success rate of 77%. Pivotal splints potentially are harmful and are rarely used.

In another study by Wassell et al.<sup>23</sup> a lower stabilizing splint was compared to a nonoccluding control. At six weeks, both splints provided similar relief. Those who preferred the nonoccluding (and switched over) were generally older and had more clicking in their TMJs. In total, 80% of the TMD patients were managed successfully using splinting.

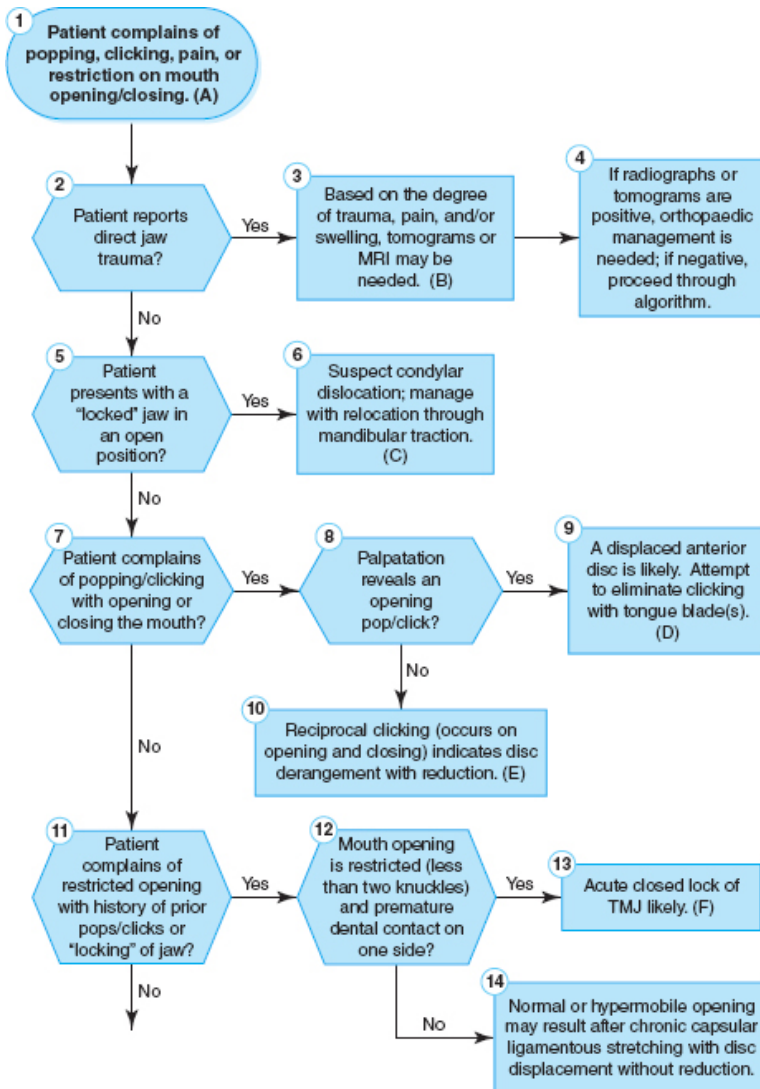

Soft splints are used for protection and therefore are commonly used with a patient who grinds the teeth. The soft splints are similar to mouth guards made out of a latex type material. It appears that the use of a soft splint may be a helpful initial approach to patients with myofascial involvement of the temporalis or masseter muscle.<sup>24, 25</sup> The soft splint does not seem to cause occlusal changes. The most popular daytime soft splint is the Aqualizer. It is inexpensive and easy to use.

Surgery is often offered as an alternative for patients with chronic TMJ disc derangement. Although there are numerous approaches, three specific surgical treatments were compared to nonsurgical treatment with regard to pain reduction and long-term effects.<sup>21</sup> These surgical techniques included discoplasty, discectomy without replacement, and discectomy with replacement of the disc with a Teflon implant. The long-term success rate was between 52% and 71%; however, there was a very high incidence of osteoarthritis development (93% to 100% in the discectomy groups).

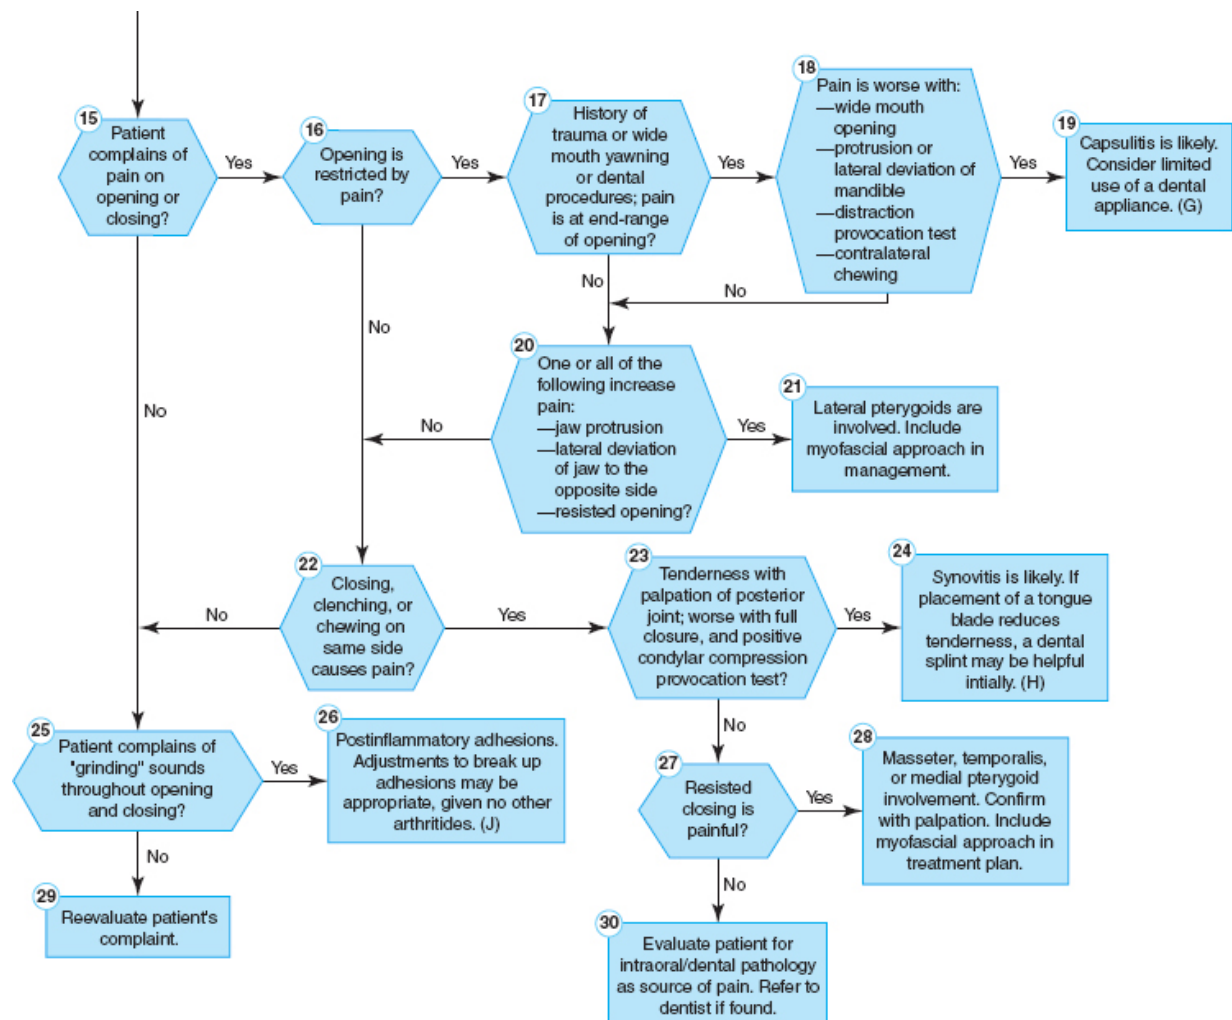

## Algorithm

An algorithm for evaluation of TMJ complaints is presented in **Figure 3-5**.

#### Annotations

- A. Always evaluate the cervical spine and head posture with regard to TMJ complaints. Forward head position or cervical dysfunction may affect TMJ function or cause referred pain.
- B. Plain film radiographs are virtually useless, except perhaps for fracture. Tomograms have limited use. 3-D volume acquisition techniques with MRI are the most sensitive. Coronal images may be necessary if the integrity of the capsule or ligaments is believed compromised.
- C. Open lock usually is the result of trauma or hypermobility of the TMJ. (See text for maneuver.)
- D. Anterior disc displacement requires the condyle to snap past the posterior part of the disc to the intermediate area, causing a click. If a tongue blade eliminates clicking, the disc is recaptured. Consider use of dental appliance or specific adjustive maneuver (i.e., superior/anterior load and thrust).
- E. Disc displacement with reduction causes a click also on closing as the condyle snaps back to the posterior aspect of the disc.
- F. Acute closed lock indicates that the condyle cannot pass over the posterior aspect of the disc to reach the intermediate area. A distractive or gapping maneuver may be used.
- G. Capsulitis due to trauma associated with marked swelling may indicate an underlying fracture.
- H. Synovitis may be traumatic or the result of posterior displacement of the condyle due to anterior disc displacement, loss of vertical height of teeth, or a hypertonic temporalis muscle.
- I. Tendinitis and trigger points may be found by increased tenderness in the belly and tendons of the masseter and temporalis.
- J. Arthritides that should be considered are rheumatoid arthritis, psoriatic, Reiter's syndrome, ankylosing spondylitis, lupus, Lyme disease, and connective tissue disorders.

**Figure 3-5** Evaluation of Temporomandibular Joint Complaints—Algorithm

## Selected TMJ Disorders

### Capsulitis

#### Classic Presentation

The patient complains of pain or tenderness at the TMJ, especially with protrusion or lateral movement, chewing on the opposite side, or opening the mouth widely. There may be a history of trauma; however, most often there is not.

#### Cause

Overstretching of the capsule may be due to numerous causes, including wide yawning or dental procedures requiring prolonged wide opening. Microtrauma from poor chewing habits or occlusal problems may stretch and irritate the capsule.

#### Examination

Movements or positions that stretch the capsule often will increase pain. A condylar stretch test (pushing the mandible forward with the mouth open) may increase the pain ([Figure 3-3](#)), as will lateral deviation of the jaw to the opposite side, and wide mouth opening. Having the patient chew on the opposite side may also increase the discomfort.

#### Management

Avoidance of provoking maneuvers coupled with attention to proper dentition and re-education of jaw opening and chewing usually will resolve the problem. Ice and rest are used in the early stages.

### Synovitis

#### Classic Presentation

The patient complains of TMJ pain that is worse with full closure on the ipsilateral side.

## Cause

Either acute direct trauma or chronic malposition may cause synovitis of the posterior TMJ. Common causes of posterior displacement of the condyle are loss of vertical height of the teeth, anterior disc displacement, and a hypertonic temporalis muscle.

## Examination

Condylar compression ([Figure 3-4](#)) by the examiner will often increase pain on the side of involvement. There may be lateral deviation to the opposite side with the mandible in the rest position. While palpating the posterior joint through the external auditory meatus, tenderness is increased on full closure. Using tongue blades, a distraction force is introduced. As the patient bites down, tenderness may decrease with one or two tongue blades placed between the teeth. Another approach is to have the patient open until a click or pop is heard, indicating an anteriorly displaced disc. A tongue blade is placed between the teeth and the patient is asked to open and close. Additional tongue blades may be added in an attempt to eliminate the click, indicating recapture of the disc.

## Management

If the tongue blade addition eliminates or decreases the pain or clicking, a stabilization appliance may be useful.<sup>26</sup> During the acute stage of synovitis, the use of mild analgesics, ice, and a soft diet with relaxation of the masticatory muscles will be helpful. If adhesions have formed as a result of chronic synovitis, adjustive maneuvers along the slope of the articular eminence may free up movement and decrease pain.

### Disc Derangement with Reduction

## Classic Presentation

The patient complains of popping or clicking while opening and closing the mouth.

# Cause

When the articular disc is displaced anteriorly or anteromedially, the condylar head rests posterior to the disc. An opening click occurs as the condyle translates into its normal central disc location. The closing click occurs because of weakness of the posterior ligament. The disc is not pulled backward, and the condyle slips into a posterior position behind the disc.

## Evaluation

Palpation in front of or inside the ear will detect the opening and closing clicks. An attempt to reduce the click can be made through the use of tongue blades. After the opening click occurs, a tongue blade or blades can be placed between the posterior teeth on the same side. If the patient closes down on the blades and no click or pop is heard or felt, reduction has occurred, indicating an underlying disc derangement.

# Management

A dental appliance may help prevent displacement of the condylar head posteriorly; however, this is a temporary solution. When adhesions are present, Saghafi and Curl<sup>27</sup> suggest using a quick, short-amplitude thrust maneuver. The patient opens until the click is felt. To stabilize the disc and condyle together, the doctor applies an axial compression through the angle of the jaw in a superior and anterior direction. Short-impulse thrusts can then be delivered along the slope of the articular eminence in a posterior superior direction.

## Closed Lock

# Classic Presentation

The patient complains of difficulty opening the mouth fully. There is pain and tenderness at the TMJ without current popping, although there may have been a history of prior popping on opening and/or closing. There may be an additional complaint of suboccipital pain, dysphagia, or tinnitus.

# Cause

An anteriorly displaced (sometimes referred to as dislocated) articular disc is usually the cause. The condyle cannot translate to the intermediate portion of the disc. This may be due to hypermobility at the joint or trauma such as

whiplash injury.<sup>28</sup> Often there is premature dental contact on the same side as disc displacement.

## **Examination**

There often is tenderness at the TMJ and the patient is unable to open fully. He or she is unable to place two knuckles in between the front teeth. There is no popping on opening. The end-feel usually is soft. Overpressure is uncomfortable but usually not very painful.

## **Management**

Manipulation is the treatment of choice. Several maneuvers are described in the literature. Curl<sup>29</sup> summarizes these gapping maneuvers into three main groups: (1) downward traction with a thrust 90° to the slope of the articular eminence, (2) forward traction of the condyle under the disc, and (3) gapping with active movement by the patient. Sedative or relaxation approaches often will assist these maneuvers. Contraindications include processes that would weaken the structure of the mandible or teeth, such as tumor, infection, periodontal disease, osteoporosis, fracture, or extreme muscle splinting.

### **Acute Open Lock**

## **Classic Presentation**

The patient presents with an acute locking of the jaw when it is fully open. The patient is extremely apprehensive. Pain is often due to the reactive spasm of the closing muscle. There may be history of trauma or previous occurrences when the mouth was opened too far.

## **Cause**

Either trauma or hypermobility allows the condyle to be dislocated anterior to the articular eminence.

## **Examination**

The patient presentation is pathognomonic: an apprehensive patient unable to close his or her mouth. If direct trauma has occurred, radiographs for

fracture may be necessary.

## **Management**

Bilateral manipulation with a downward traction is necessary to relocate the condyle.

## CHAPTER 4

# Thoracic Spine Complaints

## Context

Interest in the thoracic spine is often overshadowed by the more dramatic presentations of low back and cervical spine pain. Radicular pain into the arms and legs and its consequent functional limitations call more attention to the respective cervical and lumbar spine sources. Disc herniation is less common, as is nerve root compression in the thoracic spine, partly because of the restricted movement and stability provided by the direct attachment to the rib cage. Thoracic pain is probably as common as cervical or lumbar pain; however, it is less dramatic, due more often to the chronic consequences of postural imbalances. The pain is often of a low-grade nature and therefore less worrisome to the patient. When acute pain does occur, it is usually the result of acute muscle spasm or compression fracture. Compression fractures are usually the result of axial loading from a fall on the buttocks or, in osteoporotic individuals, minor or less memorable trauma.

Often there may be an age-related occurrence of thoracic pain or deformity. In children and adolescents scoliosis and hyperkyphosis are concerns (scoliosis is discussed in [Chapter 5](#)). The differential approach to hyperkyphosis should attempt to distinguish between simply poor posture habits and growth plate abnormalities as seen with Scheuermann's disease. In adults, the effects of chronic

postural strain from seated work environments are predominant. Also, it appears that the long-term consequences of idiopathic scoliosis are more likely to result in pain in middle-aged adults. With senior patients, the primary concern is compression fracture, often the result of osteoporosis (osteoporosis is discussed in [Chapter 30](#)).

Although the cervical and lumbar regions require an evaluation of the limb plexuses, the thoracic spine is not involved directly (except for T1-T2). The thoracic spinal cord, however, is the home of the nerve cell bodies of the sympathetic nervous system. This relationship has not gone unnoticed by the chiropractic profession. Anecdotal stories regarding improvement of “visceral” conditions abound. The questions that still need research answers are: Do these outcomes represent the normal course of these disorders? Is the pain “referred” pain (somatovisceral) and to what degree can sympathetic innervation to organs be affected by vertebral subluxation? A review article by Nansel and Szlazak<sup>1</sup> discusses some of these issues. From this review it appears that there are many local regulating factors that can compensate for more proximal sympathetic dysfunction. It would appear that a more reflex or referred phenomenon may be the cause of those conditions that respond to manipulation. More research is needed to compare chiropractic management of commonly reported responsive conditions such as asthma, peptic ulcer, reflux esophagitis, gallbladder disease, and various gastrointestinal and gynecologic disorders.

## **General Strategy**

## **History**

- Determine whether the patient's complaint is one of pain, stiffness, midscapular fatigue, deformity, or a combination of complaints.
- Screen the patient for red flags such as a history of cancer, significant trauma, use of corticosteroids, or a history of infection suggestive of tuberculosis.
- Attempt to elicit a description of any inciting event or trauma, no matter how minor, if there is a history of sudden onset.

## Examination

- Observe the patient for deformity: buffalo hump in the upper thoracic area (Cushing's syndrome), acute-angle kyphosis (compression fracture), kyphosis (Scheuermann's disease or postural), scoliosis (many causes; however, acute-angle painful scoliosis suggests osteoid osteoma or other local processes), and scapular winging (scoliosis or nerve damage causing weakness of the serratus anterior or trapezius muscle).
- Observe for skin lesions suggestive of herpes zoster (shingles) or skin cancer.
- Examine for active and passive range of motion and accessory motion.
- Perform a prone extension test on patients with a kyphosis to differentiate between a structural and a functional kyphosis.
- Perform an Adams' test (rib humping [angular rotation] suggests a structural curve) on patients with a scoliosis visible in the standing posture; also, observe the patient in the lying position in neutral and with maximum bending to the side of convexity (improvement indicates a functional component).

- Palpate and percuss the area in patients complaining of local pain.
- Remember that standard radiographs include anterior-to-posterior and lateral views; oblique films are used to evaluate the ribs for fracture and the vertebral bodies for trauma to the ring apophyses.
- Reserve special imaging, including bone scans and tomograms, for evaluation of metastatic lesions and osteoid osteoma or other tumors. Magnetic resonance imaging (MRI) is also helpful with spinal infection, tumor, and the rare disc herniation.

## Management

- Patients with infection, primary tumor or metastasis, unstable fracture, severe or rapidly progressive scoliosis or kyphosis, and complications of corticosteroid use should be referred for medical evaluation and possible management.
- Patients with uncomplicated compression fractures, mild to moderate idiopathic scoliosis that is not rapidly progressing, uncomplicated Scheuermann's disease, facet syndrome, postural syndrome, T4 syndrome, and other mechanical causes should be managed conservatively. If unresponsive to care, further evaluation or referral for comanagement may be indicated.

## Relevant Anatomy

The typical thoracic vertebrae are 2 through 8. They are heart-shaped bodies with shingle-like facets. The first thoracic vertebra is cervical-like, while the lower two thoracic vertebrae are more lumbar-like with a

corresponding change in facet orientation. The typical vertebra has two attachment sites on the body for rib articulation. The costovertebral joint is at the intervertebral disc (IVD) of the typical vertebra, supported by a capsule and intrinsic radiate ligament. Another articulation occurs at the transverse process, with the tubercle of the rib supported by the costotransverse ligament. These ligaments are innervated by both the posterior primary rami and the anterior primary rami, indicating a neurologic priority for proprioceptive input. The superior costotransverse ligaments connect adjacent ribs. The thoracic kyphosis is a primary curve (as is the sacral angle). Thus, a structural kyphosis is created by the shape of the thoracic vertebrae, whereas in the cervical and lumbar regions the lordosis is acquired.

The facets are more shingle-like, overlapping at an angle of about  $60^{\circ}$  from the horizontal in the upper thoracics and up to  $80^{\circ}$  to  $90^{\circ}$  in the lower thoracics.<sup>2</sup> The medial branch of the dorsal rami supplies the joint capsules. The intervertebral discs are quite thin in the thoracic region. Innervation is from the sinuvertebral nerve. Nerve roots exit above the IVD, making nerve root compression from disc herniation less likely.

The muscles of the thoracic region may be divided generally into two types (**Figure 4-1**). The more superficial muscles such as the trapezius, rhomboids, levator scapulae, and latissimus dorsi are primarily extremity muscles assisting in direct movement of the arm or assisting through positioning of the scapulae. The deeper muscles act to extend the spine; they rotate segmentally and, to a lesser degree, flex laterally. Although the middle trapezius and rhomboids act directly on the scapulae, weakness allows forward displacement of the scapulae with a tendency toward an increased kyphosis.

There are some interesting neural connections between the thoracic spine and other regions:<sup>3</sup>

- Portions of the T1-T3(T4) nerve roots enter the brachial plexus, supplying the axillae and medial arm and forearm (may be clinically important with thoracic outlet syndrome [TOS]-like symptoms).
- The T12 nerve root enters the lumbar plexus as the iliohypogastric nerve, with lateral branches innervating the upper lateral thigh and an anterior branch innervating the pubic region.

**Figure 4-1** Posterior view of superficial muscles of the back and those connecting the axial skeleton to the shoulder girdle.

- The lateral branch of the posterior primary rami of T2 descends paravertebrally to the level of T6 and then ascends to the acromion (considered with midthoracic or shoulder pain).

- The lateral branch of the posterior primary rami of T12 descends to the posterolateral iliac crest and lateral buttock (considered with “lumbar” or buttock pain).

The first branches of the posterior rami are descending branches. The medial branch of the posterior primary rami has recently been demonstrated to have an articular and nonarticular division with the articular supplying the facet joint and the nonarticular entering the connective tissue around the levator costalis with no direct connection to the facet joint.<sup>4</sup> The descending branches pass through a narrow space posterior to the superior costotransverse ligament. The lateral branch passes between the superior costotransverse ligament and intertransverse ligament. It has been suggested that entrapment at these sites is a possible cause of thoracic spine pain.

The thoracic spinal cord houses the nerve cell bodies for the sympathetic nervous system. Access to other areas of the body is via the sympathetic chain. These ganglia are in close proximity to the heads of the ribs. The sinuvertebral nerve, which supplies the posterior longitudinal ligaments, epidural blood vessels, periosteum of the vertebra, and outer annulus, consists of a somatic branch and an autonomic branch. The autonomic branch comes from the gray rami communicantes or from the sympathetic ganglia near the nerve root and as the sinuvertebral nerve re-enters the intervertebral foramina. Branches of the sinuvertebral nerve may travel four or five segments in the neural canal before synapsing. Interestingly, the sympathetic neurons (for vascular supply) that follow somatic nerves into the arms may originate from as far down as T8.<sup>5</sup> This may account for a condition called the T4 syndrome reported in the literature on manipulation.<sup>6</sup> Although there is still a debate regarding the effect of manipulation on the sympathetic influence on visceral organ function, it is recognized that referred pain from organs is possible. Below

are some specific organ innervations (approximate). The segmental levels specified may be painful when the organ is involved (viscerosomatic pain):

- heart—C8-T5(T8)
- lungs—T3-T5(T10)
- stomach—T5-T8(T9)
- pancreas—T7-T9
- gallbladder, liver, spleen, caecum, and duodenum—T6-T10
- appendix—T9-T11
- kidneys—T9-L2

## Biomechanics

Mobility in the thoracic region is somewhat restricted by the rib cage attachments. The physiologic priority appears to be protection of visceral organs rather than mobility. Only 2° to 6° per segment of sagittal movement is possible, with 60% of this movement being flexion. Lateral flexion is somewhat limited in the upper thoracic region (5° to 6° per segment per side), increasing in the lower thoracic region (8° to 9° per side). Lateral flexion involves a coupled movement pattern with rotation.<sup>7</sup> In the upper thoracic region, lateral bending to one side causes the spinous processes to rotate into the convexity (opposite side; similar to the cervical region), while in the lower thoracic region the spinous processes rotate into the concavity (same side; similar to the lumbar region). Rotation occurs more in the upper thoracic spine (4° to 5° per side) than in the lower (2° per side), total of about 40° per side. Rotation also causes a coupled motion with lateral flexion to the opposite side and an accompanying extension (especially in the lower thoracics). In the upper thoracics, the coupled motion is lateral flexion and sagittal flexion.

During normal respiration, rib cage movement has been described as two patterns. In one description, the lower ribs (7 to 10) move in more of a buckethandle configuration due to costotransverse and costovertebral attachments and axis of motion. What this translates into is that the side-to-side dimension of the chest increases as the ribs become more horizontal (compared to the superior-to-inferior direction in the resting lung seen from a sagittal perspective). Others also describe a caliper movement of the lowest ribs, moving more posterior and lateral on inspiration and anterior and medial during expiration. For the upper ribs (2 to 6) a description of a pump-handle movement has been proposed. During inspiration the anterior aspect of the ribs moves superiorly and anteriorly. However, an in vivo study<sup>8</sup> suggests that rib motion at all levels is similar, meaning that there are components of both analogies of movement during inspiration related to lateral and anterior movement expansion. These movements are due in part to the type of articulation and angle of articulation with the vertebrae and sternum. Inspiration is more of an active process, whereas expiration is usually more passive due to the elastic recoil of the alveoli in the lungs.

## Evaluation

## History

Careful questioning during the history taking (**Table 4-1**) can point to the diagnosis. Some historical red flags include a history of drug or alcohol abuse, use of corticosteroids, diabetes, or direct trauma to the chest or rib cage. In patients older than age 70 years, a compression fracture or metastasis should be suspected. Combined findings of weight loss, a past history of cancer, night pain, or high

fever (especially in a patient older than age 50 years)  
warrant a careful radiographic search for cancer or infection.

## **Trauma**

Trauma to the thoracic area (e.g., a direct blow) should raise the suspicion of a rib fracture. The patient should be evaluated further with compression, percussion, vibration, and radiographs. A fall onto the buttocks with resulting thoracic pain is often due to a compression fracture. If the patient was involved in a car accident, a chance fracture may have occurred over the fulcrum of the seat belt.

## **Posture**

Postural problems are common. There is a natural tendency for individuals who work at desks to accentuate the forward head—forward shoulder posture. Without frequent breaks or exercises to compensate, most individuals acquire a new “normal” posture. Asking the patient with an apparent kyphosis about his or her posture to determine the chronicity is important. It is possible that an adult had the predisposition to Scheuermann’s disease as an adolescent. This will be evident radiographically. For those who work at desks, it is important to determine the setup of the workstation. If the setup allows or encourages a forward head or slumped position, it is important to use this information in long-term planning for avoidance of postural pain. Adolescents often develop a slumped posture either because it is the posture of their friends or because of a lack of self-confidence.

**Table 4-1 History Questions for Thoracic Spine Injury**

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Did you injure yourself (e.g., car accident, lifting, twisting, bending)?	Sprain/strain, fracture, subluxation	Did you have a sudden flexion (With older patient) Did you have pain after coughing, sneezing, stepping off a curb? Did you suffer a blow to the chest?	Compression or chance fracture Compression fracture Rib fracture
Does the pain radiate around to the chest?	Intercostal strain, intercostal neuritis, herpes zoster, diabetes, neurofibroma, degenerative joint disease	Do you have any associated skin lesions? Is the pain increased with stretching (e.g., yawning)? Do you have diabetes?	Herpes zoster Intercostal strain Diabetic neuropathy
Is the pain worse at night? Is it unrelieved with rest?	Osteoid osteoma, cancer, rib fracture	Is aspirin helpful? Is it more difficult to lie on your back?	Dramatic relief suggests osteoid osteoma; if no relief, consider cancer Rib fracture
Is there associated chest or abdominal pain?	Referral or radiation from chest or abdominal disease	Is there associated epigastric pain? Do you have upper right abdominal pain?	Consider peptic ulcer, esophagitis, or pancreatitis Cholecystitis or lithiasis
Do you have chronic pain?	Myofascial pain due to poor posture, ergonomic strain at work, fibromyalgia, or depression	Do you work in a seated, forward-head position? Do you have middle or upper scapular pain? Do you have pain all over your body? On both sides? Do you have difficulty sleeping, loss of enjoyment in any activities? Is the pain associated with globally restricted thoracic spine movement?	Postural syndrome Fibromyalgia Depression Consider ankylosing spondylitis
Are you concerned about an observed deformity?	Postural kyphosis, Scheuermann's disease, compression fracture, scoliosis, scapular winging due to nerve damage	(In a senior) Did you have a sudden onset of a "hunched" appearance or gradual height loss? (In an adolescent) Are you constantly "hunched" forward? Is there curving of back with a high shoulder or bulging ribs?	Compression fracture (osteoporosis; traumatic, or pathologic) Scheuermann's disease or postural syndrome Scoliosis

## Stiffness

Stiffness should be differentiated from a sensation or an objective loss of range of motion (ROM). Many patients who complain of stiffness have normal ROM, indicating that muscles are probably being posturally strained. When a young adult patient complains of difficulty in taking a deep breath or bending forward or to the sides, ankylosing spondylitis is suggested.

# Deformity

On occasion an older patient or the parent of a child will notice a humping in the thoracic region. In the older patient, a compression fracture is likely and should be evaluated radiographically. In the child, deformity may represent simply a “bad” posture habit, Scheuermann’s disease, scoliosis, or the rare Sprengel’s deformity. The parent also may notice that the child with scoliosis has an unequal arm length evident by unequal sleeve length on shirts or blouses.

## Examination

From a postural standpoint, there are several important clues for which to look. They include scapular winging, buffalo hump, acute-angle kyphosis, generalized hyperkyphosis, and scoliosis.

## Scapular Winging

Scapular winging may be due to a scoliosis (convex side) or weakness of either the middle trapezius or serratus anterior (the muscle weakness is often secondary to nerve damage). Asking the patient to perform a pushup against the wall often will accentuate the winging. Winging that allows straight lateral drift of the scapula is due to weakness of the middle trapezius; flaring of the inferior border outward and of the upper border inward is indicative of serratus anterior weakness with probable damage to the long thoracic nerve. An unusually high scapula or small scapula may represent the uncommon Sprengel’s deformity in which scapular muscles are underdeveloped or replaced by fibrous tissue.<sup>9</sup>

# Buffalo Hump

A buffalo hump is the buildup of fat tissue in a patient with Cushing's disease or an individual on long-term corticosteroids; it should not be confused with a large lipoma or a Dowager's hump (compression fracture) or gibbous deformity (compression fracture or tuberculosis of the spine).

---

## Acute-Angle Kyphosis

Acute-angle kyphosis is often seen in older women at the site of a compression fracture (called Dowager's hump or gibbous deformity); in younger athletes, an acute-angle kyphosis at the thoracolumbar region indicates atypical Scheuermann's disease.

## Generalized Hyperkyphosis

A hyperkyphosis is common in adolescents for two major reasons: (1) poor posture, and (2) Scheuermann's disease. To differentiate between the functional (postural) type and the structural type, the patient is asked to lie prone and then to extend the trunk with the arms behind the back, lifting the chest off the table (**Figure 4-2**). If the kyphosis persists it is structural. A functional examination should include an evaluation of both the lumbar and cervical curves in an effort to determine their contribution or compensation for the thoracic kyphosis. The typical pattern is weak midscapular muscles, tight pectorals, weak deep neck flexors, tight deep neck extensors, weak abdominals, and tight lumbar paraspinals.

**Figure 4-2** Prone extension is used to differentiate between a structural and a functional hyperkyphosis. If the kyphosis improves with extension, it is primarily functional; no improvement indicates a structural cause (e.g., Scheuermann's disease).

## Scoliosis

The lateral curvature of a scoliosis is often visible in the standing patient; if present, ask the patient to flex forward at the waist at three levels ( $90^\circ$  for the lumbar region,  $60^\circ$  for the midthoracic, and  $30^\circ$  to  $45^\circ$  for the upper thoracic), keeping the head down and the arms hanging loosely with no trunk rotation voluntarily acquired. Prominence of one side compared with the other is indicative of a structural curve (**Figure 4-3**). Measurement of the degree of trunk inclination may be performed with an inclinometer such as a scoliometer. A trunk angle greater than  $7^\circ$  is an indication of a structural curve of at least  $20^\circ$ .<sup>10</sup> Another test for scoliosis is to observe how much correction occurs when the patient lies prone. This can be evaluated further by asking the patient to bend maximally to the convex side of the curve. Some improvement will occur if there is a functional component to the curve.

The neurologic examination for the thoracic spine is brief, unless there is a suspicion of nerve root involvement. This rare occurrence will cause the patient to complain of pain that radiates to the front of the body, and there may be accompanying weakness of the abdominal muscles. It would

be unusual for an upper motor neuron lesion to cause only isolated thoracic spine findings.

**Figure 4-3** The Adams' test involves forward bending in an attempt to gain a skyline view of different areas of the back. This position of approximately 60° forward flexion demonstrates angular deformity (rib humping) in the midthoracic spine on the left.

Because of the possibility of referral or radiation pain from a chest or abdominal source, it would be prudent to perform some chest and abdominal screening tests with patients complaining of both anterior and posterior pain. With costovertebral pain in the lower thoracic region, a kidney punch test might elicit a response with an inflammatory process such as pyelonephritis. If the pain is more in the middle thoracic or scapular areas, Murphy's sign for gallbladder disease may be elicited (see [Chapter 31](#)).

Palpation of the thoracic spine may be helpful in finding discrete areas of tenderness. Motion palpation is commonly used. Unfortunately, one small study indicated good intraexaminer reliability but poor interexaminer reliability.<sup>9</sup> It is important to challenge the midthoracic area in patients with diffuse arm complaints. Reproduction of arm complaints with pressure on the spinous or transverse processes suggests T4 syndrome.

Basic radiographic evaluation of the thoracic spine requires an anteroposterior (AP) and lateral view. Additional views are required in the following scenarios:

- If rib fracture is suspected, include AP and oblique views of the involved ribs.
- If associated chest pathology is suspected, include a posteroanterior and lateral view of the chest.
- If scoliosis is suspected, begin with a full spine (14 × 36) evaluation to determine involvement of the other spinal regions and, in younger patients, to determine the Risser sign. It has been recommended to take the film posterior-to-anterior to avoid increased radiation to the breasts and genitals; however, it is suggested that the Risser sign is not as accurate on this view and, given the technology available with regard to collimation, filtering, film speed, and so on, the concern is not as strong as it once was. If a scoliosis is present, recumbent films with maximum bending into the curve convexity are important to determine the degree of functional versus structural curve (see [Chapter 5](#)). Measurements include the Cobb angle for degree of angulation, Nash-Mose measurement for degree of rotation, and the Risser sign for progression of the iliac crest apophysis (indicator of bone maturity). For the rare infantile idiopathic curve, the Mehta rib angle measurement may determine those likely to progress.
- If a compression fracture is evident, determination of stability is important. Collapse of the anterior margin to less than half the height of the posterior margin or more than 20° of wedging may indicate an unstable fracture. Loss of posterior vertebral height should raise the suspicion of a pathologic fracture often due to metastasis. Other clues may be a “missing pedicle” sign, indicating an osteolytic process such as breast cancer metastasis.

Special studies are required when tumor, unstable fracture, or osteoporosis is seen or suspected. Bone scans are helpful

in determining metastatic sites in the spine and the location of osteoid osteomas. Dual x-ray absorptiometry is valuable for evaluating generalized bone mass status. MRI is valuable when nerve root compression, infection, or tumor is suspected and the degree of involvement or cause is uncertain.

## Management

- Patients with infection, primary tumor or metastasis, unstable fracture, severe or rapidly progressive scoliosis or kyphosis, and complications due to corticosteroid use should be referred for medical evaluation and possible management or comanagement.
- Patients with uncomplicated compression fractures, mild to moderate idiopathic scoliosis that is not rapidly progressing, uncomplicated Scheuermann's disease, facet syndrome, postural syndrome, T4 syndrome, and other mechanical causes should be managed conservatively. If unresponsive to care, further evaluation or referral for comanagement may be indicated.
- Patients with uncomplicated compression fractures will probably have pain for one to two months during the healing phase. Bracing or restraint in the thoracic region is not recommended because of its effect on normal breathing. The same is true for patients with cracked ribs or uncomplicated rib fractures (see [Chapter 38](#), Chest Pain).

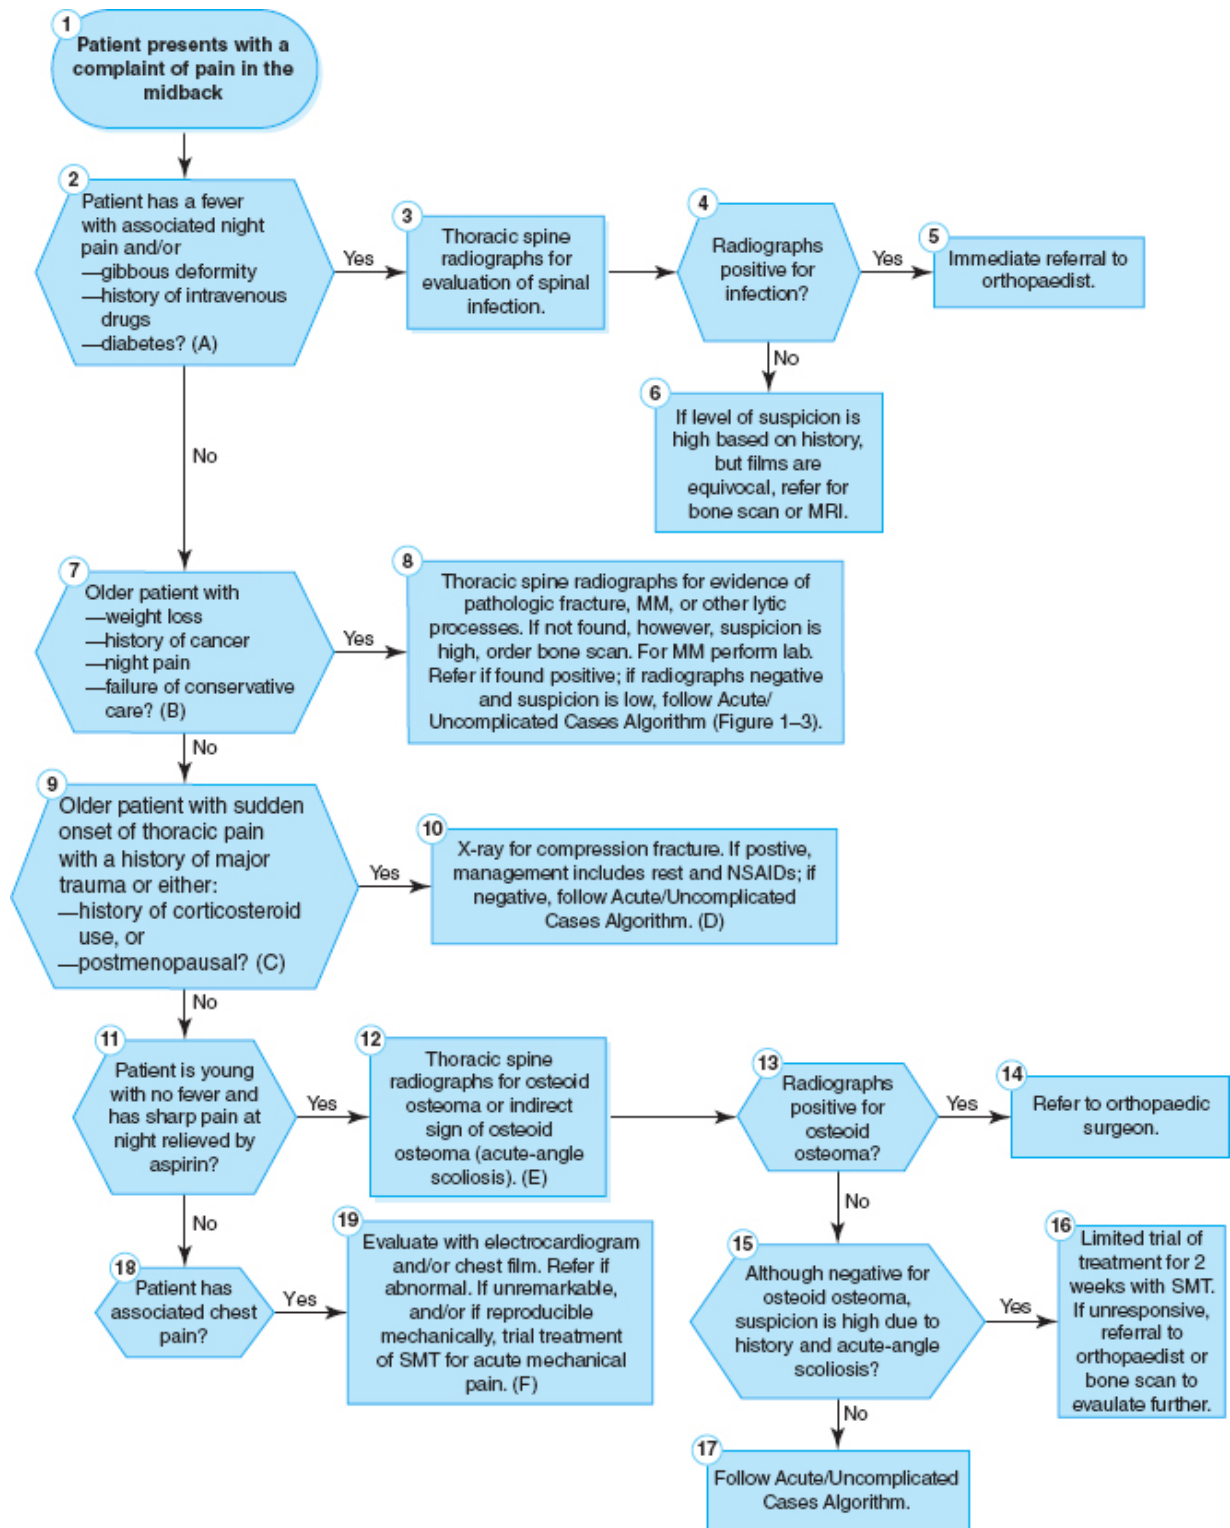

The recommendation of the Mercy Center Guidelines<sup>12</sup> is that a two-week trial of manipulative therapy at a frequency of three to five times per week (depending on severity) is appropriate for most uncomplicated mechanical problems. If

unresponsive, a second two-week trial is suggested. If the patient is responsive to either treatment trial, a reduction in frequency of care over the following several weeks is appropriate. Maintenance care may be necessary in patients with chronic problems. If the patient is still not responding after a second two-week trial, laboratory testing, special imaging, or referral for medical evaluation should be given.

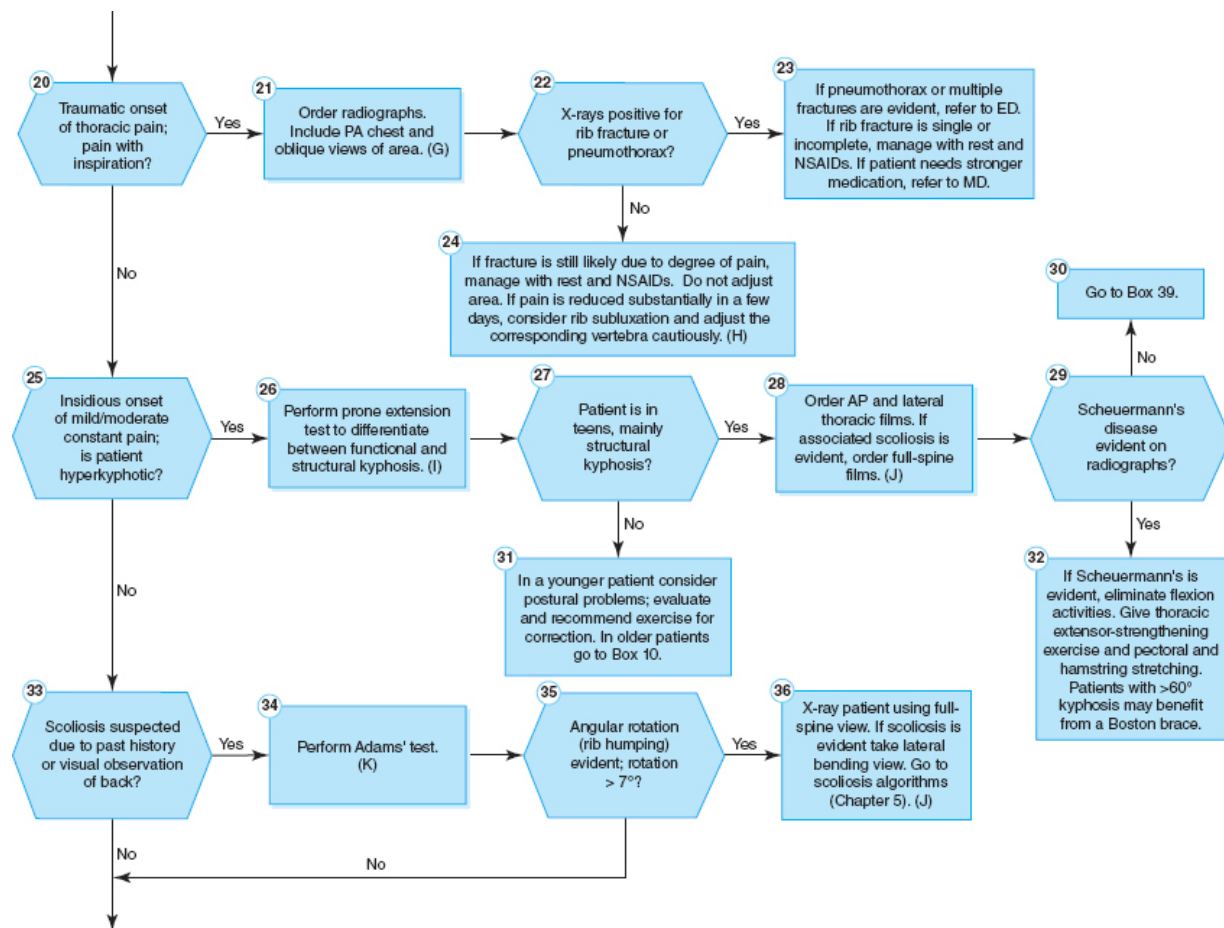

For most patients with chronic posturally induced pain, stretches, exercises, and modification of work or recreational activity patterns comprise the long-term approach to prevention. Stretching of tight pectoral muscles may be performed by leaning into a corner or doorway with the arm or arms elevated to shoulder level or above. Adding a slight contraction for a few seconds followed by relaxation may allow access to more ROM. Strengthening of the midscapular muscles can be performed prone or with the back against a corner. The emphasis is to keep the arms at shoulder level and elbows bent 90° and to maintain this position while the scapulae are squeezed together (no arm movement; only scapular movement). Patients with a kyphosis should also focus on strengthening of the lower trapezius by performing prone “superman” exercises. With the arms stretched out overhead and the hips stabilized, the patient attempts to lift the chest off the ground or table, holds for a few seconds, and slowly lowers. For generalized posture, stretching of the deep neck extensors, lumbar erector spinae, iliopsoas, and hamstrings should be coupled with strengthening of the deep neck flexors, midscapular muscles, abdominals, and gluteals.

## Algorithm

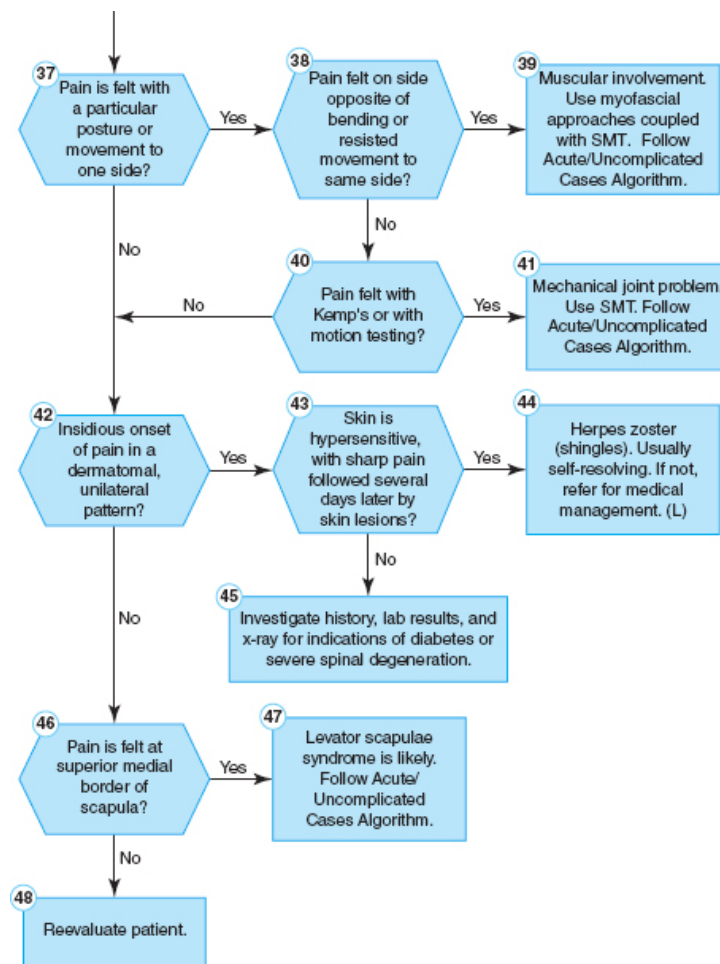

An algorithm for the management of thoracic spine pain is presented in **Figure 4-4**.

#### Annotations

- A. Osteomyelitis is most common in diabetics and intravenous drug abusers. Fever may be present and tenderness to spinous percussion or deep pain.
- B. Cancer or metastasis is suspected when there is a history of cancer, especially in patients over 50 who have experienced undesired weight loss or who have not responded to conservative care.
- C. Osteoporosis-related compression fractures are most common in postmenopausal women or those on long-term steroid use without a history of significant trauma.
- D. Fractures decreasing the anterior vertebral body height to <50% of posterior body height or causing more than a 20° angulation should be considered unstable and referred to an orthopaedist. Compression fractures are managed conservatively with rest and NSAIDs. Bracing/supports are not recommended for the thoracic area because of inhibition of normal breathing.
- E. Osteoid osteoma may cause a small acute-angle scoliosis due to local muscle spasm.
- F. Chest pain that is noncardiac is often sharp, localized, and reproduced by stretch, contraction or palpation.
- G. Rib fracture management is generally rest and NSAIDs. Rib belts are not used because of inhibition of normal breathing.
- H. Differentiating between rib fractures (cracked ribs) and subluxations of ribs is difficult; however, rib fractures do not feel substantially better in a few days.
- I. A test to differentiate between structural and functional kyphosis is performed by having the patient extend the trunk from a prone position. If the kyphosis improves, the main component is functional.
- J. Scoliosis x-rays are used to determine bone age using the Risser sign and the degree of curve using Cobb's angle. A lateral bending view with the patient bending as far into the convexity is used to compare Cobb's angles determining the functional amount of the curve.
- K. The Adams' test coupled with scoliometer measurement is able to detect curves >20 when the angular rotation is >7°.
- L. Herpes zoster usually follows a single nerve root in a dermatomal pattern; however, the appearance is patchy, not linear. Lysine and stress management may be helpful. Medical treatment may involve acyclovir.

**Figure 4-4** Thoracic Spine Pain—Algorithm

# Selected Disorders of the Thoracic Spine\*

## Scheuermann's Disease

### Classic Presentation

The patient is a young male or female (age 13 to 17 years) who presents with a complaint of midback pain and fatigue. The patient has an increased kyphosis.

### Cause

The cause of Scheuermann's disease has been debated for years. Scheuermann's disease is not an osteochondrosis. Currently, Scheuermann's is believed to be the result of vertebral growth plate trauma during the adolescent period with interruption or cessation of further growth.<sup>13</sup> It is generally agreed that wedging of greater than 5° in three consecutive vertebrae is the radiographic indicator of Scheuermann's. In addition, end-plate fractures (Schmorl's nodes) and anterior disruption (limbus bones) are evidence of discal extrusions. The midthoracic region is affected 75% of the time. The thoracolumbar region is affected 25% of the time. The incidence is as high as 8%.<sup>14</sup> There is a small male predominance and an increased incidence among family members. A unique type found in female gymnasts and adolescents performing heavy weight lifting is called atypical Scheuermann's (type II) disease or "apprentice kyphosis." There is an acute kyphotic angulation at one or two vertebral bodies in the area of T10-L4.<sup>15</sup> This represents trauma to the vertebral ring apophysis.

### Evaluation

An examination for posture often will reveal an exaggeration of the cervical and lumbar lordosis with a hyperkyphotic thoracic region. If the patient is asked to lie prone and extend the chest off the table, persistence of the kyphosis will indicate a structural cause, most often Scheuermann's disease in a younger individual. If the kyphosis improves, a functional cause (poor habitual posture) is probably the cause ([Figure 4-2](#)). The diagnosis is primarily

radiographic with classic findings of slight anterior vertebral body wedging (at least 5° per segment), Schmorl's nodes, and decreased disc height, all occurring over at least three contiguous vertebrae.<sup>16</sup> An alternate diagnostic criterion is a thoracic kyphosis greater than 45°. Additional findings include mild scoliosis and limbus bones (anterior marginal Schmorl's node representing ossification in the avulsed growth plate). The lordosis is measured using a modified Cobb angle taken off a lateral radiograph. The classic finding with atypical Scheuermann's is an anterior Schmorl's node occurring at only one or two levels at the thoracolumbar region. The anterior wedging with atypical Scheuermann's can be as much as 40% to 50%.

## Management

Complications such as disc herniation or nerve root compression are rare. General management for uncomplicated Scheuermann's and kyphotic curves less than 60° should include postural exercises and hamstring stretching. Bracing or taping for proprioceptive awareness may be helpful. Stretching anterior muscles, strengthening interscapular muscles, spinal extension exercises, and attention to compensations in the cervical and lumbar curves are the primary focus. A Milwaukee brace is recommended for curves over 60°. <sup>17</sup> The most important period is during the growth spurt in males. For curves greater than 80°, surgery may be necessary. Atypical Scheuermann's requires restriction from all gymnastics participation and extension bracing for several months. With atypical Scheuermann's, radiographs should be retaken in three to four months to determine healing. The indication for surgery is a progressive kyphosis greater than 70° or for those who have had progression with bracing and finally intractable back pain. One common result from surgical correction is the development of a junctional kyphosis (a kyphosis adjacent to the arthrodesis). There is little literature evaluating the effectiveness of new surgical implants and the degree of junctional kyphosis. A recent study<sup>18</sup> indicates that:

- Correction of kyphosis is possible through either a combined anteroposterior or posterior approach. However, there is a higher rate of complication with the combined procedure.
- Proximal junctional kyphosis occurred in 32.1% of patients related to arthrodesis caudal to the proximal end vertebra. This is influenced by pelvic incidence (see spondylolisthesis).
- Distal junctional kyphosis occurs in 5.1% of patients associated with arthrodesis cephalad to the sagittal stable vertebra.

## Compression Fracture

## Classic Presentation

In older patients, the onset of sudden thoracic (or lumbar) pain occurs after a minor event such as sneezing or stepping off a curb. In younger patients, the history will usually involve a fall on the buttocks and/or a hyperflexion injury.

### **Cause**

Compression fractures may be due to weakness in the bone, usually secondary to osteoporosis or cancer. Sufficient trauma may cause a fracture in normal bone. Approximately 35% of compression fractures in women over age 40 years are due to early menopause, 30% are due to long-term corticosteroid use, 8% are due to hyperthyroidism, and less than 2% are due to malignancy.<sup>19</sup>

## **Evaluation**

A history of long-term corticosteroid use or age greater than 70 years is suggestive of compression fracture in patients with thoracic or lumbar complaints.<sup>20</sup> Pathologic fracture should be considered in patients older than 50 years with a past history of cancer or unexplained weight loss. There is often a sharp kyphotic angle at the area of fracture. The patient will have pain on percussion and deep pressure over the involved segment. The diagnosis is essentially radiographic. The lateral view is particularly helpful in determining important differentiating factors. An anterior step defect is most common, due to the increased stress imposed by the natural kyphosis, flexion, and gravity. Collapse of the anterior margin to less than half the height of the posterior margin or more than 20° of wedging may indicate an unstable fracture. Other indicators are based on the Denis criteria.<sup>21</sup> Using a three-column concept, if two or more columns are disrupted, the fracture is unstable. The three columns are the anterior column (anterior longitudinal ligament [ALL] to midvertebral body), middle column (midvertebral body to posterior longitudinal ligament [PLL]), and posterior column (PLL to supraspinous ligament). Loss of posterior vertebral body height without a history of trauma should raise the suspicion of pathologic fracture, warranting a search for metastatic cancer or multiple myeloma. Healing of noncomplicated fractures should be evident within about three months.

## **Management**

Fractures due to metastatic cancer or multiple myeloma require medical referral. Stable osteoporotic fractures can be managed conservatively with rest and over-the-counter pain medication. The acute pain is often severe for two weeks, with persistent pain for up to three months. At three months, if pain is persistent, reradiograph the area to determine the degree of healing. If the compression fracture is in the lumbar or thoracolumbar area, a restrictive corset may be helpful to remind the patient not to bend forward or make

sudden movements. All patients with osteoporosis must avoid flexion exercises. There is a dramatic increase in compression fractures among those performing flexion versus extension exercises for low back pain (see also [Chapter 30](#), Osteoporosis).

Minimally invasive procedures designed to fill the gap of the fracture and/or increase the height of the collapsed vertebrae have been utilized for a number of years, yet there still remains quite a degree of controversy. These procedures are performed by an orthopaedic surgeon or interventional radiologist and are generally outpatient procedures using a local anesthetic and minimal general anesthetic. The earliest procedure, called vertebroplasty, involves the injection of cement, usually polymethylmethacrylate (PMMA), into the vertebrae. There are two intentions. One is to fill in the gap and potentially relieve pain in those that fail conservative management. With the introduction of the next advance, balloon kyphoplasty, the second intention is to restore the height of the vertebrae and diminish the degree of kyphosis segmentally and across segments to improve cosmetic appearance. This is accomplished by inflating a balloon in the vertebrae to create a space into which the cement is injected. Several problems emerged. One is the potential leakage of the PMMA that may result in neurologic compromise. This may occur asymptotically in as many as 65% of cases and symptomatically around 2% of the time. Pulmonary embolism from injection into the venous system is also possible, occurring in 2% to 26% of procedures.<sup>22</sup> Long-term effects are not known at this time. Additionally, randomized studies using control groups have not yet demonstrated a clinically significant difference between placebo and surgery other than some immediate improvement differences in pain with the surgical procedures.<sup>23</sup> Also, even though there have been improvements in the vertebral body height, at a segmental level, the differences are only a few millimeters at best. Reported as percentages of around 30% or so, these seem impressive but cosmetically not necessarily significant. No studies have demonstrated that there is prevention of future fracture and in fact it has been demonstrated that there may be an increase in fracture at adjacent levels. Specialty focused groups are inconsistent in their recommendations. The American Academy of Orthopaedic Surgeons in 2010<sup>24</sup> recommended against the use of vertebroplasty. Other groups such as the Australian Medical Services Advisory Committee recommend its use for those that have failed conservative management.<sup>25</sup> Others recommend its use for vertebral fractures other than compression fractures such as those due to cancer or other disease processes. Newer augmenting devices such as Kiva are being tested.<sup>26</sup> These devices are usually implants, often columns formed by coils, to form an intravertebral housing for the cement that is injected.

## **Osteoid Osteoma**

### **Classic Presentation**

The patient is usually a young male who presents with a complaint of well-localized midback pain. The pain is worse at night but relieved by aspirin (in 65% of patients).<sup>27</sup>

### **Cause**

Osteoid osteomas are benign tumors affecting mainly the posterior elements of the vertebrae. They are not exclusive to the spine. In fact, 50% occur in the femur and tibia, and approximately 10% in the spine. Occurrence is most frequent in the lamina, followed by the pedicle, facet, and spinous processes.

## **Evaluation**

The patient often has an acute-angle scoliosis at the site of the tumor (lesion on the concave side). The diagnosis is sometimes made from standard thoracic radiographs. The lesion is a small bony density that surrounds a smaller round, radiolucent nidus. Bone scans or tomograms often will be needed to confirm or identify the lesion.

## **Management**

Refer the patient for surgical excision.

### **Postural Syndrome**

## **Classic Presentation**

The patient will present with a constant aching pain in the middle and upper thoracic regions. The pain is usually relieved by activity and made worse by working at a desk.

### **Cause**

The natural imbalance between the anterior muscles and posterior muscles is often accentuated by various work postures that emphasize a “hunched,” forward-head position. The large, tight muscles such as the pectorals become chronically shortened in adapting to the position, with associated weakness and constant strain of the midscapular muscles, which contract eccentrically.

## **Evaluation**

Posturally the patient may present with a hyperkyphosis. There are often trigger points in the upper and middle trapezius, rhomboids, levator scapulae, and pectorals. Lower trapezius strength is minimal when the patient is asked to perform upper thoracic extension from a prone position with the arms held above the head (out in front of the body).

## Management

The combination of manipulation of the thoracic and related regions with deep massage can be used initially to decrease discomfort. To prevent recurrence, exercises focusing on stretching the pectorals first, followed by strengthening of the midscapular muscles and lower trapezius should follow. Postural awareness may be increased with bracing or taping. The patient's work environment must be evaluated for ergonomic strengths. Redesign of the work environment and frequent breaks for stretching and mild isometrics often help.

### T4 Syndrome

## Classic Presentation

The patient complains of upper back stiffness and achiness with associated signs of upper extremity numbness and/or paresthesias (often in a stocking and glove distribution). There may be associated headaches.

## Cause

The cause is unknown; however, it is postulated that sympathetic dysfunction somehow related to vertebral dysfunction in the upper thoracic region (T2-T7) causes a referred or reflex phenomenon in the arms or hands. Patients may report occurrence during the night or upon rising. This syndrome is more common in women (4:1 ratio) in the age range of 30 to 50 years. Prolonged sitting, sustained reaching and pulling activities, shoveling, and overhead cleaning have all been reported by patients.<sup>28</sup>

## Evaluation

The patient will often have tenderness and restriction at the involved segment(s), most often T2-T7. Pressure or movement challenge at these areas may reproduce the patient's complaints. For all patients with arm complaints, a thorough neurologic examination should be performed in an

attempt to differentiate nerve root, peripheral nerve, brachial plexus, or central nervous system disorders. The neurologic examination is normal in patients with T4 syndrome. Radiographs are not diagnostic for this syndrome.

## **Management**

Manipulation or mobilization of the involved area, coupled with postural advice and exercise, will usually resolve the patient's complaints.

## **Herpes Zoster (Shingles)**

### **Classic Presentation**

A patient presents with isolated burning and pain that developed into skin lesions in a small patch on the chest and back. These vesicles crusted over a few days and cleared over the last few days. (Note: The presentation varies with the degree of involvement.) Small local lesions are most common although full body expression can occur in some individuals. Older patients more often have involvement of the forehead than younger individuals.

### **Cause**

The cause is a latent varicella virus that resides in the dorsal root ganglion. Mechanical, emotional, or chemical stress causes activation along the corresponding dermatome. The formation of clusters of vesicles is preceded by pain, burning, and sensitivity. The average length of time for the whole process is one week.

### **Examination**

The first visible appearance is a reddening in the area of involvement, followed by the formation of vesicles. The classic appearance of the lesions usually makes this a simple recognition without the need for testing. It is extremely important to recognize that if a dermatome is affected, it is often patchy involvement not extending along the full course of the dermatome (i.e., outlining the involved dermatome). This creates patches that may appear unconnected due to angulation of the ribs and corresponding dermatome.

## **Management**

Localized involvement is self-limited and may be circumvented by avoiding recognizable triggers. Some practitioners recommend lysine; however, there is no evidence as yet to support that recommendation. For others with more involvement, acyclovir or implanted drug delivery systems are used. Seniors are at particular risk for the development of shingles. Recently, a new vaccine has been developed. Studies indicate that the new vaccine reduces the incidence by about 50%.<sup>29, 30</sup>

# CHAPTER 5

## Scoliosis

### Context

Scoliosis may be the result of detectable, cause-and-effect conditions. If scoliosis is found as part of a composite picture of a disorder (e.g., neurofibromatosis or poliomyelitis), it is categorized by cause. The list is long and includes neurologic, muscular, congenital bone anomalies, developmental (e.g., due to abnormal collagen), and several other recognizable disorders. The majority of scolioses, however, are idiopathic. The majority of scolioses do not progress; yet for those that do, cosmetic appearance, and occasionally cardiopulmonary compromise are concerns.

Idiopathic scoliosis is truly an enigma. Etiologically disguised by apparent causes that ultimately are revealed as effects, this seemingly simple spinal deviation has remained “idiopathic” for centuries despite astounding technologic advances. Sifting through the plethora of theories, it becomes apparent that no single causative factor is or probably ever will be identifiable.

The deformity seen with hyperkyphosis is an example of a sagittal plane disorder that progresses in one plane only. Scoliosis, on the other hand, causes spinal buckling resulting in a distortion into all planes. Idiopathic scoliosis radiographically masquerades as a lateral bending of the spine. In reality, the major components of the deformity in three dimensions include: (1) lordosis, (2) rotation and

torsion, and (3) lateral deformity.<sup>1</sup> Rotation and lordosis are not as conspicuous on the standard anterior-to-posterior (or posterior-to-anterior) radiograph. The lateral deformity is not necessarily the major determinant of progression, yet the Cobb angle used to measure this component of the scoliosis has always been weighted as one of the, if not the major, factors upon which management decisions are based. Most important, concerns regarding cardiopulmonary dysfunction have been grossly misinterpreted, leaving the cosmetic deformity as the predominant concern for the patient.

There have been many shortcomings and misinterpretations with regard to the percentage of the population at risk for adolescent idiopathic scoliosis (AIS) and those at risk for progression. Generally, if the criterion of a 10° curve measured by the Cobb angle is used, the prevalence of AIS (ages 10–16 years) is approximately 2–3%.<sup>2</sup> However, combining data from available epidemiologic and natural history studies, less than 1% of screened individuals and less than 10% of individuals positive for AIS on screening evaluation require treatment.<sup>2</sup>

For years chiropractors have claimed success in the management of scoliosis. Yet it is unclear whether all chiropractors were dealing with idiopathic scoliosis, or the type of scoliosis that is the painful consequence of muscle spasm, or the nonpainful scoliosis due to muscular imbalance that compensates for biomechanical asymmetry. Many chiropractors feel that by correcting asymmetry and keeping the spine segmentally and globally mobile, idiopathic scoliosis can be halted or reversed. Unfortunately, most studies indicate that although these biomechanical factors are potential factors in curve progression, especially in larger curves, they are likely not the cause. Reflex mechanisms are proposed regarding proprioceptive input from the upper cervical region.<sup>3</sup> These factors may play a role in setting the muscular response to a perceived

“normal” that is false. Yet, again, more research must be done.

A study conducted with surgeons and chiropractors tested the feasibility of conducting a larger multicenter project to evaluate the effectiveness of chiropractor care for AIS compared to standard medical care including bracing.<sup>4</sup> The results of the study indicated that patient and doctor recruitment are indeed feasible. Hopefully, a more extensive study will be conducted in the near future.

## **General Strategy**

### **History**

- Determine whether the scoliosis onset was acute or slowly progressive.
- Determine whether there is associated acute pain at the apex (reflex muscle spasm due to a local process such as a tumor, a fracture, disc disease, etc.) or chronic pain (common in patients aged 40 years and above with idiopathic curves).
- Determine whether there was a previous diagnosis of scoliosis and whether radiographs were taken or treatment was rendered; if a brace or electrical stimulation was prescribed, determine whether the patient was compliant.
- Determine in children and young adults whether there is a family history, whether a female has reached menarche, whether a child has gone through a growth spurt, and whether indications of progression have been noticed by the parent or child.

### **Evaluation**

- Determine whether there are any associated findings (congenital scoliosis), including clubfoot or other foot deformities, café au lait spots or patches (neurofibromatosis), or patches of hair along the spine (spina bifida).
- Observe the patient from behind for evidence of a scoliosis; perform an Adams' test; observe the patient with lateral bending into the convexity and lying prone (improvement indicates a functional component).
- Observe or measure any obvious asymmetries with regard to shoulder or hip height, winging of scapulae, or head tilt; measure with a plumb line to determine whether the scoliosis is compensated or uncompensated.
- Evaluate the patient for asymmetries of the lower extremities, including pronation, tibial torsion, femoral anteversion/retroversion, and leg length discrepancy; also test for asymmetric weakness or tightness of lower extremity musculature.
- Use a full-spine film to initially radiograph patients with scoliosis. The films should be evaluated for signs of congenital scoliosis (i.e., hemivertebrae, bar vertebrae), location of the curve, and pelvic unleveling. Measure the severity with a Cobb angle, rotation with the Nash-Moe method, and bone age with the Risser sign (iliac crest apophysis).
- Take films with the patient recumbent and laterally bending into the convexity (or with a push-prone technique) and the Cobb angle measured to determine the degree of flexibility of the curve. Subtraction of the recumbent Cobb angle from the standing Cobb angle will give an approximation of the functional component of the curve.

## Management

- Most cases of congenital scoliosis should be sent for an orthopaedic consultation.
- Correlate history and examination findings to gauge the tendency to progression. The primary indicators are gender (females progress more often), severity of the curve, and the Risser sign; important secondary indicators are age at menarche, type of curve, flexibility of curve, and familial predisposition.
- Idiopathic scoliosis may be managed within given ranges (dependent on age, tendency to progress, patient/parent choice) if there is no progression. Progression should be monitored radiographically every three to four months unless there are signs of rapid progression. Nonradiographic monitoring is optional using Moire topography (not commonly in use anymore). Curves that show signs of progression prior to age of menarche in girls should be referred for bracing; in girls past the age of menarche, large curves may require surgical correction. With boys, the relationship to a growth spurt may be helpful in determining a tendency to progress (more progression during the growth spurt).
- Idiopathic curves may become painful in patients 40 years of age or older; management is for pain and correction of any obvious biomechanical or spinal dysfunction. Progression to instability or severe pain warrants an orthopaedic consultation.

## **Idiopathic Scoliosis Etiology**

Although genetic factors have been proposed, it has not yet been determined what they are. Recurrence among relatives has been reported to be between 25% and 35%.<sup>5</sup> With immediate relatives such as parents and grandparents, the incidence appears to be three or four times

higher. When both parents are affected, the number of children with significant curves was 40%, much higher than those without affected parents.<sup>6</sup>

The common thread running through many theories regarding the development and progression of idiopathic scoliosis is that sensory information is either aberrant or information processed at the spinal cord level, or more likely at higher levels such as the cortices, is misinterpreted, leading to inappropriate output information regarding body orientation in space.<sup>7</sup>

Several recent research studies shed some light on possible problems. In one study,<sup>8</sup> visuo-oculomotor and vestibulo-ocular functions were studied with video-oculography. Altered visuo-oculomotor functions were detected, especially for the saccadic latency for patients with a Cobb angle of 15° or more. The researchers propose that this may represent a dysfunction of oculomotor pathways at the cerebellar and/or brainstem level although it is unclear whether this is a cause or result of the scoliosis.

In another recent study,<sup>9</sup> measuring bioelectric activity of the brain in AIS patients matched to controls (i.e., those without AIS), patients with AIS appeared to demonstrate a premature shift of bioelectric focus to structures of the left hemisphere (including the left thalamus), which was increased with the severity of the curve. Although this shift is natural for older adolescents (aged 15–17 years) and healthy adults, it does not usually occur in healthy children (aged 7–14 years). This may represent a premature shift in postural control more representative and normal for older adolescents, but when occurring during pubescence may represent an altered output of muscle tone or even growth.

Regarding the potential effect of brainstem function in the progression of scoliosis, researchers have provided some preliminary evidence that vestibular dysfunction may have an asymmetrical effect on bone growth.<sup>10</sup> It is known that integration and interaction among the central nervous

system, brainstem, and sympathetic nervous system help regulate bone remodeling. The type or severity of vestibular dysfunction is not known; further research is necessary to determine whether a specific type of dysfunction is identifiable and amenable to management.

Balance is often a problem in children with idiopathic scoliosis compared with those without.<sup>11</sup> Obviously, integration of proprioceptive, visual, and vestibular information is a factor.

It is known that curves greater than 30° are more likely to progress, having reached a point at which gravity has the advantage.<sup>12</sup> However, other concerns about progression center around the length of the spine, the length of the curve, and the size of the vertebrae.

One mechanical model that attempts to explain why females are prone to development of a progressive scoliosis has to do with the slenderness of their vertebrae. The model holds that the size of the vertebrae determines the load that can be accommodated. It is known that females, on average, have more slender spines than males. While their vertebral height increases by 50% during adolescent growth, the vertebral width increases by only 15%.<sup>13</sup> In addition, their growth spurt occurs during a time when their kyphosis is at a minimum, thereby decreasing the absorptive effect of the sagittal curves. In contrast, males have thicker vertebrae and achieve their growth spurt during a time when their kyphosis is at a maximum, which may explain why they are more prone to the development of Scheuermann's disease.<sup>14</sup>

Another important concept is that the spine has a critical load capacity past which it will begin to deform. When children grow, especially when they grow rapidly, the increase in height coupled with the increased slenderness of the spine causes a decrease in the critical load needed to cause deformation. This results in a 20% decrease in the critical load level for only a 10% increase in height. Add to

that any weight gain and the critical load is more likely to be exceeded while the spine is most subject to deformity.

There are several biologic models regarding the cause and progression of idiopathic scoliosis. One model states that differential pressure on end-plates leads to asymmetric growth, which results in scoliosis development. Although the Hueter-Volkman law states that increased pressure across a growing epiphysis (end-plate) will lead to decreased growth, it has been found that the disc is more fluid in growing individuals and is able to dissipate the forces more equally across the end-plates than in the adult spine. Therefore, the effects of increased pressure due to wedging are thought to be negligible, at least in smaller curves. Dickson et al.<sup>15</sup> feel that the posterior elements, in particular the facets, not having the advantage of disc cushioning, are more likely to change as a result and may then be more the cause for asymmetric growth. Two studies<sup>16,17</sup> have demonstrated pressure changes in the histologic structure of the intervertebral disc with effects in collagen and glycosaminoglycan content. This occurs after the scoliosis develops, indicating that it is a response rather than a cause.

One of the newest theories is that a defect in melatonin synthesis or metabolism is a cause of idiopathic scoliosis or is associated with its progression. The theory is based primarily on studies performed on pinealectomized chickens.<sup>18</sup> Later studies indicated that the effect of scoliosis development with removal of the pineal gland occurred only in bipedal animals.<sup>19</sup> Evidence for the role of melatonin in humans is less consistent. Machida et al.<sup>20</sup> demonstrated that with progressive cases of scoliosis, melatonin levels were lower compared with normals; however, progressive cases of congenital scoliosis had normal melatonin levels. Studies by Hillbrand et al.,<sup>21</sup> Fagan et al.,<sup>22</sup> and Bagnall et al.<sup>23</sup> were unable to demonstrate differences in melatonin levels between scoliosis patients and controls.

Another association may be between calmodulin and melatonin metabolism. It is proposed that the calmodulin-melatonin interaction represents a means by which regulation and synchronization of cell physiology occur. Calmodulin is a calcium-binding receptor protein and is a major mediator of cellular calcium function, including interaction with actin and myosin, regulation of a number of enzymatic processes, and cellular calcium transport across the cell membrane. Using the logic that the contractile protein synthesis systems of platelets and skeletal muscle (actin and myosin) are similar, an underlying systemic disorder might affect both. Increased calmodulin levels have been associated with adolescent idiopathic scoliosis. This role of calmodulin has recently been evaluated measuring platelet calmodulin levels in individuals with adolescent idiopathic scoliosis.<sup>24</sup> The findings indicate that levels correlate closely with curve progression and treatment results using bracing and surgical stabilization. However, correlation with curves that were nonprogressive was not consistent. It is known that there are transient changes in melatonin production based on age and that melatonin secretion is also governed by circadian rhythm.<sup>25</sup> At this time, it is likely that melatonin is related more to progression of AIS versus the cause or initiator of AIS.<sup>26</sup> Related theories are based on the role of serotonin and growth-producing hormones as associated with, but not causes of, idiopathic scoliosis.<sup>27,28</sup>

Finally, a recent study<sup>29</sup> calls into question the role of leptin. The researchers determined that there was abnormal leptin bioavailability in AIS girls. What this means diagnostically or therapeutically is still in need of investigation.

Although it may appear that an imbalance of muscular activity or strength may cause a scoliosis, the evidence suggests that any changes are reactions to the curve, not the causes. Asymmetric activity is found only in curves

greater than 25°. <sup>30</sup> If asymmetric activity were the cause, these imbalances would be evident with lesser degrees of curvature. Comparison of bilateral muscle strength does not indicate any differences between scoliotic children and those without scoliosis.

## Evaluation

The prime directive with scoliosis management is to prevent progression and reverse the deformity if possible. Making decisions regarding treatment may seem easy given the limited options available. The ingredients in this decision equation are not discrete, however, and they are based on risk-to-benefit ratios and outcome desires, which vary among doctors and patients. The primary concern for the patient is cosmetic. With severe scoliosis the physician may have additional concerns regarding cardiopulmonary function, although this is actually a rare complication. <sup>31</sup>

Recognition of the scoliosis at the earliest point is imperative. The first distinction that is requisite for management of a scoliosis is whether there is a known cause or whether it fits the larger group of idiopathic curves. Known causes often have associated nonspinal clues that should be screened for in all patients, not only those with an apparent curve. Bunch and Patwardhan <sup>30</sup> demonstrated how adequate compensation may camouflage the degree of distortion present. They use an analogy of a Christmas tree that appears to be symmetric; however, when stripped to the trunk it reveals a gross rotational distortion.

The next distinction is to determine whether a curve is primarily structural or functional. Structural curves are the end result of bone remodeling with a subsequent rotary distortion that then becomes evident superficially as a lateral curvature. This rotation is always into the concavity when using the spinous process as the reference point. In

addition, structural curves do not correct with postural changes such as bending forward (Adams' test, **Figure 5-1**), lying down, or maximally bending into the convexity in a supine position (**Figure 5-2**).

Functional (nonstructural) curves have no permanent rotary component and correct or overcorrect with the positional changes noted above. Functional curves are usually compensatory to biomechanical problems or are the result of muscle spasm. The key difference is that scoliosis due to muscle spasm has a pain component that is often aggravated by bending forward. Idiopathic scoliosis is rarely the cause of spinal pain until later in life.

**Figure 5-1** Rib hump in forward bending test. (A) Posterior view. (B) Anterior view. The two sides are compared. Note the presence of a right thoracic prominence. (C) Measurement of the prominence. The spirit level is positioned with the zero mark over the palpable spinous process in the area of maximal prominence. The level is made horizontal and the distance to the apex of the deformity (5 to 6 cm) noted. The perpendicular distance from the level to the hollow is measured at the same distance from the midline. A 2.4-cm right thoracic prominence is shown.

Reproduced from *Scoliosis and Other Spinal Deformities*, J.H. Moe, et al., p. 17, © 1978, with permission from Elsevier.

**Figure 5-2** The value of the side bending to determine whether a curve is structural or nonstructural. (A) The patient is standing erect and both curves seem to be in balance. The question is: Are both curves structural, and therefore do both require treatment, or is one of the curves secondary and functional? (B) The patient bends to the left side and the lumbar curve straightens out and actually overcorrects. This curve is therefore a functional and nonstructural curve, and if surgery were required for the upper curve, this curve would not need to be fused. (C) The patient is bent to the right side and the upper curve does not correct completely. This indicates that the thoracic curve is structural and does require treatment.

Curves are named by the regional location of their apices. Single curves are relatively easy to identify; however, when two or three curves are present it is necessary to determine the major curve and compensatory (minor) curves. In general, the major curve is larger and more structural (greatest degree of rotation). Minor curves are generally smaller and more flexible.

Idiopathic scoliosis is also classified according to age: infantile—birth to 3 years (males predominate); juvenile—4 to 10 years of age (female ratio higher); and adolescent—more than 10 years of age (strong female to male ratio, 7:1 or higher).

Parents or guardians, a child's doctor, or school screening can detect scoliosis. Referral to one pediatric orthopaedic

practice indicated that 42% of cases were discovered on school screenings, while 39% were discovered by the patient's primary care physician.<sup>32</sup> Detection by a parent is usually based on either noticing shoulder or scapula elevation or noticing that clothes hang unevenly.

Unfortunately, this is not always readily apparent, and signs may be minimal where compensation has camouflaged the deformity. When scoliosis screening was introduced in the 1940s in the United States, the goal was to identify scoliosis due to poliomyelitis. As the program expanded, the goal changed to identification of children at a stage of scoliosis development early enough to allow a period of bracing in the hope of avoiding surgery. At present, school screenings are mandatory in approximately one third of the schools in the United States, with screening occurring between the ages of 10 and 16 years (grades 5 through 9).<sup>33,34</sup>

The statistical risk of having a scoliosis that progresses to the point that treatment is needed is only 0.2%. The referral rate averages 5%; however, the rate is suspected to be at least twice that because referral documentation forms are not available for a large percentage of patients.<sup>35</sup> Williams and Herbert<sup>36</sup> reviewed the results of several screening programs and found a false-positive rate of at least 60% and a false-negative rate of 23%. Viewed from a different perspective, Dickson<sup>37</sup> found that as few as 10% of children who screened positive for trunk asymmetry had a scoliosis that was progressive. These observations have raised serious concerns about the value of school screening. Given the low prevalence of progressive curves, given that at least one third of patients are detected by their primary care physician, and given that mainly girls with large curves premenarche are likely to progress, either modifications to screening or elimination of screening has been proposed. Modifications would include: (1) use school screening only for those who do not have access to a primary care physician, (2) screen only premenarcheal girls, and (3) do

not conduct school screening for boys. The U.S. Preventive Services Task Force (USPSTF) concluded that on the basis of available evidence, a recommendation for or against routine screening of asymptomatic adolescents for idiopathic scoliosis could not be made at this time.<sup>38</sup>

A consensus paper by Grivas et al.<sup>39</sup> lists some recommendations based on questions posed to experts. For school screenings, it was advised to screen with the patient seated to eliminate adding problems associated with lower extremity asymmetries.

The basis of screening is to check the standing patient for signs of asymmetry and scoliosis. The patient then bends forward to enable the examiner to check for humping (Adams' test) indicating the side of convexity of a structural curve. It is felt that this is a simple process, yet many screening personnel are not adequately trained. When faced with an equivocal case, the tendency is to refer. This purely observational (subjective) approach has no support from a quantifiable measurement. In addressing these concerns, several recommendations have been made to potentially reduce the false-positive referral rate:

- Train personnel. Have them screen in the presence of a trained supervisor before being allowed to screen alone.
- View the spine in at least three positions of forward bending. As the patient bends forward he or she is to clasp the hands and allow them to hang dependently. The examiner views from in front or behind first at about 45° to view the thoracic "skyline," then at a few degrees more of flexion for the thoracolumbar region, and finally at a right angle for the lumbar region.
- Use a scoliometer to measure the degree of rib "humping," or more preferably called the angle of inclination or trunk rotation. This device is basically an inclinometer that measures in degrees the amount of

rotation of the trunk. The instrument is reliable and seems to allow discrimination between curves that are greater than 20°. <sup>40</sup> It has been determined that if 5° of inclination is found, it is likely that 20° of structural curve exists, requiring further evaluation. Bunnell <sup>40</sup> feels that using the scoliometer criterion of 5° of rotation would decrease the false-positive referral rate by half. Some feel that this criterion should be extended to 7° to avoid false-positive results.

- Rescreen the child in six months when uncertain, instead of immediately referring.
- Establish several referral centers where an experienced examiner with access to radiographic facilities can examine the children at no cost. This suggestion is based on the observation that there is a very low rate (less than one third in one study) of compliance for follow-up evaluation. <sup>32</sup>

A presentation by Braun in 2007 <sup>41</sup> indicates that a recent study identified 12 DNA markers that were used to accurately predict progression of curve severity in patients with adolescent idiopathic scoliosis by categorizing patients into high-risk and low-risk groups. If supported by future studies, this approach may revolutionize decision making with regard to conservative versus surgical correction.

## **Congenital Scoliosis**

Congenital scoliosis, although not as common as idiopathic scoliosis, should always be screened for in a young patient. All children under the age of 10 years have an increased incidence of neuron axis deformities. <sup>42</sup> The most common causes generally may be divided into two categories: (1) failure of formation such as occurs with hemivertebrae, and (2) failure of segmentation such as occurs with unilateral

bar vertebrae. It is more common for these to occur in various forms of combination as opposed to discrete entities. It is extremely important to remember that these congenital abnormalities occur in all three planes and may be underestimated with regard to progression when viewed on a single radiograph. In addition, cartilaginous tissue, not visible on the radiograph, may play a role in asymmetric growth.

Prognosis regarding progression is difficult; however, some generalizations may help guide the clinician with a warning that there are always exceptions to these generalities.<sup>30</sup>

- Single hemivertebrae in areas other than the thoracic spine are generally not rapidly progressive.
- Hemivertebrae on opposite sides with only a few normal vertebrae separating them are not likely to progress.
- Hemivertebrae may be further divided into fully segmented, partially segmented, or nonsegmented. The distinction is based on whether a disc space exists on both sides (fully), one side (partially), or not at all (non). In general, the disc space represents the degree of growth potential and therefore the progression potential for the scoliosis. Nonsegmented hemivertebrae are the least likely to progress.
- Predictions of progression with unilateral bar vertebrae are less difficult. The presence of a unilateral bar is strongly suggestive of progression and warrants surgical referral.
- An example of a combination of congenital deformities likely to progress would be a unilateral bar vertebra with paired hemivertebrae on the opposite side.

Unlike idiopathic scoliosis, additional diagnostic clues exist outside the spinal column and musculoskeletal system.

Interference with the development of the mesoderm in utero is usually associated with multiple affected areas.

- Twenty percent of patients with congenital scoliosis were found to have genitourinary abnormalities. Six percent had serious obstructive problems.<sup>43</sup>
- Heart defects were found in 15% of patients with a congenital scoliosis.<sup>44</sup>
- Ten percent of patients with congenital scoliosis will have spinal dysraphism, with half of these being diastematomyelia.<sup>45</sup> The rest will have anomalous bands, lipomas, or a tight filum terminale. Patients fall into three groups. The first group has the scoliosis as the prominent external sign. The other two groups may show excess hair growth, dimpling, or pigmentation problems (café au lait spots) over or around the spine. All patients should be observed for these subtle indicators. Other associated findings include a clubfoot, a congenitally dislocated hip, or an anatomically short leg.

## Decision Making with Congenital Curves

The clinician must be aware of the different progression rates of congenital scoliosis. Given the significant numbers of extraspinal abnormalities that may coexist with congenital scoliosis, a thorough physical examination must be performed. It would then be appropriate to refer the patient to an internist if heart or genitourinary abnormalities are present or to a neurologist if there is a suspicion of neurofibromatosis or spinal dysraphism.

If the patient has a unilateral, nonsegmented hemivertebra or bilateral hemivertebrae separated by a few

normal vertebrae, the patient should be monitored radiographically every three to six months. The least likely to progress are nonsegmented hemivertebrae. However, if there is a single segmented hemivertebra in the thoracic spine or a unilateral bar vertebra, refer for orthopaedic consultation because they are likely to progress.

If there are combined defects and the curve is less than  $20^{\circ}$  or less than  $40^{\circ}$  with a balanced trunk, the patient should be monitored radiographically every six months for progression. Refer if progressive. If there are combined defects and the curve is between  $20^{\circ}$  and  $40^{\circ}$  with an unbalanced trunk and flexible spine, bracing is appropriate. Curves with combined defects that are progressive, and those greater than  $40^{\circ}$  should be referred for orthopaedic surgical consultation.

## Idiopathic Scoliosis

Prognostications regarding the natural history of an individual's idiopathic scoliosis are primarily hinged on three primary and several secondary factors. The primary gauges of progression are the severity of the curve, the apex location, and the skeletal maturity of the individual. Secondary indicators include genetic tendencies, gender, and curve flexibility.

Although the severity of the curve is relatively easy to determine radiographically, skeletal maturity is a more complex variable. Two methods are used to determine skeletal maturity: (1) the Greulich-Pyle atlas, and (2) the Risser sign. The Greulich-Pyle atlas is a comparative reference to match with a patient's left wrist radiographs. The Risser sign is a grading of iliac crest apophysis development (**Figure 5-3**). The upper pelvic rim is divided into four equal units. Radiographically the line of apophyseal growth progresses laterally to medially. It is believed that

little growth (less chance for progression) occurs after a + 4 Risser sign. Compared with a 36% progression with a Risser sign of 0, only 11% progressed with a Risser sign of 2.<sup>46</sup>

Various investigators have classified idiopathic curves into commonly occurring patterns. A widely accepted classification system by King<sup>47</sup> has not been shown to have a sufficient intraobserver or interobserver reliability to help guide decision making using spinal fixation surgery.<sup>48,49</sup> These curves are primarily structural and may lead to development of compensatory curves. The only way to distinguish among curves that appear to be of equal severity is to note the degree of rotation and with side-bending films to determine which curves are flexible. A list of these patterns is given with some clues to recognition.

- Double major—This includes two curves of equal or close to equal size, both of which fail to correct much on lateral-bending films. The thoracic apices are at T7; the lumbar at L2. The upper end vertebra for the thoracic component is T5 or T6, with the lumbar being T11. The pattern is consistently right thoracic/left lumbar convexity. This is such a common pattern (90% of the time) that when the opposite is found it is suggested that consideration for further evaluation with magnetic resonance imaging (MRI) is necessary. A relatively common cause is syringomyelia or the type I Arnold-Chiari syndrome.<sup>50</sup> Arai et al.<sup>51</sup> found that although the incidence was only 4% for syringomyelia and Arnold-Chiari type I malformation each (total 8%), scoliosis was the only presenting complaint in 40% of these cases. Nineteen percent of these cases had a left convex thoracic curve. A recent study<sup>52</sup> attempted to determine the clinical indications for MRI of intraspinal abnormalities. The investigators found that if neck pain and headache (especially exertional headache) and neurologic findings such as ataxia, weakness, and a

cavus foot were used as criteria for ordering MRI, all intraspinal abnormalities would be found.

**Figure 5-3** Grading the development of iliac crest apophysis according to the Risser sign. The iliac crest is divided into four quarters, and the excursion or stage of maturity is the amount of progression. In this example, the excursion is 50%; the Risser sign is 2.

- Right thoracic—This initially single curve extends from about T5 to T11 with the apex at about T8. Often confused with a double major curve, the right thoracic usually has a compensatory curve in the lumbar region that may at times be of equal size; however, it is flexible. The right thoracic curve is an excellent example that the thoracic curve is not commonly a mechanical compensation for a lumbar curve, but in fact it is the reverse. This demonstrates that an unlevel pelvis or sacrum is not often the stimulus for scoliosis formation with many curves.
- Lumbar—Usually extending from about T11-T12 to L3-L4; apices L1-L2. This curve is usually left convex (70%

of time). Thoracic compensation is not uncommon; however, it occurs to a much smaller degree.

- Thoracolumbar—Extending from about T8 to L3; apices T11-T12. This single curve is less likely to have clearly compensatory curves associated with it. It is primarily right convex (80% of time).
- Double thoracic major—With an upper left curve extending from T2 to T7 and a lower right curve extending from T7 to L1, these two primary curves are usually compensated for in the cervical spine.

The standard King classification for scoliosis has been recently challenged by newer systems: the Conrad system<sup>53</sup> and the Lenke system.<sup>54</sup> The King system was developed in relation to decision making using Harrington rod surgery and is a uniplanar (coronal plane only), potentially outdated approach. One of the newer systems is the Conrad system, a coronal pattern classification system. There are 21 pattern categories further separated into 11 curve types (these include the King curve patterns). Another newer system is the Lenke system used primarily for surgical planning,<sup>55</sup> and although this system appears to be more reliable than the older King system, proper classification of high thoracic and lumbar curves may remain difficult. Lenke has made some recommendations for reducing these areas of disagreement on classification.<sup>56</sup> Generally, the Lenke system is based on three components:<sup>57</sup>

1. Curve types—Type 1 (main thoracic: MT), Type 2 (double thoracic: DT), Type 3 (double major: DM), Type 4 (triple major: TM), Type 5 (thoracolumbar/lumbar: TL/L), and Type 6 (thoracolumbar/lumbar main thoracic: TL/L-MT)
2. A lumbar spine modifier—based on severity of lumbar deformity (based on central sacral vertical line and the apical lumbar vertebrae; A = line between the

pedicles, B = line between the medial aspect of the concave pedicle and the concave margin of the apical vertebral body, and C = line entirely medial to the concave aspect of the apical vertebral body)

- 3.** A sagittal thoracic modifier—defined as the Cobb angle from T5-T12 (hypokyphotic [-],  $< 10^\circ$ ; normal [n],  $10^\circ$ – $40^\circ$ ; and hyperkyphotic [+ ],  $> 40^\circ$ )

The five most common curve patterns based on this system appear to be 1AN, 1BN, 2AN, 5CN, and 1CN, accounting for 58% of all operative curves.<sup>56</sup> Determining structural characteristics includes the use of bending and sagittal views. Proximal thoracic curves are determined to be structural, with a maximum residual Cobb measurement of  $\geq 25^\circ$  or T2-T5 kyphosis  $\geq 20^\circ$ . A main thoracic or thoracolumbar/lumbar curve is determined to be structural if there is a residual Cobb angle  $\geq 25^\circ$  or thoracolumbar T10-L2 kyphosis  $\geq 20^\circ$ .

Double curve patterns tend to progress more than single curve patterns. However, single curves with little compensation are more deforming, as are high thoracic curves. Lumbar curves are generally far less progressive compared with the other major curve patterns.<sup>14</sup> The most important indicator of a good prognosis (slim chance of progression) is the closure of vertebral growth plates, generally indicating skeletal maturity. Because this event cannot currently be viewed directly, we are left, as often is the case, with indirect and therefore inaccurate clues.

Age is only an indirect measure of an individual's skeletal maturity. This is so primarily because hormonal factors are variable: one individual may achieve menarche and a growth spurt at a relatively early age while another may undergo these events two to three years later. This broad difference in growth spurt is an obvious normal distinction between boys and girls and in some ways may be one reason why scoliosis is less likely to progress in boys.

Growth potential is the critical factor. If the growth potential is known, the degree of concern for progression can be approximated. In other words, when the patient has attained most of his or her adult height, there is significantly less chance of progression. The end of the adolescent growth spurt, therefore, is a good indicator of relative stability in curve size.

The growth spurt is considered to be about a 3½-year period.<sup>58</sup> The peak height velocity when the rate of growth is greatest occurs during the first 1½ years. The rate decreases during the last two years. Several studies have pointed to an apparent difference in the timing of the growth spurt. Goldberg et al.<sup>59</sup> noted that girls with adolescent idiopathic scoliosis appear to have an early pubertal growth spurt, but no abnormality of total growth or development. Therefore, they simply reach the adult height at an earlier age than matched controls. Numerous studies<sup>60-63</sup> have demonstrated that girls with idiopathic scoliosis were significantly taller than matched controls. This was most apparent in the younger groups and much less apparent in the older groups. Final adult height comparisons showed no significant differences. Several studies<sup>64-66</sup> indicate that there may be increased growth hormone in girls with idiopathic scoliosis, particularly in the early stages of puberty.

A good indicator of the first rapid phase of height growth is the development of secondary sex characteristics. A staging for both girls and boys has been developed by Tanner.<sup>67</sup> Five stages for breast development and the development of pubic hair are used for girls; for boys, genitalia development and pubic hair growth (see [Chapter 53](#)). For modesty requirements, it may be necessary to use a modification of the Tanner criteria. This modification allows the patient to choose from a written description or pictorial rendition of each Tanner stage of pubic hair development.

In matching the Tanner staging to age, menarche, and peak height growth, a pattern appears. In the United States the average age for menarche is 12½ years (with a standard deviation of 1 year).<sup>12</sup> Menarche appears to occur earlier in girls with idiopathic scoliosis. It is significant that most authors<sup>68</sup> support Scoles et al.<sup>69</sup> in finding that height increased less than 3% after menarche. Therefore, it appears to signal the slowing of the growth spurt. Menarche corresponds to stage 4 breast and pubic hair growth using the Tanner criteria. This correlates with at least a year into the peak height growth phase. Boys, however, will usually reach peak height velocity in stage 4, later than girls.

It is often stated that idiopathic scoliosis is more common in females. When the data are examined more closely, however, it is clear that there is male predominance with infantile curves and that the ratio of males to females is generally equal with curves less than 20°. <sup>70</sup> Females dominate significantly with curves greater than 30°. Curves in need of surgical treatment show a dramatic female predominance of 7:1.

Flexibility is an important determination for distinguishing among the different curve patterns and may be a factor in the tendency to progress. Duval-Beaupere et al.<sup>71</sup> have determined two types of flexibility that must be considered: (1) collapse, the degree of increase in curvature when gravity acts as an axial force on the scoliosis (standing position), or the opposite is true, the degree to which the curve improves with recumbency; and (2) reducibility, the degree of correction that occurs with corrective forces such as bracing, laterally bending into the convexity, muscle stimulation, and so forth.

It was suggested that reducibility is not a constant that helps with prediction of which curves are likely to progress; however, it was suggested that those curves with the largest collapse tendencies (corrected most when lying) had the slowest evolution rates.

Although the flexibility of the curve is screened with an Adams' test, quantification is important to determine the degree of flexibility. Radiographically this is measured by comparing the Cobb angle from the standing anterior-to-posterior (AP) or posterior-to-anterior (PA) radiograph and a recumbent radiograph with the patient bending maximally into the convexity of the curve being evaluated. Another suggested approach, especially for surgeons estimating the degree of correction, is the "push-prone" technique.<sup>72</sup> It combines the above-described collapsibility and reducibility concepts by having assistants push on apical areas (using lead gloves) while the prone radiograph is taken. This approach was valuable for thoracolumbar and lumbar curve surgeries predicting the effects that correction of the primary curve has on curves above and below fusion.

Right and left lateral bending films are traditionally used to measure the flexibility of a scoliotic curve. A curve is classified as structural if it does not "bend out" or reduce to less than 20°. A study<sup>73</sup> determined that a single supine, non-effort-related radiograph is predictive of curve flexibility. Curves were classified using the Lenke classification system taken from measurements in the coronal plane for the proximal thoracic, main thoracic, and thoracolumbar Cobb angles. Sagittally, measurements were at T2-T5, T5-T12, and TL/L. Use of a formula allowed accurate determination of flexibility and reduced the large variation inherent in the older effort-based lateral bending films. Details are found in the article by Cheh et al.<sup>73</sup>

## **Summary of Scoliosis Evaluation**

In an effort to synthesize the foregoing information, a summary approach to the young scoliotic patient is

presented. Physical examination of all infants, children, and adolescents should include a screen for signs of both congenital defects in vertebral development and scoliosis. Congenital problems should be suspected when bony abnormalities are evident through deformity, hip dislocation, clubfeet, and the like, and dermatologic signs such as pigmentation changes and hair growth over affected areas.

Next, a standard standing observation for asymmetry should be performed followed by an Adams' test performed in three positions. Any humping should be quantified with a scoliometer. Radiographs should be obtained for patients whose angular rotation deformity (humping) is greater than  $5^{\circ}$ . If prior radiographs are available they should be ordered for comparison purposes. If radiographs are not recent and there is a suspicion of progression, new films should be ordered. If no films are available a baseline series must be ordered.

Radiographs should include a full-spine ( $14 \times 36$ ) posterior-to-anterior (PA) or anterior-to-posterior (AP) if the AP incorporates rare-earth screens and appropriate shielding. The suggestion of a PA view is based on the significant reduction in radiation exposure to developing breasts. A lateral full spine should complement the AP or PA in an effort to determine the degree of sagittal effect from the scoliosis (lordosis and kyphosis) and to glean a better idea of the degree of vertebral body involvement if a congenital defect is found. Cruickshank et al.<sup>74</sup> demonstrated that a lordosis or flattening is usually found at the apical region of structural curves rather than the visually perceived kyphosis. They demonstrated that this visual impression is incorrectly confirmed on the lateral radiograph. When a mean kyphosis of  $41^{\circ}$  was measured on the lateral view, it was found to represent an area of lordosis when the lateral view was corrected for rotation.

Finally, recumbent, laterally bending films should be included for each curve to determine the degree of curve

flexibility. This involves the patient's maximally bending into the convexity of the curve. The Cobb angle is then compared between the standing and recumbent, laterally bending views. Subtraction of these two values indicates the functional aspect of the curve. This helps determine which curves are major curves and which are compensatory curves.

The Cobb angle is the standard measurement of the degree of curvature. Although there are some problems with this approach, its universal acceptance allows comparison with follow-up views taken in consultation and referral. The angle is based on determining the end vertebrae. These are the upper- and lowermost vertebrae that tilt last into the concavity of the curve and demonstrate no rotation based on pedicle location. By drawing lines along the end-plates of the vertebrae toward the concavity of the curve, it will be found that the first vertebra outside the curve will have lines that diverge from the other lines (**Figure 5-4A**). After choosing the end vertebra, a line across the top of the upper-end vertebra and across the bottom-end vertebra is drawn toward the concave side. Perpendicular lines are then drawn from each of these lines. The intersection of these lines equals the Cobb angle. It has been shown that there is some diurnal variation in the Cobb angle, as much as 5°. <sup>75</sup> This variation suggests repeating follow-up views at the same time of day if possible.

Determination of bone age (skeletal maturity) is made with the Risser sign. <sup>76</sup> With the iliac crest divided into four equal divisions, a determination is made regarding the extent of apophyseal fusion. Although the apophyseal advancement is from anterior-to-posterior and then medially, on a two-dimensional image such as a radiograph it appears as a lateral-to-medial growth. One study <sup>77</sup> demonstrated that the Risser sign may not be accurately viewed on a PA radiograph. When the line of growth has extended through the last quadrant, a Risser sign of 4 has

been reached. At this stage there is still a radiolucent separation between the apophyseal line and the crest. Closure of this space is considered a Risser sign 5, indicating full skeletal maturity. There are some flaws with this measurement; however, it still is a major indirect indicator of vertebral end-plate closure, thereby indicating the end of scoliosis progression during adolescence. The time of appearance is relatively standard; however, the time of fusion is variable. It appears that vertebral end-plate closure has probably occurred by the time a Risser sign 4 is seen in some but not all individuals.<sup>78</sup> So, although a Risser sign 5 is a confirmation of closure, it appears that the Risser sign may be a late indicator of end-plate closure. Still, the Risser sign is considered one of only three significant predictive factors with regard to scoliosis development.<sup>79</sup>

**Figure 5-4** Measurement on a radiograph of degree of curvature in scoliosis according to the (A) Cobb angle and (B) Nash-Moe method.

Rotation is another important observation made radiographically. The standard measurement is the Nash-Moe method. Using the pedicle shadows as reference points to a line drawn through the center of the vertebrae, the degree of deviation from the center line is determined (**Figure 5-4B**). A large rotational component to the curve suggests a structural type. The degree of rotation can be so great as to give the appearance of an oblique radiograph of the region.

Rotation that does not fit the pattern of a typical structural, idiopathic curve (body toward convexity, posterior elements toward the concavity) should suggest a functional, possibly muscle spasm, cause. Also if no rotation occurs, it is likely that the curve is more flexible. Both no rotation and body rotation into the concavity indicate a functional curve, and when coupled with a patient presenting with back pain, muscle spasm is likely the cause.

Nonradiographic evaluation for progression is usually topographically based. Moire topography and integrated shape investigation system (ISIS) screening are the two most commonly used instrumentations; however, they are not widely used in the United States. Moire topography is utilized primarily in Japan for school screening of idiopathic scoliosis.<sup>80</sup> It uses light sources that superimpose a grid on the patient's back.<sup>81</sup> A Polaroid photograph is taken of this surface distortion pattern. As on a geographic map, lines that diverge indicate higher elevations (posteriority) and lines that converge indicate less height (anteriority). Although designed as a tool to replace the positional examination at school screenings, Moire topography has not been found to be significantly valuable. Moire topography is most valuable as a nonradiographic monitoring tool for detecting scoliosis progression. Although there are some problems with false-positive results, it is helpful in indicating in most patients when a radiographic evaluation should be performed to determine the degree of progression. ISIS screening is more high-tech; therefore, it is more expensive and less available.<sup>82</sup> The principles are the same as those of Moire topography; however, a computer is used to generate an approximation of the coronal and sagittal curves. Again, it is not a good screening tool but may help with monitoring progression.

Recent advances have led to a genetic test called ScoliScore, which is a saliva-based test that incorporates 28 progression and 25 protection-associated markers. Along

with the patient's Cobb angle at the time of testing, the ScoliScore attempts to predict progression. In a recent study,<sup>83</sup> the ScoliScore risk distribution in the study population was 36% low risk, 55% intermediate risk, and 9% high risk. Using the clinical approach (i.e., the Lonstein/Carlson categorization) on the same patients, the risk distribution was 2% low risk, 51% intermediate risk, and 47% high risk, demonstrating that the clinical approach under-identified the low-risk and over-identified the high-risk group assuming the ScoliScore is a better predictor of progression. Only 25% of patients were in the same risk category for both systems. Only the Cobb angle showed significant correlation with ScoliScore. ScoliScore predicted nearly 16 times more low-risk patients and more than five times fewer high-risk patients. Practically, this means that the ScoliScore approach may rank patients more often in the low-risk category and remove some of the concern for patients categorized as high-risk using the older system. The problem is that ScoliScore testing is expensive and not very accessible.

Another recent study<sup>84</sup> indicated that the severity of the curve was the best predictor of progression. It was valuable only for low- and high-risk individuals, but not for intermediate-risk patients. The low-risk group had curves less than 18° on the day of presentation to the provider's office. The high-risk group were those with curves more than 26° on the day of presentation. This still leaves the grey zone of curves between 18°–26° where it is difficult to determine risk of progression either using the clinical approach or the ScoliScore approach.

## Management

The literature regarding scoliosis development and progression, screening, and treatment is voluminous. The

difficulty is that when criteria used for inclusion or exclusion are not held constant, meta-analysis and extrapolation based on this analysis are extremely difficult.

It would seem that decision making in scoliosis management would be a simple process. A curve exists where a straight line should be. Push on the apices of the curve (or curves), distract the curve to assist straightening, and finally level out the base on which the spine sits, avoiding any “compensatory” curve development. This “mechanical” approach fails for two major reasons: (1) the development of a curve or curves has a mechanical component that becomes a significant factor only after the curve reaches 30°, and (2) the curve is not two-dimensional. A large rotational component is found with structural scoliosis also affecting the sagittal curves (kyphosis, lordosis). Individuals grow at different rates. In addition, one individual with a 30° curve may have progression while another may not for no known reason. Therefore, clinical decisions should err on the side of caution.

Prognosis is based on the following primary and secondary factors:<sup>2</sup>

- *Primary*
  - Double curve patterns progress more often than single curves (single curves cause more deformity).
  - The greater the curve at detection the greater the risk of progression.
  - There is a greater chance of progression if the onset is before menarche in females.
  - The lower the Risser sign at the time of diagnosis, the greater the chance of progression.
  - Males with similar sized curves have much less risk of progression than the corresponding female.
- *Secondary*
  - Curve progression may be higher for those with an associated thoracic kyphosis.

- Risk of progression decreases significantly at skeletal maturity; however, it may progress based on the severity and location of the curve.

The risk of progression in skeletally mature individuals is fairly low; however, the following statistical predictors have been identified:<sup>2</sup>

- Thoracic curves—those greater than 50° Cobb angle, with apical vertical rotation greater than 30°, or a Mehta angle greater than 30° are more likely to progress.
- Lumbar curves—those greater than 30° Cobb angle, with apical vertical rotation greater than 30°, right convex curves, and those with translatory shifts (seen with a high intercrest line [an interiliac crest line falling at or above the fourth or fifth lumbar disc space allowing third lumbar shift on the fourth]) have a greater chance of progression.
- Thoracolumbar curves—those greater than 30° Cobb angle, those with apical vertical rotation greater than 30°, or those with translatory shifts are more likely to progress.
- Pregnant females have a chance of progression during pregnancy, only if curves are greater than 50° at time of pregnancy.

The key questions a clinician needs to ask in making a decision regarding management of idiopathic scoliosis are as follows:

- What is the risk of progression?
- What is the effectiveness of various conservative options versus operative options?
- What is the risk of using chiropractic methods versus bracing or surgery regarding progression?

- If bracing or surgery is needed, what are the criteria for referral (at what level of severity or age are they most effective)?
- What are the risks of surgery?
- What outcome is desired (reduction of curve, prevention of progression, improvement of cardiopulmonary function, etc.)?

The incidence of infantile scoliosis has decreased so markedly that the condition is rarely seen.<sup>85</sup> This fact, coupled with the finding of a left convex thoracic curve, suggests that infantile scoliosis may represent a form separate from idiopathic scoliosis. Environmental factors are believed to be the explanation. If a clinician does encounter an infantile scoliosis, congenital and paralytic causes should be ruled out. If the infantile form is still a consideration, an orthopaedist can predict progression using the Mehta rib-vertebra angle measurement.<sup>86</sup> The rib-vertebra angle measurement is formed by drawing a vertical line through the center of the vertebra. Lines drawn through the long axis of the right and left ribs intersect this line. If the difference between the right and left angles is greater than 20°, progression is likely. Conservative treatment using a serial elongation derotation flexion (EDF) cast approach has been demonstrated to be very effective in preventing progression with infantile scoliosis.<sup>87</sup>

Although it might be easy to set a cutoff point for conservative versus surgical care based on the severity of the curve, real life contains too many variables to allow such a clean black-and-white decision. Measurements of skeletal maturity must be included in an effort to determine likelihood of progression. Outcome desires are ultimately what guide the clinician in equivocal scenarios. Outcome predictability for orthotic treatment, adapted from Bunch and Patwardhan,<sup>31</sup> might include: (1) ability to halt progression, (2) chance of progression while braced, and (3)

cost and complications associated with bracing (medical and psychologic). Outcome predictability for surgical management may include: (1) correction potential without complications, (2) infection and pseudarthrosis development, and (3) late complications.

In general, the predictability is fairly well known for each factor when matched with age (skeletal maturity) and curve severity. Still, there are scenarios where a “successful” outcome is fairly equal for both options. Then it is often the decision of the clinician based on the value he or she places on each of the outcome factors. For example, a 12-year-old girl with a 35° curve and a Risser sign of 3 might have an equal chance of a successful outcome with either treatment approach. However, the risk of infection, pseudarthrosis, and late complications is fairly low with surgery. A surgeon might consider this an acceptable tradeoff compared with one or two years of bracing, which carries with it about a 10% chance of progression, compliance issues, and psychologic complications. In the mind of the chiropractor or conservative orthopaedist, however, the lower cost of bracing and the avoidance of some of the rare but serious complications of surgery might be more appropriate. Neither is an incorrect choice. However, the desires of the parents and the child must be factored in before a decision is made. This requires a full discussion with the parents and the child of the options and their associated advantages and disadvantages.

Always keeping in mind the complexity that may exist in individual cases, the following is a suggested baseline approach to decision making based on severity of the curve and maturity. It is important to note that these are idiopathic curves, meaning that congenital and transient curves due to muscle spasm are not included.

- Curves less than 20° may be treated chiropractically.

- 1.** If the patient has not reached skeletal maturity, observation using nonradiographic means should be used to determine progression. Radiographs should be taken if there are signs of progression. Radiographs may be needed during periods of rapid growth to better gauge progression.
- 2.** If the patient has reached skeletal maturity, treatment for progression is not needed. If biomechanical faults are present, such as unilateral pronation or a significant leg length deficiency, correct them and obtain a radiograph to determine effectiveness. There is little chance of progression in this range of scoliosis, however.
- Curves between 20° and 40° are still within the conservative management range.
  - 1.** If the patient has not reached skeletal maturity and the curve is less than 30°, initial chiropractic care may be applied; however, the clinician must be vigilant in monitoring for progression. Any signs of progression should result in referral for bracing. This is the range at which bracing has been shown to be most effective.<sup>68</sup>
  - 2.** If the patient has reached skeletal maturity, progression is not likely. Correct biomechanical faults and observe periodically.
- Curves greater than 40° may require surgery.
  - 1.** If the patient has a Tanner score of less than 2 and/or a Risser sign of less than 3, bracing should be tried for six months. If ineffective, refer for surgical consideration (see discussion below).
  - 2.** If the patient has a Tanner 3 or a Risser 4, surgery is recommended.

A dilemma often exists for the chiropractor faced with a patient with a progressive or large curve who is seeking alternatives to bracing and surgery. The chiropractor is

considered the last hope for the patient. It is important to explain fully to the patient and the parents the consequences of allowing the curve to progress and weigh against this the advantages of bracing or surgery. The consequences of progression are mainly cosmetic. The larger the curve at skeletal maturity, the more likely it will progress in adulthood. If cardiopulmonary function is normal as an adolescent, it is unlikely to become worse as an adult as a result of the scoliosis. In fact, forced vital capacity in nonsmokers does not decrease significantly until curves progress to 100° to 120° (a rare occurrence even in adulthood).<sup>88</sup> It is also likely that as an adult, chronic back pain is more likely. Therefore, with cosmesis as the central issue, it is a decision that is difficult to make not knowing an individual's future adult perspective on appearance. What might help put the decision in perspective is that it has been found that scoliotic patients have a high percentage of psychosocial adjustment problems, unemployment, delayed marriage, or no marriage.<sup>31</sup>

Comanagement with an orthopaedist is recommended when curves enter an equivocal range wherein decisions become difficult. Finding a knowledgeable and reasonable orthopaedist for comanagement guarantees that all alternatives are explained to the patient and the doctors understand each other's rationale and concerns. The patient is then able to make more educated choices not based on fear tactics from either camp.

## **Conservative Treatment Options**

# **Lateral Surface Stimulation**

The principle of electrical surface stimulation is based on providing a constant load through contraction of the larger

trunk muscle via the lever arm of the ribs. It was hoped that by using stimulation for eight hours during the night the effects of creep and relaxation could be used in a positive way to effect change. The spine and its surrounding soft tissue support represent viscoelastic material. Viscoelastic material will undergo permanent change in length only when a constant load is applied over long periods of time. Although the initial reports<sup>89</sup> on electrical stimulation for scoliosis correction were extremely encouraging, subsequent studies have demonstrated an unacceptably low rate of success.<sup>90</sup>

## Bracing

Bracing recently has come under attack as a viable conservative treatment option for progressive curves. The first doubts were raised when it was determined from school screening programs that curves in the 15° to 20° range that appeared to be successfully treated by bracing probably would have done as well without bracing. The study by Moe and Kettleson<sup>91</sup> initially indicated excellent results with bracing; however, the follow-up review of these patients by Carr et al.<sup>92</sup> indicated loss of correction the longer patients were off the brace. Finally, Emans et al.<sup>93</sup> reported on the effectiveness of part-time bracing as opposed to the tried-and-true full-time approach. A misrepresentation of who the braced group is compared with the control group may be a serious flaw in the interpretation of many studies. One study indicated that patients prescribed a brace actually were compliant to only 10% of the prescribed time-in-brace.<sup>94</sup> Comparison studies between groups that were braced and those that were not often inadvertently compared typically highly progressive curves that were not braced with curves less likely to progress that were braced (e.g., thoracic curves for nontreatment versus thoracolumbar curves that

were braced). This bias toward bracing curves less likely to progress gave an unfair success ratio to the braced groups. A small group study and review of the literature by Goldberg et al.<sup>95</sup> suggests no difference between braced and nonbraced skeletally immature adolescent girls. The Iowa Group report of 1996 indicated that it is still impossible to clearly state that bracing alters the natural history of idiopathic scoliosis in immature patients at high risk for progression.<sup>96</sup>

Many orthopaedists and chiropractors will still make the choice to brace or refer for bracing. If bracing is used, the following two factors, based on the current literature, may be important in patient selection:

- 1.** Girls who were braced before and at the time of menarche had the best results. Those who were braced months or more postmenarche had the least success. It is suggested that for this latter group bracing is little more than a “holding” device. (This may be true for most braced patients.)
- 2.** The degree of curvature is crucial in determining the appropriateness of bracing. Curves less than 20° (and not progressing) probably will do as well without bracing. Curves greater than 40° are likely to lose substantial degrees of correction postbracing.

Therefore, girls who are at premenarche or menarche with curves in the 20° to 40° range have the greatest chance of success with bracing. It should be noted that although bracing was required for 23 hours a day in the past, bracing time is more commonly 16 to 18 hours with current prescriptions. A recent study indicated that bracing for 23 hours is more effective than the more commonly used 16- to 18-hour regimen.<sup>97</sup>

Bracing must be performed by an experienced orthotist at facilities that have experience in scoliosis brace

fabrication. They are given specific design specifications by the orthopaedist. The corrective principles with bracing are based on applying pressure at the apices. This cannot be done directly, so the corrective pad is applied to the rib attached to the apical vertebra in the thoracic region. This places the pad below the apex from a surface perspective. The lumbar pad is applied to the paraspinal muscles over the transverse processes. Corrective pads are attached to the shell of the brace. Braces such as the Milwaukee brace may also apply distractive forces with a large metal superstructure extending to the occiput.

There are basically four types of brace designs:

- 1. Thoraco-Lumbo-Sacral Orthosis (TLSO)** (also known as the Boston brace or “underarm” brace)—Fitted and custom molded from plastic. Basic principle is to apply three-point pressure to the curve.
- 2. Cervico-Thoraco-Lumbo-Sacral Orthosis** (also known as the Milwaukee brace)—Similar to the TLSO brace but also includes a neck ring held in place by vertical bars attached to the brace. Worn 23 hours a day, it can be removed for swimming, sports, or gym class. More often used for thoracic spine curves.
- 3. Charleston Bending Brace**—Called the “nighttime” brace because it is designed for limited use during sleeping. The brace is molded with the patient bending to the side thereby applying more pressure against the curve.
- 4. Dynamic Bracing** (e.g. SpineCor)—Unlike rigid braces, these flexible braces use a system of corrective bands to accomplish derotation and other corrective forces. The idea is to allow more spinal mobility while being braced. Early results suggest that it may be an option for patients with small curves around 20 degrees. In one study,<sup>98</sup> 48% of patients were corrected, 28% were stabilized, and 14% progressed. In another

study<sup>99</sup> for patients in the same severity range, it appeared that exercise fared as well as the SpineCor group with regard to curve improvement if determined as a change of 5°. The question of natural history is still unanswered due to lack of a control group.

A formal review by Rowe et al.<sup>100</sup> is similar to conclusions held by the Scoliosis Research Society—that the Milwaukee brace worn 23 hours is effective at halting progression. Lateral electrical surface stimulation was less effective than observation only. Wearing the brace for 8 to 16 hours a day was more effective than observation but less effective than 23 hours of use. In the brace manual for the Scoliosis Research Society, Rowe concludes from the available reviewed literature that curves kept under 45° tend not to progress over a lifetime. The average lifetime progression for braced curves was 7.9° compared to 23° in the untreated population. There was a subgroup that progressed more than 10° but this group could not be distinguished based on demographic indicators. He concludes that curves under 35° require full-time bracing. For curves greater than 40°, bracing will likely not be effective. A study published in 2013<sup>101</sup> demonstrated that for patients between the ages of 10 and 15 years, with a Risser grade 0, 1, or 2, and a Cobb angle between 20° and 40°, bracing was more effective at preventing progression to 50° (considered treatment failure in this study) when compared to an observation group. The success rate for bracing was 72% versus 48% in the observation group. This was dependent on length of time for wearing the brace. Although the mean time for brace wear was around 12 hours, those who wore the brace less than 7 hours had a treatment success equal to the observation group versus a 90% to 95% success rate for those who wore the brace around 13 hours per day.

One study by Katz and Duranni<sup>102</sup> indicated that 36% of a group of braced patients needed surgery. It would seem that

for those patients in whom bracing is helpful the outcome is quite optimistic; however, not all braced patients will have success.

---

## **Exercise**

It is still debated as to whether specific exercises alter the natural course of idiopathic scoliosis. A number of small studies by Weiss<sup>103,104</sup> indicate a potential; however, no large trial has demonstrated a significant difference between exercise versus natural history. In fact, a recent Cochrane review<sup>105</sup> concluded that there was insufficient evidence and that only one low-quality study suggested that exercises may be more effective than electrostimulation, traction, and postural training to avoid scoliosis progression. It is agreed that exercise as a single-therapy approach is not successful in reversing or slowing the progression of scoliosis. It is agreed that exercises are a necessary adjunct to bracing therapy with a focus on abdominal strengthening, strengthening of the muscles on the convex side of the curve, and stretching of the muscles on the concave side. An interesting study published a number of years ago by Mehta<sup>106</sup> indicated that the use of an active side-shift exercise had a beneficial effect on small curves. The exercise, called the side-shift, involves shifting the trunk (without laterally bending or rotating) away from the curve convexity as far as the spine will allow, holding for 10 seconds, and then relaxing. This is prescribed as an “as often as possible” exercise.

## **Chiropractic Adjustments**

Four general concepts are used in defense of chiropractic manipulative treatment of scoliosis, as follows:

1. By freeing up movement at each segmental level, the spine is kept more flexible and scoliosis is less likely to progress.
2. By a reflex reaction, adjusting (manipulation) of the cervical spine may influence righting reflexes in an effort to balance the spine.
3. Removal of segmental dysfunction may eliminate sources of aberrant sensory input and consequent output problems such as pain and accompanying muscle spasm. Proprioceptive input would then be normalized, providing an appropriate database for higher cortical decisions of body positioning.
4. By leveling the pelvis and sacrum, a scoliosis can be corrected. It has been demonstrated previously, however, that although contributory, an unlevel pelvis or sacrum is not the cause of an idiopathic curve. If this were so, the first curve to develop would be a lumbar compensation followed by a thoracic curve. Another archaic belief is that by adjusting the apical vertebra toward the concavity the curve may be lessened. Force applied at this level would have to be applied for long periods of time (such as a brace) for any correction to occur. Viscoelastic tissue such as the spine has a tendency to return to its original shape unless a constant load is applied over long periods of time.

Troyanovich<sup>107</sup> has piloted a new approach to a thoracolumbar curvature based upon a determination of improvement radiologically using a sequential approach to correction based on the Codman's paradox principle (see [Chapter 7](#) on the shoulder; sequence of movement patterns influences achieved final position). The flexibility of the curve is evaluated with a focus on the order of corrective exercises and position for inverse posture spinal adjustments. After a standard anterior-to-posterior view is

taken, two follow-up views are performed with the patient attaining “corrective” positions in a predetermined sequence. One begins with thoracic translation and then thoracic lateral flexion. The second, a reverse in sequence, begins with thoracic lateral flexion followed by thoracic translation. The sequence that obtains the most correction is used in performing inverse posture adjustments and exercises. For example, if the neutral thoracolumbar view demonstrated right translation displacement of the thorax in relation to the pelvis and left lateral flexion malposition of the thorax in relationship to the pelvis, and if correction is most apparent with the sequence of right thoracic lateral flexion followed by left thoracic translation, the patient would be instructed to perform exercises that emphasize this pattern. Adjustments would be delivered with the patient in this position of “correction,” usually using a drop table.

At this time there is no large-study research evidence (only a few isolated case reports) that chiropractic manipulative therapy (adjusting) affects the natural history of an idiopathic scoliosis. Certainly more research must be done to determine chiropractic’s role in scoliosis management.

Romano and Negrini<sup>108</sup> performed a systematic review for manual therapy as a conservative treatment for idiopathic scoliosis and had to concede that no conclusions could be drawn based on the current paucity and quality of the available literature. Goldberg,<sup>109</sup> in a review of the etiology, detection, and management for idiopathic scoliosis, believes that it is difficult to draw any conclusions based on the current evidence.

## **Surgery**

The use of surgery for AIS has been criticized recently with concerns that the tradeoff of complication rates to

prevention of progression is not always justified and that natural history effects are not as serious as assumed. A critical appraisal by Weiss and Moramarco<sup>110</sup> expressed concern that surgeons do not always fully explain the potential consequences and potential benefits with all patients. They concluded that the complication rates over a lifetime may reach as high as 50%. A rebuttal<sup>111</sup> to this article states that although informing patients of potential risks is important, the statistics used to arrive at a 50% complication rate were including patients who had received older forms of surgery. They conclude that the newer forms with pedicle screws are more stable and less inclined to require re-surgery. They cite recent evidence that the infection rate of acute infections for AIS range from 0.5–6.7% and late onset infection (>12 months) range from 2.77–4.7%.

It is beyond the scope of this discussion to give a detailed description or recommendation for specific surgical techniques. Some general principles are outlined. The two main goals of surgery are to: (1) straighten the spine in the coronal plane and correct for sagittal contour (kyphosis or lordosis), and (2) stabilize the spine through arthrodesis. Various surgeons have developed an array of instrumentation for these corrective procedures. The original Harrington rod implantation has been modified over the years. The rods are used for distraction to straighten the spine and for compression to correct for kyphosis if appropriate.<sup>109</sup> To add stability to the rods, sublaminar wiring (Luque) or spinous-process wiring (Drummond et al.<sup>113</sup>) was devised. The sublaminar wiring carries with it a risk of neurologic complication.<sup>114</sup> It also did not produce a significant advantage in correction or stability. The Cotrel-Dubousset instrumentation focuses on correction of the rotational component in an effort to decrease rib humping.<sup>115</sup> This is accomplished through a cross-linking that connects the two rods. The apparatus is relatively

stable in all planes.<sup>116</sup> Correction of sagittal plane deformity is at least as important as coronal correction. One study indicated that the Cotrel-Dubousset approach is successful in the correction and maintenance of sagittal plane deformity.<sup>116</sup> A 10-year follow-up study<sup>121</sup> of patients who had undergone surgery for idiopathic scoliosis with the Cotrel-Dubousset instrumentation found a very high rate of satisfaction. An interesting finding was that 45% of respondents indicated they had consulted a physician or physiotherapist for back pain during the last year before the follow-up.

It is finally feasible to test the long-term results of how AIS is managed. Studies have surfaced that measure quality of life, pain, and function in patients who have been managed either conservatively or with surgery. Taken together it appears as though 10 to as many as 60 years later, there are no significant differences. However, pain did seem to be a commonality for those with curvature progression and this was directly related to curve size.<sup>118-121</sup>

## Adult Scoliosis

Although the main focus of this chapter is idiopathic scoliosis in the growing patient, the adult patient may present with unique management problems that warrant discussion. Adult scoliosis may be a residual from earlier idiopathic development or may develop in later years.<sup>122</sup> If, in fact, idiopathic scoliosis is not part of the patient's history, a search for cause should include the following:

- Scoliosis may be due to reactive muscle spasm. When muscle spasm is the cause, any pain-provoking entity is possible. Common causes include reactions to vertebral disc and facet injuries, visceral disorders, and

spinal cord or nerve root involvement due to bony stenosis or tumor.

- Scoliosis may be due to degenerative and osteopenic disorders of the spine. When this results in instability, a mechanical (compensatory or buckling) scoliosis may develop.

It is important to consider that there are generally three periods in which scoliosis may be progressive: (1) infancy, (2) adolescence, and (3) after age 50 years. Past age 50 the most common causes are bone-softening disorders and degenerative instability. Although it is more common for scoliosis to be a residual to an earlier idiopathic or congenital beginning, it is possible for a new, progressive scoliosis to develop as a result of the above-mentioned structural disintegrations.

Adults have a higher incidence of nonflexible lumbar curves. In addition, pain is more likely to be a presenting complaint with adult scoliotic patients.<sup>123</sup> Some studies, however, demonstrate the incidence to be no higher than that in the general population.<sup>124</sup> If pain is reported, it is described as more of a dull, aching sensation or a sensation of fatigue in the area. Only with severe scoliosis have there been reports of direct nerve root compression.

Physicians traditionally have been instructed to be cognizant of several concerns. A brief description of each follows:

- Many physicians are concerned with cardiopulmonary function with an adult case. If the patient did not have difficulty as a child or adolescent, new problems are not likely to develop as an adult unless he or she smokes.
- Some investigators<sup>125</sup> suggest that an increase in mortality occurs with adult scoliosis. However, other studies<sup>126</sup> do not support this observation.

- Pregnancy is a concern due to the suspicion that the increase in weight and the hormonal influences of soft tissue relaxation will lead to progression. However, there is no indication that pregnancy acts as an accelerator of scoliosis development in the adult patient unless initially  $50^\circ$ .<sup>127</sup>
- Although progression of an adult idiopathic scoliosis curve is not as aggressive over short periods of time as an adolescent curve, progression may amount to  $1^\circ$  per year averaged over time, with the most progression occurring after age 50. Curves greater than  $50^\circ$  are more likely to follow this pattern, whereas curves of  $30^\circ$  and less are relatively stable.<sup>128</sup>

## Decision Making with Adult Scoliosis

Management decisions for the adult patient with scoliosis are directed by the same outcome desires as for the adolescent patient with scoliosis, but with different response factors. Adult scoliosis is not generally as progressive, the curves are generally less flexible, pain may be a consequence of the deformity and an equal or dominant concern of the patient, correction is less dramatic, and complications of surgery are much higher, running in the range of 30% to 60%.<sup>129</sup>

Balancing these positive and negative factors results in a consensus that the major concern is to reduce the pain component and prevent progression. Correcting the deformity is not a primary goal not only because it is more difficult but also because it is limited severely by the maturity of the spine, eliminating any adaptive structural changes and the accompanying secondary structural degenerative changes. The only component that is

amenable to correction is the soft tissue component, the functional component of the curve.

Conservative management focuses on pain amelioration and strengthening of spinal and abdominal muscles with caution in the osteoporotic patient, who should avoid flexion exercises. The postmenopausal osteoporotic patient should be given exercise and diet recommendations; however, the possibility of estrogen replacement therapy also should be discussed. Chiropractic manipulative therapy should be incorporated, but radiographic evidence of instability or osteopenia should alert the clinician to modify treatment approaches and refer the patient if unresponsive.

A formal system review of conservative treatment of adult scoliosis was performed by Everett and Patel.<sup>130</sup> They concluded that there is only Level IV evidence for physical therapy, chiropractic care, and bracing, and Level III evidence for injections. They state that the available literature does support further clinical research for conservative management.

## Algorithms

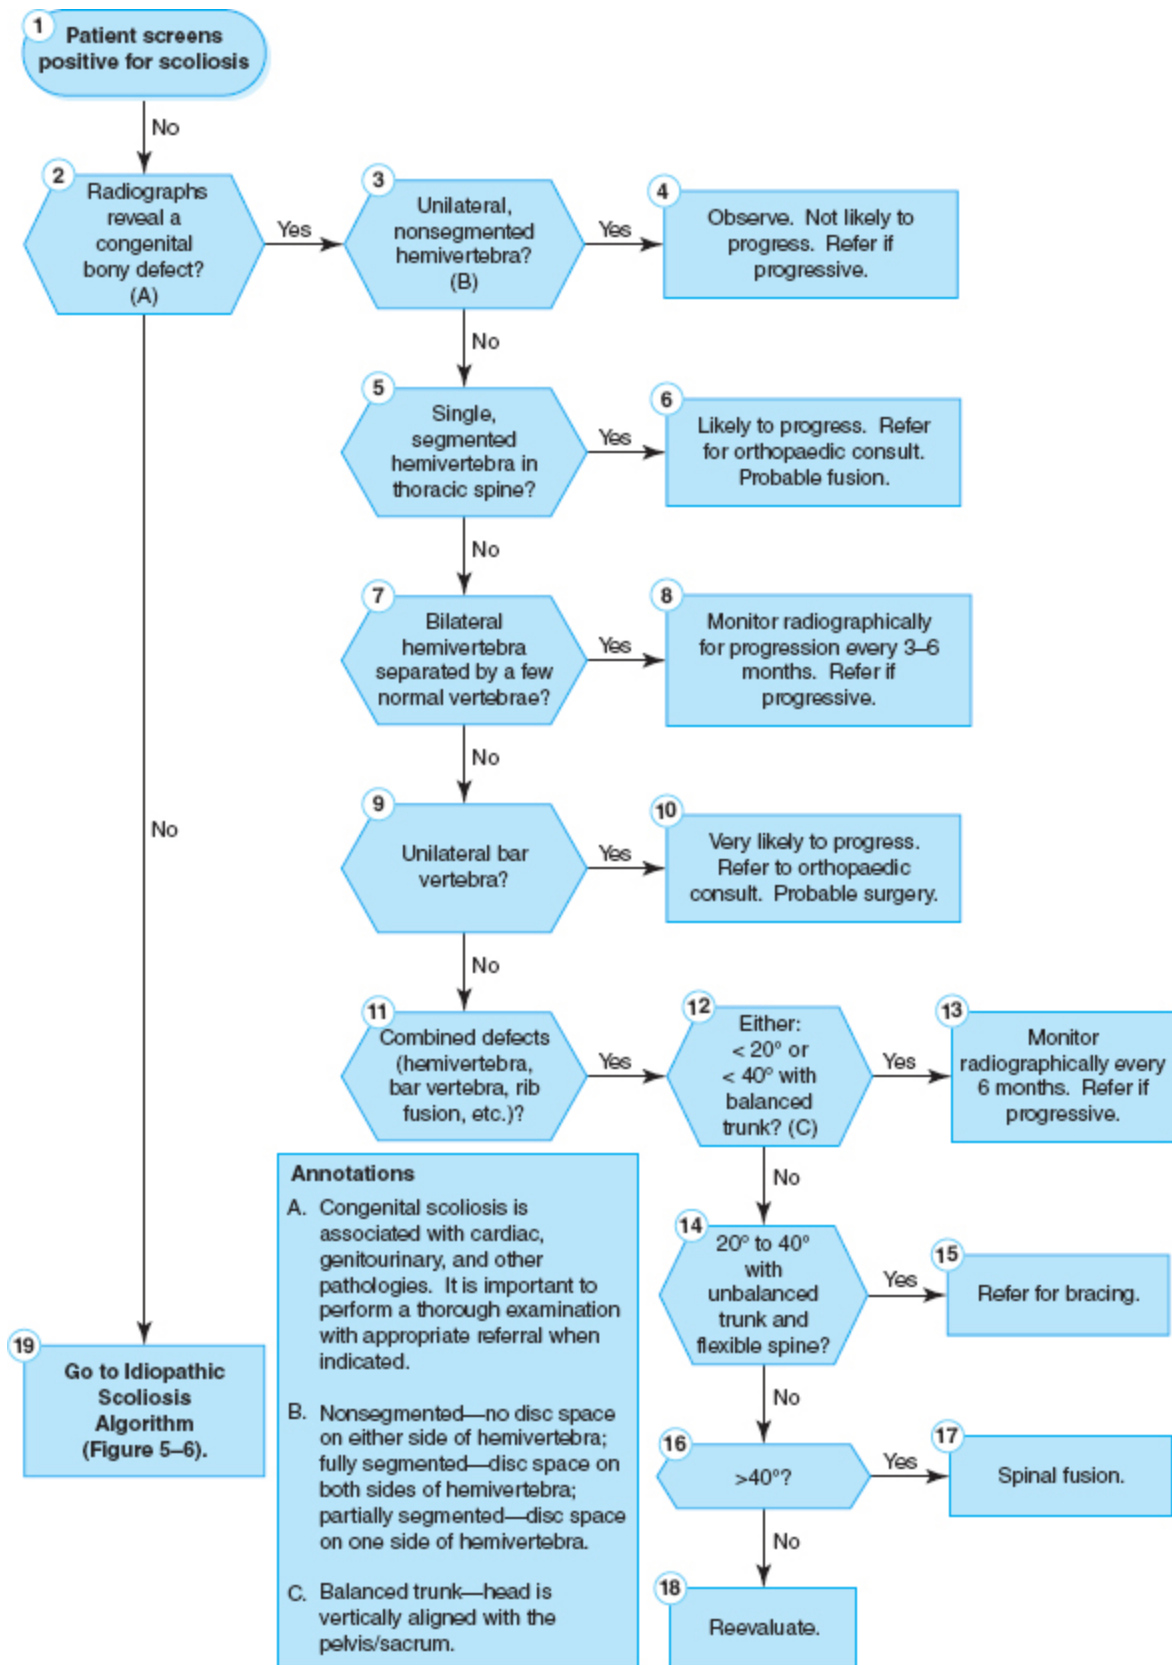

Algorithms for evaluation and management of congenital, idiopathic, and adult scolioses are presented in **Figures 5-5** through **5-7**.

## Summary

Understanding that not all scolioses are idiopathic focuses the examination first on identifiable causes. One of these causes is transient muscle spasm, which will present differently. In addition to contributing to back pain, the patient's scoliosis will not fit a typical pattern found in idiopathic scoliosis. Often there is little rotation or the

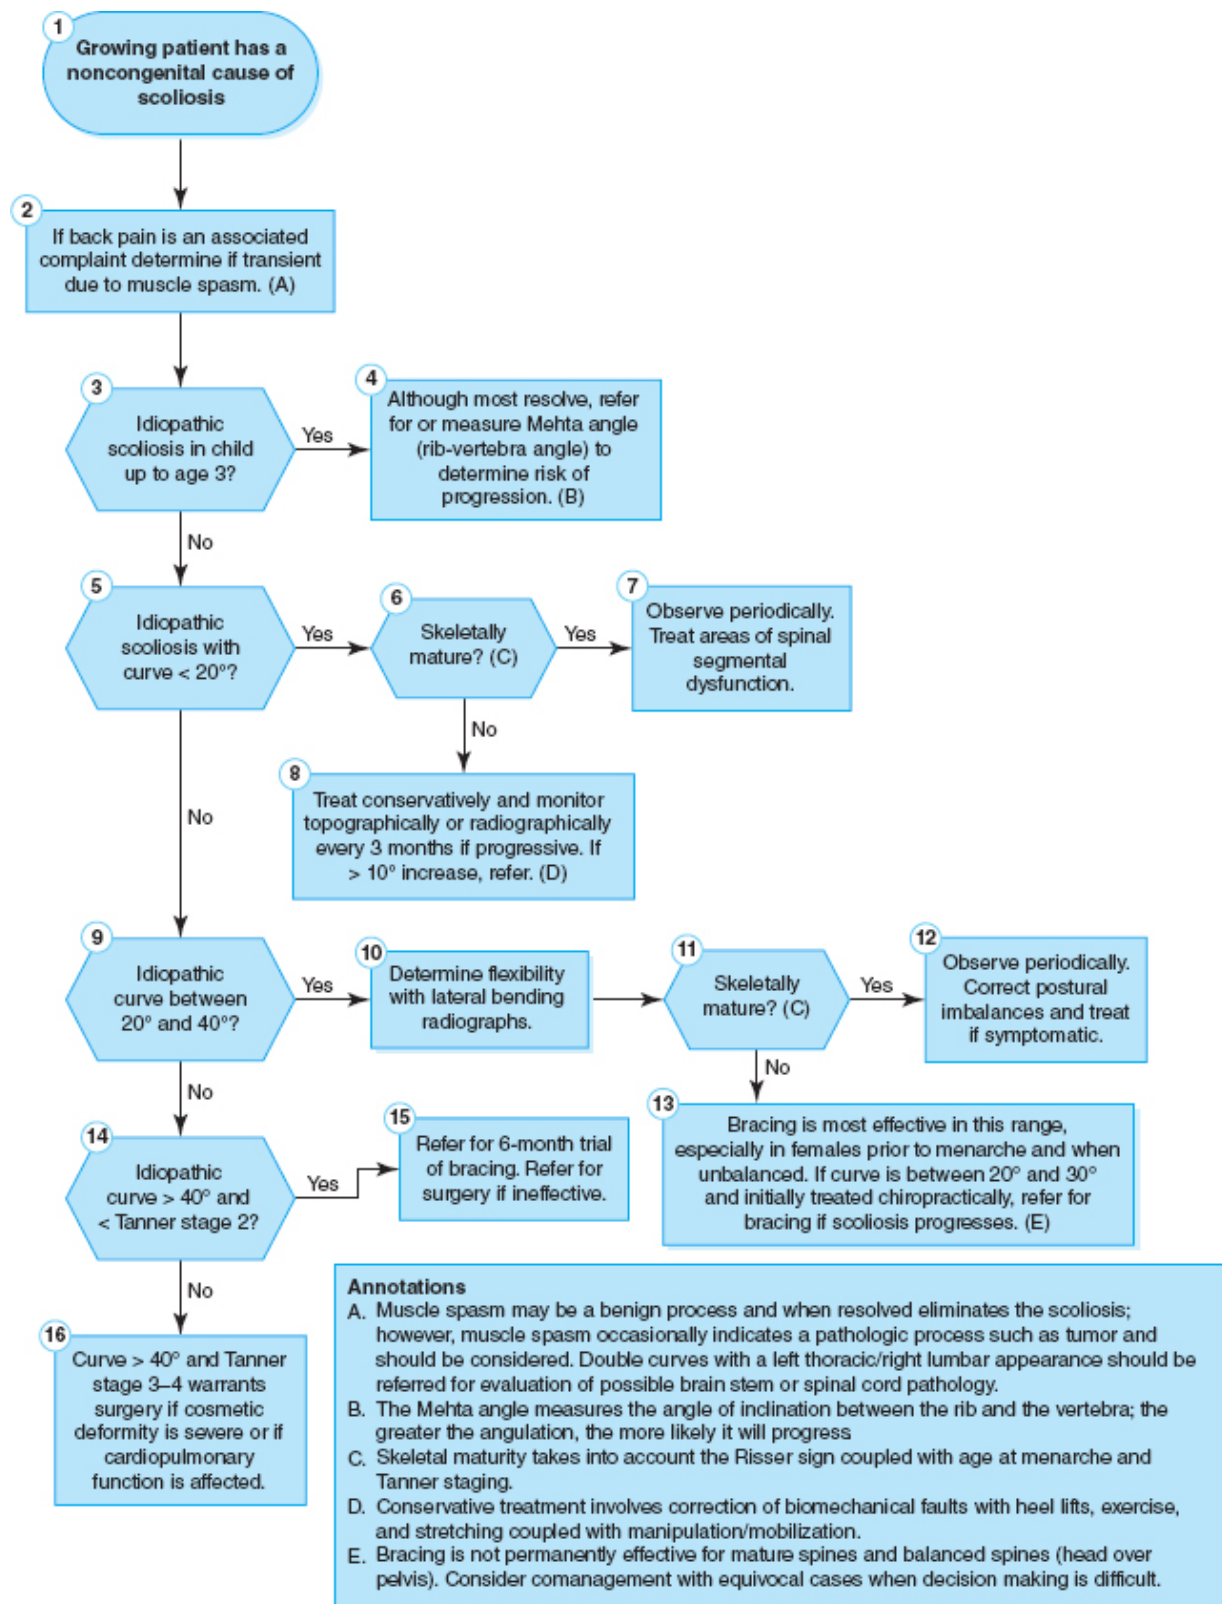

spinous processes rotate into the convexity. When these signs are present, it is likely that chiropractic care will be beneficial. If unresponsive, consider that muscle spasm may occur as a result of serious neurologic and other pathologic processes. When a double curve pattern is evident but the apical pattern is left thoracic/right lumbar, consider referral for evaluation of possible brainstem or spinal cord abnormalities.

With idiopathic scoliosis it is important for the chiropractor to realize that justification for treating a progressive scoliosis is indefensible. Using the factors of age, skeletal maturity, severity of the curve, and location, the clinician should be able to determine adequately when to treat and monitor and when to refer. In equivocal situations it is prudent to obtain an orthopaedic consultation.

# Lumbopelvic Complaints

## Context

Low back complaints account for a majority of presentations seen in chiropractic practice.<sup>1</sup> In the general population the estimated one-month prevalence for low back pain (LBP) is between 35% and 37%.<sup>2</sup> Approximately 80% of adults will have LBP at some time in their lives; however, only 14% will complain of pain lasting longer than two weeks.<sup>3</sup> It appears that adolescents with LBP are more likely to have problems as adults.<sup>4</sup> Although it is often quoted that 90% of patients with acute low back pain have resolution within four weeks (even without intervention), research indicates a more complicated natural history when viewed beyond the one-month window:

- Croft et al.<sup>5</sup> found that although 90% of patients had stopped consulting for LBP symptoms at three months, only 25% were symptom-free at one year.
- Von Korff<sup>6</sup> has shown that a significant amount of even acute LBP patients have persistent pain if followed for one to two years.
- Hestbaek and colleagues<sup>7</sup> systematically reviewed a number of papers and concluded that as many as 62% of patients will have one or more relapses during one-year follow-up of an index episode; 40% still with LBP at six months.<sup>8</sup> Initial relapses tend to occur at six- to

seven-week intervals with a decreasing number of cases suffering renewed pain each time.

- Schiotzz-Christensen et al.<sup>9</sup> looked at the longterm prognosis for acute low back pain in general practice and found that in relation to sick leave, there was a 50% return to work within the first eight days and only 2% remained on sick leave after one year. It was noted though that 15% had been on sick leave during the following year and about half continued to complain of discomfort.

This indication of chronicity and recurrence varies partly on the measures used to indicate recurrence. A recent study by Marras et al.<sup>10</sup> evaluated this variance. Two hundred and six workers who reported low back pain were interviewed one year after return to full duty. Return to work was measured based on recurrent low back pain according to symptom reports, medical visits, self-reported lost days, and employer-reported lost days due to back pain. By measuring recurrent symptoms, the rate was 58% ( $P = 0.0001$ ). Using medical visit as the recurrence criterion, the rate was 36% ( $P = 0.0001$ ). The recurrence rate for self-reported lost time was 15%. Using employer-confirmed lost time as the indicator of recurrence, the rate was only 10% ( $P = 0.0077$ ). Clearly, recurrence is dependent on the measure by which it is assessed. Of the 70% of individuals who have some back pain at some point in their lives, 25% will have symptoms of sciatica. The lifetime prevalence for lumbar disc herniation is between 1% to 5%.

In a study by Davis et al.<sup>1</sup> published in 2012, it was estimated that between the years 1997 and 2005, the total estimated expenditures for patients with spine problems in the United States increased 65%. Surgery for occupational back injury accounts for approximately 21% of these increased costs. Wasiak et al.<sup>2</sup> published in *Spine* in 2006 that 84% of total medical costs for LBP were related to

recurrence. Approximately 13.6 million patient visits for spine care occurred in 2008. Despite population growth, only approximately 6% of adults sought medical care for a spine-related condition. The mean inflation-adjusted expenditure for medical care increased by 95% (from \$487 in 1999 to \$950 in 2008). For chiropractic care, the mean expenditure varied much less, fluctuating between a low of \$473 in 1999 and a high of \$662 in 2007. The annual combined direct and indirect costs for low back pain were estimated at \$100 billion in 2000.<sup>11</sup> Clearly, given the current cost of health care, this amount has significantly increased.

Clinical determination of the specific tissue cause of LBP is often difficult, if not impossible. Literally any structure in the low back that is innervated could be a potential source of pain. Although clinically difficult, some diagnoses can be determined on the basis of a combination of radiographic or special studies. The traditional medical and chiropractic assumption of nerve root pressure as the primary source of low back and leg pain has not been supported in the literature. Clinically, only 1% of patients with LBP have neurologic deficits, and only one half of these patients elect for surgery.<sup>12</sup> Although the disc as a source of pain is still viable, the mechanism is rarely through compression of a nerve root. More often it is the result of an inflammatory process. Approximately 39% of patients will have LBP due to disc disruption.<sup>13</sup> Specifically, 5% of patients will have a disc herniation, 15% to 40% (dependent on study) will have facet involvement, 4% will have a compression fracture, 3% will have spondylolisthesis, and only 0.3% will have ankylosing spondylitis.<sup>14</sup> Malignant neoplasms account for only 1% of all causes of LBP.<sup>15</sup> Spinal infection accounts for only 0.01% of LBP cases.<sup>16</sup> Spinal stenosis represents what is considered a common cause in the older adult as a result of the above-mentioned disorders augmented by associated

congenital causes or acquired degenerative processes. The role of the sacroiliac (SI) joints in causing low back and/or leg pain has only recently begun to be investigated. However, for most chiropractors SI joint subluxation (fixation) represents a common cause of LBP that appears to respond dramatically to manipulation.<sup>17</sup>

The chiropractor's initial role is to identify the patient with "ominous" signs. The evaluation may require special studies or referral to a specialist. If these signs are absent, it is imperative to distinguish the patient with LBP alone or LBP with radiation into the leg(s). For patients with low back and leg pain, it is important to determine those with frank neurologic signs indicating nerve root irritation versus those with referral of pain (no nerve root pathology). Focusing on the assessment of functional and neurologic status, decisions regarding management, comanagement, type of treatment, and prognosis can be broadly determined.

The effectiveness of chiropractic manipulation in the treatment of LBP has been recognized in several ways. Several past studies have demonstrated the cost effectiveness of chiropractic care.<sup>18</sup> Patient satisfaction has also been demonstrated.<sup>19</sup> The level of satisfaction for patients seeking care from a chiropractor versus a medical doctor was evaluated in the UCLA Low-Back Pain Study.<sup>20</sup> Satisfaction with chiropractic care was rated higher compared to medical care. The primary difference in satisfaction was the perception that chiropractors communicated more, giving advice and information about their low back pain. The appropriateness of chiropractic management of LBP was recognized by the Rand study.<sup>21</sup> More recently, recommendations made by the Agency for Healthcare Research and Quality (AHRQ) guidelines strongly favor manipulation as the primary delivered care to patients with acute LBP. The British randomized study by Meade et al.<sup>22</sup> has set the stage for the defense of longterm effectiveness of chiropractic manipulative therapy for LBP. In

2006, the European Guidelines for Low Back Pain were published in the *European Spine Journal*. A summary of recommendations for acute nonspecific low back pain included manipulation.<sup>23</sup> A series of articles appeared in a 2008 full issue of the *Spine Journal* devoted to evidence-informed management of chronic low back pain. Manipulation with exercise was judged as having moderate support in the literature.<sup>24</sup>

## General Strategy

### History

- Screen the patient for “red flags” that indicate need for immediate radiograph/special studies or referral to a specialist: severe trauma, fever or recent bacterial infection, saddle anesthesia, severe or progressive neurologic complaints, recent onset of bladder dysfunction in association with the LBP, unexplained weight loss, prior history of cancer, intravenous drug abuse or immunosuppression, or pain that is worse with recumbency or worse at night.
- Determine whether there was a history of trauma and determine the mechanism and severity.
- Determine whether the complaint is LBP alone or a combination of LBP and leg complaints such as pain, numbness or tingling, or weakness.
- If there are leg complaints, determine whether they are made worse with coughing, sneezing, or straining at stool.
- Determine the level of pain and functional capacity with a questionnaire (e.g., Oswestry, Roland-Morris).

# Examination

- For patients with signs of cauda equina or rapidly progressing neurologic deficits, refer immediately for neurologic evaluation.
- For patients with suspected fracture (e.g., those in a motor vehicle accident, those who have fallen from a height, or those with osteoporosis), infection, or cancer, radiograph the area.
- For patients with LBP only, perform a thorough examination of the low back, including inspection, observation of patients' movements, palpation of soft and bony tissues, motion palpation of the spine, passive and active range of motion (using inclinometer or Schober method), functional assessment (e.g., Lewit/Janda and/or McKenzie approach), and orthopaedic examination.
- For patients with radiation of symptoms into the legs, add a thorough neurologic examination, including nerve stretch maneuvers, deep tendon reflexes, sensation testing (include pain, temperature, light touch, and vibration), and myotome testing.
- For patients with conflicting findings, inclusion of nonorganic testing may be helpful.
- Laboratory testing should be reserved for those patients suspected of having infection, cancer, or underlying diabetes.
- Patients with apparent multilevel neurological involvement should first undergo radiographic evaluation; consideration of computed tomography (CT) or magnetic resonance imaging (MRI) should be given if the patient is unresponsive to conservative care.
- If pain appears mechanical, the use of radiographs for three to four weeks can be delayed; however, if

information gained from a radiographic evaluation is likely to change the treatment approach to the patient with regard to a specific technique or management approach, radiographs have value as an initial evaluation tool.

- For patients who are unresponsive to care after one month, consideration should be given to the use of MRI, CT, or electrodiagnostic studies.

## Management

- Patients with clinical, radiographic, or laboratory evidence of tumor, infection, or fracture (other than a stable compression fracture) should be sent for medical evaluation and management.
- Patients who appear to have a mechanical cause of pain should be managed conservatively for one month; if unresponsive, further testing or referral for a second opinion is suggested.

## Relevant Anatomy, Physiology, and Biomechanics

Many studies have attempted to localize tissues responsible for LBP and to determine where the pain is felt with regard to each of these structures. Approaches have included various relief and provocative injections, electrical stimulation, and pulling on surgically implanted strings, among others. It seems clear that when sciatica is present, it can occur only if the nerve root is already compromised by stretch, swelling, or compression.<sup>25</sup> This does not mean that sciatic pain cannot be mimicked by other tissues. Certainly, the intervertebral disc is a potential source of pain that in and of itself may lead to segmental referral of pain without

frank neurologic findings (discussed below under “The Disk”). **Exhibit 6-1** illustrates the innervations of deep spinal structures including the disc, annulus, dura, posterior longitudinal ligament, and facet joints. The vascular structure for the dorsal root ganglia (DRG) includes primarily an internal arterialization with a superficial venous drainage. This anatomical arrangement may render the DRG vulnerable to ischemic consequences of external pressures and/or internal edematous swelling. A compartment-like syndrome may develop due to perforaminal degenerative changes or other space-occupying effects.<sup>26</sup>

### **The Three-Joint Complex**

There are essentially three joints at each functional segment of the spine: the intervertebral joint and the two-facet or zygapophyseal joints. Kirkaldy-Willis<sup>27</sup> proposed a model of progressive dysfunction with regard to this three-joint complex whereby a shared functional relationship exists. The typical vertebra is composed of a body connected to a posterior arch via superiorly placed pedicles. The pedicles form the upper roof of the neural foramen. The vertebral canal is formed by the body, pedicles, and posterior arch. This canal can be congenitally narrowed or narrowed through acquired projection of osteophytes or disc material or by thickening of the ligamentum flavum. The flaval ligaments serve as the attachments between adjacent laminae.

**Exhibit 6-1 Innervation of Deep Spinal Structures. The deepest structures are innervated by the sinuvertebral nerve (SVN) including the posterior annular fibers of the disc, the dura, the posterior longitudinal ligament, and the vertebral body. The posterior branch of the posterior primary**

**rami (PPR) innervates the facet joints. The SVN has an anastomosis with the opposite side leading to the conscious perception of central pain when irritated. The facet joints are innervated by branches of the PPR that span several segments. Pain is more likely perceived as more localized and sided (i.e. right versus left). These deeper structures represent sclerotogenous innervations which may lead to radiation of pain that is not radicular (e.g. non-dermatomal).**

Recurrent Meningeal Nerve (Sinuvertebral Nerve)

- Posterior vertebral body & internal and basivertebral veins
- Posterior longitudinal ligament (PLL) and posterior intervertebral disc (IVD)
- Anterior dura

Medial Branch of the Posterior Primary Rami (PPR)

- Facet joints & periosteum of posterior vertebral arch
- Deep muscles
- Interspinous, supraspinous, & intertransverse ligaments
- Ligamentum flavum

Sympathetic Trunk & Gray Rami Communicantes

- Anterior & lateral vertebral body
- Anterior & lateral aspects of intervertebral disc (IVD)
- Anterior longitudinal ligament (ALL)

## Neurology of the Disc and Deep Structures

The innervation of the lumbar area is primarily from the posterior ramus of the spinal nerve. The sinuvertebral nerve (also called recurrent meningeal nerve or nerve of Luschka) supplies the periosteum, posterior longitudinal ligament, the outer fibers of the annulus fibrosus, and the epidural vessels. There is a diffuse arrangement of anastomosis over several segments that may explain why localization to a specific level or side is difficult.

Discogenic pain is often sympathetic pain mediated by the sinuvertebral nerves. In numerous studies<sup>28</sup> in the rat

model, lower lumbar discs and joint capsules have been demonstrated to be innervated by sensory neurons from the L1 and L2 dorsal root ganglia through the paravertebral sympathetic trunk. Also it has been demonstrated by Unimura et al.<sup>29</sup> that there is a “hole” in the segmental sensory innervation of L3 through L5 and that through the rami communicantes afferent information from these levels reaches the L2 spinal ganglion via the sympathetic chain; not from segmental dorsal root ganglia at each level of L3, L4, and L5. The afferent fibers are primarily nociceptive; the efferent fibers primarily vasomotor.

Also, Wakai et al.<sup>30</sup> have clearly demonstrated in the rat model that nerves that were thought to travel to a single structure can travel to other structures. Nerve cell bodies located in the DRG send two branches: one to the primary structure and the other to related structures. The sensory nerves that travel to the facet joints, SI joints, and IVD may also travel to the multifidi muscles. Although about 83% of fibers did not dichotomize, of the remaining 17% that do about 7% are from the facets, 7% from the SI joints, but only 3% from the IVDs. Also, Samedia et al.<sup>31</sup> demonstrated that in rats, sensory nerves to the facet joints also travel to the sciatic nerve. This likely explains why referral pain mimics radicular pain.

## **The Disc**

The lumbar intervertebral disc (IVD) is essentially divided into two parts: (1) an inner nucleus pulposus, and (2) an outer annulus fibrosus. The annulus fibrosus fibers cross each other at angles of 60° to 70° in successive layers, providing a strong resistance to rotational forces. Resistance to flexion and extension is strong with the nucleus pulposus bulging posteriorly on flexion while the annulus fibrosus bulges anteriorly.

The disc has been accused of being one of the major causes of LBP. It appears that it may play more of a primary role than that of direct compression of nerve roots. The outer third of the annulus fibrosus is supplied with nerve endings from branches of the sinuvertebral nerves, the gray rami communicantes, and the lumbar ventral rami.<sup>32</sup> Although it has been suggested that innervation is the result of ingrowth of granulation tissue only after disc injury, it has been demonstrated that the fetal and infant disc are innervated.<sup>33</sup> Correlated with the finding of outer annulus innervation, it has been demonstrated using discography that inner tearing of the annulus causes less pain than tearing that extends to the outer third of the annulus. Also, it has become clear that intervertebral discs do not fail by prolapsing (nucleus pulposus herniation). Even if an experimentally induced tear is created in the annulus, the nucleus does not herniate. Repeated flexion and extension also fail to induce herniation in partially herniated discs. Compression at the disc is more likely to result in vertebral end-plate fracture. It has been proposed that because the nucleus pulposus is without blood supply and therefore segregated from the body's immune system, end-plate fracture (exposure to the vertebral spongiosa) or prolapsed nuclear material that reaches the epidural space induces an immune response. Proteoglycans of the nucleus are, in essence, foreign material. The resulting immune inflammatory response causes further degradation of the nuclear matrix. It has been proposed that exposure of the nucleus pulposus to the vascular supply of the area activated the release of matrix metalloproteinases (MMPs). These include collagenases, gelatinase, stromelysin, and elastase. Now these are termed MMP-1, MMP-2, MMP-3, and MMP-12 respectively. This process is terminated by tissue inhibitors of metalloproteinases (TIMPs). MMP/TIMP balance is essential for restoring balance.

This degradation changes the biomechanical support provided by the nucleus. Also, erosion of the annulus fibrosus along radial fissures may occur. This inside-out process is referred to as “internal disc disruption.” The combination of denaturing of the nucleus with loss of its normal cohesiveness and the erosion of the annulus may set the stage for the rare occurrence of herniating nuclear material with subsequent irritation or compression of nerve roots. Disc degeneration is associated with obliteration of the normal anastomosing arteries in the posterior longitudinal ligament with increased vascularity of the annulus (vertical orientation connecting to adjacent vertebrae).<sup>34</sup> Regression analysis demonstrated that these vascular changes occur prior to disc degeneration.

When the disc material is large enough to compress a nerve root, frank neurologic signs become evident. However, the most recent theory is that the herniated disc material causes more often an inflammatory reaction due to the release of irritating substances and/or as the result of an autoimmune inflammatory reaction.<sup>35</sup> A recent study<sup>36</sup> supported the growing opinion that disc herniations usually have a natural course of self-reduction through shrinkage. In this study, approximately 63% of patients had a natural reduction in the size of the disc herniation. The belief is that through resorption (caused by lack of nutrient supply), desiccation, and/or phagocytosis, the size of many disc herniations reduces over time. The old belief that herniations regress back into the annulus has not been supported. It is also true that in many cases where resolution of clinical symptoms occurs, there is no change in the size of the herniation.<sup>37</sup> When a disc “herniates” it can either be contained (annulus fibers are intact) or not contained (outer annulus failure allows prolapse into the vertebral canal). The terminology used to describe variations on this basic distinction is often confusing. Depending on whether the describer is a radiologist or a

clinician, the same term may be used to describe different events, or a different classification system entirely may be developed.

## The Facets

The facet joints of the lumbar spine allow a fair degree of flexion and some extension. Lateral bending and rotation are restricted by the mainly sagittal orientation of the facets. The orientation of segments L1-L4 has been compared to a J shape, where the anterior portion is oriented more medially. The L5-S1 facets are essentially coronal, allowing more freedom in flexion with rotation resisted by the iliolumbar ligaments. Facet tropism is a congenital anomaly in which there is a turning of the orientation of the facet articulation so that a facet that should be more sagittal, for example, is more coronal. Tropism is common, being found in 21% to 37% of the entire population, most occurring at the L4-L5 or L5-S1 facets.<sup>38</sup> Although this must alter biomechanics at that segmental level, it has not been demonstrated to cause a higher incidence of LBP in patients who have it. The facets take up approximately 16% to 18% of compressive loading on the lumbar spine; however, the facets accept approximately 33% of the shear force across a segment.<sup>39</sup>

The medial branch of the dorsal rami innervates the facets.<sup>40</sup> Thus, there is a unilateral distribution with some overlap between the inferior facets above and the superior facets below the segment. In other words, each facet theoretically has innervation from at least two levels. Therefore, it is theoretically possible for somewhat more localization to occur when the facet joint is the site of pain production as opposed to deeper pain-producing tissue that has an anastomosis innervation via the sinuvertebral nerve. The medial and lateral branches of the dorsal rami

innervate the posterior muscles. Although the facet joints are possible sources of LBP, it is worth noting that facet joint blocks have been associated with a high placebo response rate (as much as 32%);<sup>41</sup> yet facet dysfunction seems to account for a significant number of low back complaints.

Degeneration of the facet proceeds from a nonspecific synovial reaction. Both distention of the joint capsule and degeneration of the hyaline cartilage that covers the facets follow, allowing for ligament laxity. The result is a joint that may potentially subluxate and cause narrowing of the lateral canal. If the process continues, older patients may have inferior facet enlargement that often occurs in a medial direction, causing central canal narrowing.

Osteophytic superior facets usually project in an anterior direction to produce narrowing of the lateral recesses. Each process is a potential source of nerve root compression.

In addition to possible contribution to LBP through laxity of the joint capsule or bony hypertrophy with possible compressive effects, another possible facet pain source is the trapped meniscoid.<sup>42</sup> The meniscoid is an intra-articular joint inclusion that may become caught between the articular surfaces. It has been proposed that manipulation releases the meniscoid—relieving LBP.

## Ligaments and Muscles

It is interesting that there are few ligaments in the lumbar region. The supraspinous ligament does not exist below L3 and above this level represents more or less the aponeurosis of the erector spinae or latissimus dorsi.<sup>43</sup> The interspinous ligament represents more of a tendinous extension of the erector spinae. Even the iliolumbar ligament is primarily muscle before age 30 years. The posterior longitudinal ligament is less broad than it is in the cervical region, posterolateral disc migration.

In simple terms, the muscles of the lumbar spine are divided into three layers: (1) those passing inside the ribs, (2) those passing outside the ribs, and (3) an intermediate layer. All three layers are supplied by the anterior primary rami with the exception of the erector spinae group, which is supplied by the posterior primary rami. The innermost layer is primarily composed of flexors such as the psoas. The intermediate layer is composed of the quadratus lumborum and the internal and external intercostal muscles. The erector spinae group is subdivided into three layers. Unlike the thoracic region, the lumbar region has no deep rotators. The multifidus in the middle layer of the erector spinae group attaches from the laminar and mammillary processes to the spinous processes of the vertebrae several levels above.

## Biomechanics

As mentioned above, flexion is the most accessible movement pattern. Some extension and lateral bending are allowed; however, they are blocked by soft tissue and posterior joint orientation. Very little rotation occurs and is left primarily to the thoracic spine. When single-plane movements occur, there are often coupled motion patterns. With lateral flexion, there is a coupled movement of the segment so that the spinous process rotates toward the same side.<sup>44</sup> Also, a small amount of flexion occurs at the segment if the lumbar lordosis is in effect. Without a lordosis, there is slight extension at the segment. This coupling pattern may vary with posture.<sup>45</sup> In other words, laterally bending in flexion is not the same as it is in neutral. Most important, some investigators feel that abnormal coupled patterns may occur during flexion or extension and may be a predictor of low back problems.<sup>46</sup>

When an individual flexes forward at the waist, the paraspinal muscles support the trunk eccentrically through the first 30° to 60° while the gluteals and hamstrings keep the pelvis locked. Then the gluteals and hamstrings relax (eccentrically contract) to allow the pelvis to rotate at the hips to allow further flexion. This may be limited by tension in the hamstrings. At full flexion, the paraspinals are relaxed, with support provided mainly by ligaments. Lifting from this position can damage ligaments or strain muscles.

It appears that there are two general mechanisms for the cause of disc herniation: (1) sudden loading with the spine in flexion, and (2) degenerative failure of the annulus from repeated or prolonged mechanical stresses.<sup>47, 48</sup> The side-posture manipulation has often been accused as a possible cause of disc herniation. It is likely, though, that the limitation imposed by the restriction of the posterior facets is sufficient to prevent excessive rotation at the disc; however, Slosberg<sup>49</sup> cautions the doctor that this is true only if the facets are loaded in extension by maintaining a lordosis and the degree of rotation is controlled by the adjuster.

## **Sacroiliac Joint**

The SI joint has, after much debate, regained the status of a true diarthrodial (synovial) joint capable of some movement.<sup>50, 51</sup> The joint is composed of an auricular-shaped surface with an upper vertical and a lower horizontal section. A synovial membrane covers the lower two thirds (ventral portion); the upper third (posterior) is mainly fibrous without synovial tissue. Stability is largely ligamentous. Movement has been described as nutation and counternutation. Nutation involves an anteroposterior movement around a transverse axis. Thus, when rising from a recumbent position, the sacral promontory moves forward

a few millimeters.<sup>52</sup> This also occurs unilaterally, so that when standing on one foot, the SI joint on the side of weight-bearing reaches maximum nutation. SI joint innervation is from a broad area including both sacral and lumbar plexuses (L3-S2). This may explain the varied presentation of referred pain patterns with SI joint involvement.

## Evaluation

### History

## Ominous Signs

Screening the patient for ominous signs can be performed quickly, yet relatively reliable information can be gained with regard to the need for further specialized evaluation or referral (**Table 6-1**). Cauda equina syndrome is a rare but serious condition. The most sensitive historical indicator is urinary retention (sensitivity = 0.90, specificity = 95%).<sup>53</sup> Therefore patients without urinary retention (or eventual overflow incontinence) are unlikely to have cauda equina syndrome. Although LBP is due to cancer only 1% of the time, it is obviously crucial to search for indicators of this possibility. Deyo<sup>53</sup> indicated in one study that the cancer patient will present with at least one of four historical findings: (1) older than age 50 (about 80% of patients with cancer-caused LBP), (2) previous history of cancer (specificity = 0.98), (3) unexplained weight loss, and (4) failure to respond to conservative therapy over a one-month period. It is important to remember, however, that only one third of patients eventually diagnosed with cancer as the cause of their LBP have a prior history of cancer (sensitivity = 0.31%). Another sensitive but nonspecific clue is that

most patients with cancer report pain that is unrelieved by bed rest.

When screening for the extremely rare occurrence of a spinal infection, it is important to ask about urinary tract infections, an indwelling urinary catheter during a recent hospital stay, injection of illicit drugs, and any indications of skin infection.<sup>53</sup> A fever is highly specific for infection; however, 2% of patients with mechanical back pain may have a fever (possibly virus-related).<sup>54</sup>

## Other Possibilities

In all older patients, a suspicion of compression fracture is warranted. The factor of age is most important for patients older than 70 years; the specificity is 0.96. Although it might seem logical that there would be a report of identifiable trauma, this finding has a low sensitivity (0.30); however, long-term corticosteroid use was highly specific (0.99). The sudden onset of pain with coughing, sneezing, or sudden flexion unassociated with radicular complaints should warrant a radiologic search for compression fracture.<sup>14</sup>

Combining four screening questions, a high level of suspicion may be gained for ankylosing spondylitis (AS): (1) Is there morning stiffness?, (2) Is there improvement in discomfort with exercise?, (3) Was the onset of back pain before age 40 years?, and (4) Has the pain persisted for at least three months? If at least three positive responses are given, AS should be suspected (sensitivity as high as 0.95 with specificity as high as 0.85).<sup>55</sup> However, it is always important to consider the predictive value, which is dependent on the prevalence of the disorder. Because AS is relatively rare, the positive predictive value is quite low (0.04).

**Table 6-1** History Questions for Low Back Pain

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Did you injure yourself (car accident, fall, lifting, etc.)?	Disc lesion, muscle strain, facet injury, fracture	Did you fall on your buttocks? Was this a sudden hyperflexion injury? Did the pain appear while lifting or with sudden twisting? Did you have a sudden extension injury?	Compression or coccygeal fracture  Disc lesion or muscle strain Facet injury
Does the pain continue into the buttocks or leg?	Disc lesion, tumor, stenosis, referral from facet or trigger point (TrP)	Does the pain extend below the knee?  Does the pain extend into the buttocks or to the knee?	Nerve root pain due to disc, stenosis, or tumor; facet and TrP are less likely Lumbar facet, SI joint, and TrP
Do you have any difficulty with urination or defecation?	Cauda equina syndrome, prostate disease, disc lesion (Valsalva effect), constipation	Do you have any numbness around the groin or genital area? Do you have leg pain when you defecate, cough, or sneeze? Do you have to urinate often and/or have difficulty stopping or starting?	Cauda equina syndrome Space-occupying lesion indicating tumor or disc lesion in most cases Prostate cancer is possible.
Is there associated abdominal pain?	Genitourinary cause, abdominal aneurysm	Is this associated with your menstrual period?  Does the pain radiate around to the groin? Is there associated weakness in the legs?	Dysmenorrhea (if severe consider endometriosis), pelvic inflammatory disease Kidney (infection or stone) Abdominal aneurysm
Is there marked weight loss?	Cancer, depression, diet	Do you have a past history of cancer, night pain, pain unrelieved with rest?	Cancer
Is there any weakness in the legs with activity?	Neurogenic or vascular claudication	Is it relieved quickly with rest? Is it better when flexed and/or relieved after 15–20 minutes of rest?	Vascular claudication Neurogenic claudication (canal stenosis)

## Low Back Pain with Radiation in the Leg(s)

One of the first historical discriminators between a disc and a referred (facet or muscular) source is whether or not the pain travels below the knee. Pain below the knee is suggestive of a disc lesion with nerve root irritation. Paresthesia or numbness is more commonly found with disc lesions than with referred causes, especially in the foot or ankle area. Patients with disc lesions often will have a history of recurrent episodes of back pain without leg pain.

It is likely that the patient will be between the ages of 30 and 50 years. This age range is due in part to the observation that the disc's nucleus pulposus dehydrates with aging, leaving little to herniate. The patient with a disc lesion may report a twisting injury accompanied by immediate leg pain. The leg pain is often more of a concern than the back pain. In the younger patient with a disc lesion, pain is often worse with sitting (due to increased disc pressure) and less with standing or walking. The older patient with leg pain is more likely to have compressive insult of a nerve root due to various forms of stenosis. The older patient has more difficulty with walking or standing because of the compressive effect created by the loading of the posterior elements (where most of the stenosis occurs).

In a study<sup>56</sup> published in 2013, a group of senior participants with low back pain and leg radiation were compared to determine if there were any findings that might help differentiate the cause. For patients identified as having a disc herniation as the cause, pain was experienced in the front of the thigh and shin more often. This reflects the finding that unlike a young population L3-L4 was one of the most common sites of herniation (40%). For patients with disc-related pain, unilateral leg pain was found in all, whereas for stenosis-related leg pain, bilateral leg complaints were found with 52% of patients. For patients with stenosis-related leg pain, they were more likely to experience pain in the posterior aspect of the knee.

## Other Factors

It is always important to screen the patient with regard to medication use. Oral corticosteroid use would suggest the possibility of a compression fracture. Anticoagulant therapy may suggest epidural or spinal cord bleeding.

Antidepressants may suggest an underlying psychologic

component, especially in the patient with chronic pain. Increased body weight has been shown to be a possible weak risk indicator for LBP.<sup>57</sup> What may be surprising to the general public is that cardiovascular risk factors are significantly and independently associated with symptoms of lumbar disc herniation.<sup>58</sup> Smoking is the most significant, with a dose-dependent effect; the more cigarettes per day the higher the risk. A series of studies by Kauppila et al.<sup>59-61</sup> indicate that the blood supply to the lower lumbar vertebra is at risk compared to higher lumbar levels. Vascular anastomotic networks between vertebrae become obliterated with age and this process is likely accelerated with the occlusive effects of atherosclerosis.

If the patient is injured in a work-related accident or is involved in personal injury litigation, it is important to gain an appreciation of the patient's attitude toward employment and the desire to obtain compensation. Patient questionnaires with regard to pain and functional capacity are important baseline data, especially with these patients.

## Questionnaires

Although it may seem logical that improvement is better measured with apparent objective findings through clinical examination, outcome measures through the use of questionnaires may prove to be more reliable and reproducible. Deyo<sup>62</sup> reviewed the reliability and reproducibility of outcome measures used in back pain trials. Standard measures such as range of motion and ankle dorsiflexion strength were far less reliable (0.50/1.00) than a questionnaire measuring the ability to perform daily activities (sickness impact profile—0.90/1.00) or pain measurement (visual analog scale [VAS]—0.94/1.00). Passive straight leg raising fared somewhere in between (0.78/1.00). The meta-analysis performed by Anderson and

Meeker<sup>63</sup> also demonstrated better correlation between “functional” outcome assessment tools (questionnaires) than objective measures.

For patients with LBP, there are a number of questionnaires available. Two of the most popular that have been demonstrated to be valid and reliable are the Oswestry Disability Index for Low Back Pain and the Roland-Morris Low Back Pain Questionnaire.<sup>64</sup> The Oswestry Questionnaire (**Exhibit 6-2**) is a simple tool utilizing only 10 sections with six possible answers for each.<sup>65</sup> The answer choices are rated from 0 to 5, ranging from less to more disability. A percentage disability can be calculated by scoring and adding the answer choices and multiplying by 2 (**Exhibit 6-3**). For example, if a patient marked five answers that indicated moderate disability (e.g.,  $3 \times 5 = 15$ ) and five for more severe disability (e.g.,  $4 \times 5 = 20$ ) multiplying the total by 2 ( $2 \times 35$ ) results in a disability of 70%. This value could then be used as a comparison for future improvement. The Roland-Morris Questionnaire (**Exhibit 6-4**) is a behavioral measuring tool for patients with low back pain.<sup>66</sup> The 24-item survey is simple for the patient to complete by marking each description that fits his or her perceptions. For example, one statement is: I find it difficult to get out of a chair because of my back. When all the marked statements are added together, a score is generated. The higher the score, the greater is the disability. Many doctors add a visual analog scale (VAS) to the Roland-Morris.

A recent shift in thinking regarding the use of questionnaires has been based on the observation that patients who develop chronic LBP impose an inordinate financial burden on society. It has also been observed that there are indicators and predictors of patients who develop chronic pain. The New Zealand guidelines for LBP contain a screening tool for what are termed “yellow flags” for psychosocial predictors of chronic pain (see **Figure 6-1**).<sup>67</sup>

The guidelines attempt to screen for these psychosocial factors and suggest strategies for more appropriate management of acute LBP in an attempt to decrease risk for the development of chronic LBP and associated disability. The questionnaire and strategies for intervention are given in **Exhibits 6-5** and **6-6**.

## **Exhibit 6-2 Oswestry Questionnaire**

### **Please read**

This questionnaire has been designed to give the doctor information as to how your back pain has affected your ability to manage in everyday life. Please answer every section, and mark in each section ONE BOX that applies to you. We realize you may consider that two of the statements in any one section relate to you, but please just mark the box that most closely describes your problem.

### **Section 1—Pain Intensity**

- My pain is mild to moderate: I do not need painkillers.
- The pain is bad, but I manage without taking painkillers.
- Painkillers give complete relief from pain.
- Painkillers give moderate relief from pain.
- Painkillers give very little relief from pain.
- Painkillers have no effect on the pain.

### **Section 2—Personal Care (Washing, Dressing, Etc.)**

- I can look after myself normally without causing extra pain.
- I can look after myself normally, but it causes extra pain.
- It is painful to look after myself, and I am slow and careful.
- I need some help but manage most of my personal care.
- I need help every day in most aspects of self-care.
- I do not get dressed; I wash with difficulty; and I stay in bed.

### **Section 3—Lifting**

- I can lift heavy weights without extra pain.
- I can lift heavy weights, but it gives extra pain.
- Pain prevents me from lifting heavy weights off the floor, but I can manage if they are conveniently positioned (e.g., on a table).
- Pain prevents me from lifting heavy weights, but I can manage light weights if they are conveniently positioned.

- I can lift only very light weights.
- I cannot lift or carry anything at all.

## **Section 4—Walking**

- I can walk as far as I wish.
- Pain prevents me from walking more than 1 mile.
- Pain prevents me from walking more than  $\frac{1}{2}$  mile.
- Pain prevents me from walking more than  $\frac{1}{4}$  mile.
- I can walk only if I use a stick or crutches.
- I am in bed or in a chair for most of every day.

## **Section 5—Sitting**

- I can sit in any chair as long as I like.
- I can sit in my favorite chair only, but for as long as I like.
- Pain prevents me from sitting more than 1 hour.
- Pain prevents me from sitting more than  $\frac{1}{2}$  hour.
- Pain prevents me from sitting more than 10 minutes.
- Pain prevents me from sitting at all.

## **Section 6—Standing**

- I can stand as long as I want without extra pain.
- I can stand as long as I want, but it gives me extra pain.
- Pain prevents me from standing for more than 1 hour.
- Pain prevents me from standing for more than 30 minutes.
- Pain prevents me from standing for more than 10 minutes.
- Pain prevents me from standing at all.

## **Section 7—Sleeping**

- Pain does not prevent me from sleeping well.
- I sleep well but only by using tablets.
- Even when I take tablets I have less than 6 hours sleep.
- Even when I take tablets I have less than 4 hours sleep.
- Even when I take tablets I have less than 2 hours sleep.
- Pain prevents me from sleeping at all.

## **Section 8—Sex Life**

- My sex life is normal and causes no extra pain.
- My sex life is normal but causes some extra pain.
- My sex life is nearly normal but is very painful.
- My sex life is severely restricted by pain.
- My sex life is nearly absent because of pain.

- Pain prevents any sex life at all.

## Section 9—Social Life

- My social life is normal and causes me no extra pain.
- My social life is normal but increases the degree of pain.
- Pain affects my social life by limiting only my more energetic interests (dancing, etc.).
- Pain has restricted my social life, and I do not go out as often.
- Pain has restricted my social life to my home.
- I have no social life because of pain.

## Section 10—Traveling

- I can travel anywhere without extra pain.
- I can travel anywhere, but it gives me extra pain.
- Pain is bad, but I manage journeys over 2 hours.
- Pain restricts me to journeys of less than 1 hour.
- Pain restricts me to short necessary journeys under 30 minutes.
- Pain prevents my traveling except to the physician or hospital.

## Exhibit 6-3 Scoring the Oswestry Questionnaire

The following are key points to scoring of the Oswestry:

- Generally, the patient fills out the questionnaire in approximately 5 minutes with scoring by the doctor taking approximately 1 minute.
- The patient attempts to mark the most relevant answer for each of the 10 sections.
- The scoring includes only those sections that have been marked by the patient.
- Scoring is on a scale of 0 to 5 with the first possible answer in the sequence being a “0” and the last in the sequence being a “5.”
- For each section, the maximum possible score is 5. The total score is calculated by adding all the scores together and dividing by the total possible number of points.

For example, if all sections were marked (i.e.,  $10 \times 5 = 50$  points) and the total points were 20, then the following calculation would be performed:

$$\frac{20 \text{ (total score/points)} \times 100}{50 \text{ (total possible score/points)}} = 40\% \text{ points}$$

If conversely only 8 out of the 10 sections were completed (i.e.,  $8 \times 5 = 40$  points) and the total points were 20, then the following calculation would be performed:

$$\frac{20 \text{ (total score/points)} \times 100 = 50\% \text{ points}}{40 \text{ (total possible score/points)}}$$

Although there is no real standard for the interpretation of these percentage points, the following is a commonly used reference for interpretation:

<b>Percentage Points</b>	<b>Degree of Disability</b>
0-20% points	Minimal disability
21-40% points	Moderate disability
41-60% points	Severe disability
Over 60% points	Patient is severely disabled due to pain in several aspects of life

A standard approach is to administer the questionnaire over time to determine changes in perceived function. An improvement in the index indicates an improvement in the patient's perception of function and may indicate changes not necessarily reflected in objective orthopaedic or neurological testing.

## **Examination**

# **General Evaluation**

Examination "red flags" include the following:

- The patient has saddle paresthesia (cauda equina).
- Weight loss in an older patient with a prior history of cancer and associated neurologic findings on examination suggest cancer.

- Fever (specificity = 0.98) associated with spinal tenderness to percussion (percussion sensitivity = 0.86) suggests spinal infection in a patient who has a history of intravenous drug usage, has a urinary tract infection, or is immunocompromised.

### **Exhibit 6-4 Roland-Morris Low Back Disability Questionnaire**

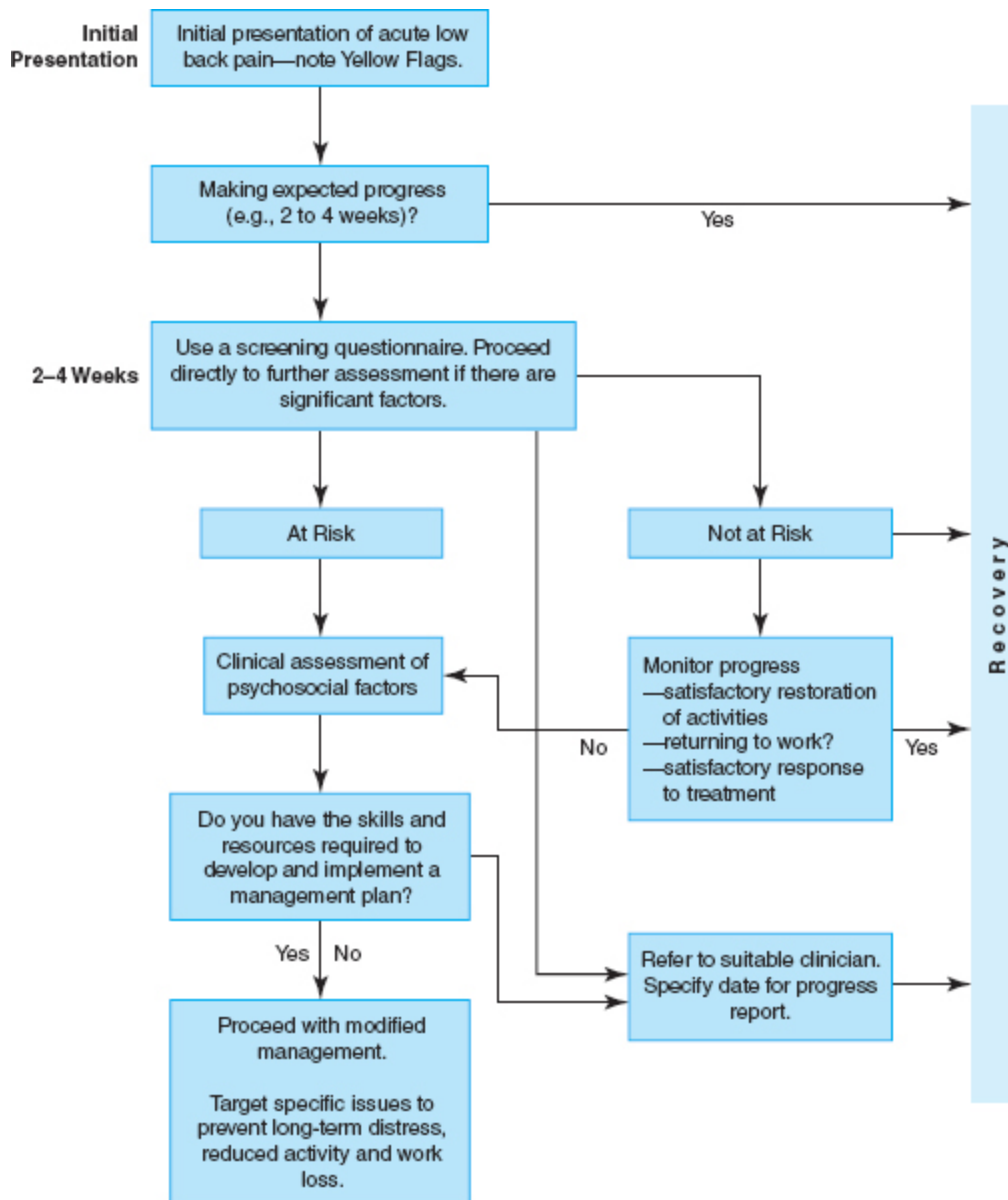

**Instructions** When your back hurts, you may find it difficult to do some of the things you normally do. This list contains some sentences that people have used to describe themselves when they have back pain. When you read them, you may find that some stand out because they describe you *today*. As you read the list, think of yourself *today*. When you read a sentence that describes how you feel *today*, check the box next to it. If the sentence does not describe you, then leave the box blank and go on to the next one. Remember, only check the sentence if you are sure that it describes you today.

- ☐ 1. I stay home most of the time because of my back.
- ☐ 2. I change position frequently to try to get my back comfortable.
- ☐ 3. I walk more slowly than usual because of my back.
- ☐ 4. Because of my back, I am not doing any of the jobs that I usually do around the house.
- ☐ 5. Because of my back, I use a handrail to get upstairs.
- ☐ 6. Because of my back, I lie down to rest more often.
- ☐ 7. Because of my back, I have to hold on to something to get out of an easy chair.
- ☐ 8. Because of my back, I try to get other people to do things for me.
- ☐ 9. I get dressed more slowly than usual because of my back.
- ☐ 10. I only stand up for short periods of time because of my back.
- ☐ 11. Because of my back, I try not to bend or kneel down.
- ☐ 12. I find it difficult to get out of a chair because of my back.
- ☐ 13. My back is painful almost all the time.
- ☐ 14. I find it difficult to turn over in bed because of my back.
- ☐ 15. My appetite is not very good because of my back.
- ☐ 16. I have trouble putting on my socks (stockings) because of the pain in my back.
- ☐ 17. I only walk short distances because of my back pain.
- ☐ 18. I sleep less well because of my back pain.
- ☐ 19. Because of my back pain, I get dressed with help from someone else.
- ☐ 20. I sit down for most of the day because of my back.
- ☐ 21. I avoid heavy jobs around the house because of my back.
- ☐ 22. Because of my back pain, I am more irritable and bad tempered with people than usual.
- ☐ 23. Because of my back, I go upstairs more slowly than usual.
- ☐ 24. I stay in bed most of the time because of my back.

Rate the severity of your pain by checking one box on the following scale.

0	1	2	3	4	5	6	7	8	9	10
NO PAIN					UNBEARABLE PAIN

The scope of the orthopaedic-neurologic examination often can be based on the distribution of a patient's complaint and a suspected underlying cause. The patient with LBP only (i.e., no leg pain) warrants an examination designed to determine whether the pain is reproducible and to what extent there is limitation in range of motion and/or function. If the pain is not reproducible mechanically, further tests to evaluate visceral possibilities such as genitourinary

causes should be performed. Patients with radiation into the leg(s) must be categorized into those with nerve root lesions and those with referred signs or symptoms. The primary distinction between these two broad categories is that patients with referred etiologies would rarely have hard neurologic evidence. For example, although the pain projection is in the distribution of the sciatic nerve, patients with referred causes often will have pain that does not extend below the knee. In addition, patients with referred pain would be highly unlikely to demonstrate myotome weakness, dermatome sensory abnormalities, or a decrease in reflexes (**Figure 6-2**).

It would seem logical that the clinical examination for radiculopathy (i.e., nerve root or spinal nerve compression) would be based on two principles: (1) reproduction of the radiation through mechanical maneuvers (i.e. orthopaedic testing), and (2) objectively determining neurological deficit, the result of nerve damage (i.e., the neurological examination). However, recent reviews examining the value of the orthopaedic and neurological evaluation of patients with radiating complaints have revealed some consensus that may be different from what is taught and assumed by practitioners based on this logic.

Flags in Acute Low Back Pain: Risk  
Factors for Long-Term Disability and Work  
Loss**

**PATIENT INFORMATION****SCREENING QUESTIONNAIRE (Linton & Halldén 1996)**

Name: \_\_\_\_\_ ACC Claim Number: \_\_\_\_\_

Address: \_\_\_\_\_ Telephone (Home):(0) \_\_\_\_\_

\_\_\_\_\_ Telephone (Work):(0) \_\_\_\_\_

Job Title (Occupation): \_\_\_\_\_ Date stopped work for this episode: \_\_\_\_/\_\_\_\_/\_\_\_\_

These questions and statements apply if you have aches or pains, such as back, shoulder or neck pain. Please read and answer each question carefully. Do not take too long to answer the questions. However, it is important that you answer every question. There is always a response for your particular situation.

1. What year were you born? \_\_\_\_\_
2. Are you:  
☐ male    ☐ female
3. Where do you have pain? Place a check (✓) for all the appropriate sites.  
☐ neck    ☐ shoulders    ☐ upper back    ☐ lower back    ☐ leg
4. How many days of work have you missed because of pain during the past 18 months? Check (✓) one.  
☐ 0 days [1]    ☐ 1–2 days [2]    ☐ 3–7 days [3]    ☐ 8–14 days [4]    ☐ 15–30 days [5]  
☐ 1 month [6]    ☐ 2 months [7]    ☐ 3–6 months [8]    ☐ 6–12 months [9]    ☐ over 1 year [10]
5. How long have you had your current pain problem? Check (✓) one.  
☐ 0–1 weeks [1]    ☐ 1–2 weeks [2]    ☐ 3–4 weeks [3]    ☐ 4–5 weeks [4]    ☐ 6–8 weeks [5]  
☐ 9–11 weeks [6]    ☐ 3–6 months [7]    ☐ 6–9 months [8]    ☐ 9–12 months [9]    ☐ over 1 year [10]
6. Is your work heavy or monotonous? Circle the best alternative.  
Not at all    0    1    2    3    4    5    6    7    8    9    10    Extremely
7. How would you rate the pain that you have had during the past week? Circle one.  
No pain    0    1    2    3    4    5    6    7    8    9    10    Pain as bad as it could be
8. In the past three months, on average, how bad was your pain? Circle one.  
No pain    0    1    2    3    4    5    6    7    8    9    10    Pain as bad as it could be
9. How often would you say that you have experienced pain episodes, on average, during the past 3 months? Circle one.  
Never    0    1    2    3    4    5    6    7    8    9    10    Always
10. Based on all the things you do to cope, or deal with your pain, on an average day, how much are you able to decrease it? Circle one.  
Can't decrease it at all    0    1    2    3    4    5    6    7    8    9    10    Can decrease it completely
11. How tense or anxious have you felt in the past week? Circle one.  
Absolutely calm and relaxed    0    1    2    3    4    5    6    7    8    9    10    As tense and anxious as I've ever felt
12. How much have you been bothered by feeling depressed in the past week? Circle one.  
Not at all    0    1    2    3    4    5    6    7    8    9    10    Extremely
13. In your view, how large is the risk that your current pain may become persistent? Circle one.  
No risk    0    1    2    3    4    5    6    7    8    9    10    Very large risk
14. In your estimation, what are the chances that you will be working in 6 months? Circle one.  
No chance    0    1    2    3    4    5    6    7    8    9    10    Very large chance
15. If you take into consideration your work routines, management, salary, promotion possibilities and work mates, how satisfied are you with your job? Circle one.  
Not at all satisfied    0    1    2    3    4    5    6    7    8    9    10    Completely satisfied

Here are some of the things which other people have told us about their back pain. For each statement please circle one number from 0 to 10 to say how much physical activities, such as bending, lifting, walking or driving, would affect your back.

**16. Physical activity makes my pain worse**

Completely disagree 0 1 2 3 4 5 6 7 8 9 10 Completely agree

**17. An increase in pain is an indication that I should stop what I am doing until the pain decreases.**

Completely disagree 0 1 2 3 4 5 6 7 8 9 10 Completely agree

**18. I should not do my normal work with my present pain.**

Completely disagree 0 1 2 3 4 5 6 7 8 9 10 Completely agree

Here is a list of 5 activities. Please circle the one number which best represents your current ability to participate in each of these activities.

**19. I can do light work for an hour.**

Can't do it because of pain problem 0 1 2 3 4 5 6 7 8 9 10 Can do it without pain being a problem

**20. I can walk for an hour.**

Can't do it because of pain problem 0 1 2 3 4 5 6 7 8 9 10 Can do it without pain being a problem

**21. I can do ordinary household chores.**

Can't do it because of pain problem 0 1 2 3 4 5 6 7 8 9 10 Can do it without pain being a problem

**22. I can go shopping.**

Can't do it because of pain problem 0 1 2 3 4 5 6 7 8 9 10 Can do it without pain being a problem

**23. I can sleep at night.**

Can't do it because of pain problem 0 1 2 3 4 5 6 7 8 9 10 Can do it without pain being a problem

## Exhibit 6-6 Suggested Steps to Improve Early Behavioral Management of Low Back Pain Problems

1. Provide a *positive expectation* that the individual will return to work and normal activity. Organize for a regular expression of interest from the employer. If the problem persists beyond two to four weeks, provide a "reality-based" warning of what is going to be the likely outcome (e.g., loss of job, having to start from square one, the need to begin reactivation from a point of reduced fitness, etc.).
2. Be directive in scheduling *regular reviews of progress*. When conducting these reviews, shift the focus from the symptom (pain) to function (level of activity). Instead of asking "How much do you hurt?" ask "What have you been doing?" Maintain an interest in improvements, no matter how small. If another health professional is involved in treatment or management, specify a date for a progress report at the time of referral. Delays will be disabling.
3. *Keep the individual active and at work* if at all possible, even for a small part of the day. This will help to maintain work habits and work relationships. Consider reasonable requests for selected duties and modifications to the workplace. After four to six weeks, if there has been little improvement, review vocational options, job satisfaction, and any barriers to return to work, including psychosocial distress.

Once barriers to return to work have been identified, these need to be targeted and managed appropriately. Job dissatisfaction and distress cannot be treated with a physical modality.

4. *Acknowledge difficulties* with activities of daily living, but avoid making the assumption that these indicate all activity or any work must be avoided.
5. Help to *maintain positive cooperation* between the individual, an employer, the compensation system, and health professionals. Encourage collaboration wherever possible. Inadvertent support for collusion between “them” and “us” can be damaging to progress.
6. *Make a concerted effort to communicate that having more time off work will reduce the likelihood of a successful return to work.* In fact, longer periods off work result in reduced probability of ever returning to work. At the six-week point *consider suggesting vocational redirection, job changes*, the use of “knight’s move” approaches to return to work (i.e., same employer, different job).
7. Be alert for the presence of individual beliefs that he or she should stay off work until treatment has provided a “total cure”; watch out for expectations of simple “*technofixes*.”
8. Promote *self-management and self-responsibility*. Encourage the development of self-efficacy to return to work. Be aware that developing self-efficacy will depend on *incentives and feedback* from treatment providers and others. If recovery only requires development of a skill such as adopting a new posture, then it is not likely to be affected by incentives and feedback. However, if recovery requires the need to overcome an aversive stimulus such as fear of movement (kinesiophobia), then it will be readily affected by incentives and feedback.
9. Be prepared to ask for a second opinion, provided it does not result in a long and disabling delay. Use this option especially if it may help clarify that further diagnostic work-up is unnecessary. *Be prepared to say “I don’t know”* rather than provide elaborate explanations based on speculation.
10. Avoid confusing the *report of symptoms* with the presence of emotional distress. Distressed people seek more help, and have been shown to be more likely to receive ongoing medical intervention. Exclusive focus on symptom control is not likely to be successful if emotional distress is not addressed.
11. *Avoid suggesting* (even inadvertently) that the person from a regular job may be able to *work at home*, or in their own business because it will be under their own control. This message, in effect, is to allow pain to become the reinforcer for activity—producing a deactivation syndrome with all the negative consequences. Self-employment nearly always involves more hard work.
12. Encourage people to recognize, from the earliest point, *that pain can be controlled and managed* so that a normal, active or working life can be maintained. *Provide encouragement for all “well” behaviors,*

including alternative ways of performing tasks and focusing on transferable skills.

- 13.** If barriers to return to work are identified and the problem is too complex to manage, referral to a multidisciplinary team as described in the *New Zealand Acute Low Back Pain Guide* is recommended.

---

Courtesy of New Zealand Guidelines Group, Auckland, New Zealand.

The difficulty in reaching conclusions from the literature regarding the value of the clinical examination for patients with radiating complaints includes the following variables:

- Are the patients in a study evaluated in a primary, secondary, or tertiary care center? As patients progress through the staging of practitioner seen, a concentration effect results in a likelihood that there is a higher proportion of patients in the tertiary care setting with radiculopathy making the results of studies examining sensitivity/specificity more likely to demonstrate a higher detection ability.
- Do the patients seen in a study have confirmation from special imaging or surgery that they have a structural cause (i.e., disc herniation, tumor, stenosis) for their radiculopathy? Without this confirmation, patients assumed to have a radiculopathy may not.
- Are patients categorized by a specific level to determine the accuracy of the examination or are they categorized into general categories or radicular versus nonradicular? The value of the examination may be rated low if the outcome measure is accuracy of identifying a specific disc level or nerve root level versus whether the patient has a radiculopathy or not.
- Are orthopaedic tests, the neurological examination, or a combination of the two being tested for validity against a gold standard?
- Is there consistency of the orthopaedic tests being performed?
- Are the positives for a test the same in all studies?

Given that 98% of all disc lesions occur at the L4-L5 or L5-S1 discs, the likelihood of positive neurologic signs will be highest for the L5 or S1 nerve roots.<sup>68</sup> In earlier studies, the ability to localize the nerve root and disc level was determined to be quite good. An L5-S1 disc rupture was 86% probable if all three S1 signs were found: (1) pain projection into the S1 area, (2) a pathologic Achilles reflex, and (3) a sensory defect in the S1 dermatome.<sup>69</sup> Localization to the L4-L5 disc was 87% probable with all three L5 signs: (1) extensor hallucis (EH) weakness, (2) pain projection into the L5 area, and (3) a sensory defect in the L5 dermatome. It is important to remember that pain projection into the S1 area can be found with any lumbar disc herniation; however, EH weakness and pain projection into the L5 area together are reliable indicators of an L5 nerve root lesion even when accompanied by S1 findings. With L5 nerve root involvement it is not uncommon also to find ankle dorsiflexion weakness with EH weakness. McCombe et al.<sup>70</sup> evaluated the reproducibility of several physical signs for LBP. Buttock wasting, toe standing, and heel standing were considered unreliable. The Achilles reflex was considered a reliable interexaminer finding; however, the patellar reflex was not. The sensory examination was considered reliable. It is important to keep in mind that numbness is usually most evident distally. In other words, although the patient may complain of pain or numbness extending down the length of the leg to the foot, numbness may be demonstrated only distally at the foot.

**Figure 6-2** Common disc syndromes: neurologic findings.

More recently, the orthopaedic and neurological examination has come under attack for its poor diagnostic

accuracy. In 2013, a study<sup>71</sup> published in *The Spine Journal* was a systematic review and meta-analysis of the value of the peripheral nervous system examination in patients with radiculopathy due to disc herniation. They utilized the three standard exam findings for detecting radiculopathy including motor testing, sensory testing, and deep tendon reflexes. The following summarizes their findings:

- For surgically and radiologically confirmed disc herniation, sensory testing demonstrated low diagnostic sensitivity at 0.40 and 0.32 respectively.
- Specificity was higher for all the three reference standards (0.59—sensory, 0.72—motor, and 0.64—deep tendon reflexes).
- Motor testing for weakness demonstrated diagnostic sensitivities of 0.22 for surgically confirmed and 0.40 for imaging confirmed disc herniation and moderate specificity values (0.79 and 0.62 respectively).
- The sensitivity for muscle atrophy was 0.31 and the specificity was 0.76 for surgically determined disc herniation.
- For reflex testing, specificity values were 0.78 and 0.75, respectively for surgically confirmed versus imaging confirmed herniation. Sensitivities for surgically and radiologically confirmed levels of disc herniation were 0.29 and 0.25; quite poor.
- The pooled positive likelihood ratios for all neurological examination components ranged between 1.02 and 1.26, indicating literally almost no value when looking across all testing.

Simply put, neurological examinations alone are not good for screening patients with suspected radiculopathy, but when positive, they have a moderate value of helping to rule in a radiculopathy. Said another way, you can more confidently know that someone has a radiculopathy when

testing is positive but when negative, you cannot rule out a radiculopathy.

Although there are well over 50 orthopaedic tests listed in the literature for the low back and more than 15 for the SI joint, most are based on a common approach with some minor variations. Many tests can be classified as nerve tension tests, attempting to stretch a spinal nerve or nerve root. The second group of tests attempts to increase pressure or compression at various potential pain-producing sites (e.g., facet joints).

The most studied test is the straight leg raise (SLR).<sup>72</sup> This nerve tension test is considered quite valuable in distinguishing patients who have disc herniation from those who do not. A positive finding is reproduction of pain down the back of the leg to the foot with passive raising of the leg (**Figure 6-3**). Several observations are important to keep in mind while interpreting the response to an SLR.<sup>73</sup> This nerve tension test is considered quite valuable in distinguishing patients who have disc herniation from those who do not. A positive finding is reproduction of pain down the back of the leg to the foot with passive raising of the leg (**Figure 6-3**). Several observations are important to keep in mind while interpreting the response to an SLR:<sup>73</sup>

**Figure 6-3** The straight leg raise test. Nerve root compression is likely when posterior leg pain is provoked below 45°.

- A positive finding between 15° and 30° is a reliable indicator of disc herniation.
- A positive finding above 60° provides little diagnostic information.
- A positive finding when adding either passive dorsiflexion of the ankle (Braggard's test), medial hip rotation, or flexion of the cervical spine.

It is important to question the patient about a positive response to better guarantee that the response is not due to hamstring stretching. Medial hip rotation may also call into question possible involvement of the piriformis muscle with referred leg pain consequences. Combining the SLR findings with neurologic findings will usually be sufficient. For example, an apparently positive SLR without hard neurologic findings would be more suspect of a referral source. The well-leg raise test is less sensitive; however, it is much more specific for a disc lesion. Therefore, a positive response is virtually diagnostic for a disc lesion. Additional testing may include a Valsalva maneuver in an attempt to increase intrathecal pressure. A space-occupying lesion such as a tumor or a disc may then increase the leg pain complaint of the patient. Disc lesions that are further lateral than the typical posterolateral herniation may be clinically confusing.<sup>74-77</sup> Far-lateral (sometimes called "far-out" lateral) lesions primarily cause leg complaints. Thecal signs are usually absent because the point of compression is beyond the dural sleeve. Higher lesions tend to cause anterior thigh pain and weakness with a decreased quadriceps reflex. S1 lesions are uncommon with far-lateral lesions unless there is an extra vertebra (L6). The degree of tropism may also be a factor and may be associated with farlateral lesions.

In a cohort study using patients with signs and symptoms of radiculopathy confirmed with MRI results, researchers compared the sensitivity and specificity of a seated SLR compared to a supine SLR.<sup>78</sup> The results indicated that the

supine SLR is more sensitive in reproducing leg pain than the seated SLR.

Poiraudeau et al.<sup>79</sup> performed an interesting study evaluating the ability of two lesser known clinical findings in differentiating patients who had “sciatica” into those with and without disc herniation. Unlike most studies, the gold standard was radiographic rather than surgical. Either MRI, CT, or myelography was used to determine disc involvement. The two clinical tests were the Bell test (BT) and the hyperextension test (HT). These were compared to the Lasegue’s sign (LS: Straight Leg Raise) and the Crossed Lasegue’s (CL) sign. There were several interesting observations. None of the tests demonstrated high degrees of interexaminer reliability using the interclass correlation coefficient (ICC). In fact, the range for the LS was 0.27–0.47. The most reliable among examiners was the CL with a range of 0.42–0.72. The BT ranged from 0.58–0.64 with the HT at 0.35–0.50. For sensitivity and specificity, the best performing tests were the LS with the best sensitivity, and the CL with the best specificity. The positive and negative predictive values for all four tests were similar. The combination of HT and the CL had the best PPV at 0.67–0.85. The BT was performed with the patient standing. The examiner exerted thumb pressure between the spinous processes of L4-L5 or L5-S1 or a nearby paraspinal area in an effort to reproduce the patient’s leg pain. If only localized pain was produced, the test was regarded as negative. The HT was also performed with the patient standing. With the patient’s knees kept straight, the examiner passively extended the patient slowly. If the patient’s leg pain was reproduced, the test was positive; localized pain production was considered a negative test. It appears from this small study that adding the HT and correlating a positive finding with a CL sign may add some value in determining disc involvement with patients who have posterior radiation of pain down the leg.

There are many variations on neural tension testing, most of which have no literature support for or against their use. A sitting version is often called Bechterew's (**Figure 6-4**), but a newer test referred to as the flip test is similar. With passive extension of the knee with the patient in the seated position, the flip test is supposed to cause a sudden falling of the leg or flipping back of the trunk due to pain. A study<sup>80</sup> evaluating the flip test concluded that due to the finding that only one third of patients demonstrated a "flip," the term "sitting SLR test," is a less misleading and more accurate name. In their study, 33% of patients felt no pain, 39% felt pain on full extension of the knee, and 28% resisted full extension of the knee due to pain.

**Figure 6-4** Bechterew's test. The seated patient is asked to extend the knees in an effort to determine whether leg pain is provoked. Having the patient flex the neck forward, hold his or her breath, and bear down (Valsalva maneuver) may increase the sensitivity of the test.

Finally, a combination of provocation and relief testing is attempted with the slump test. The slump test (**Figure 6-5**) is performed with the patient seated with the arms behind the back. The patient is then asked to slump forward as much as possible while the examiner applies overpressure into flexion. The next step involves asking the patient to

extend the involved knee (or in some descriptions the examiner extends the patient's knee). The examiner then applies passive dorsiflexion to the ankle. Neck flexion is then added to increase tension. If positive for radiation, neck flexion is released to determine if there is a decrease or abatement of symptoms. Compared with the SLR, one study found that the slump test is more sensitive.<sup>81</sup>

**Figure 6-5** Slump test.

A Cochrane review<sup>81</sup> published in 2010 summarized the literature to that date regarding the physical examination for lumbar radiculopathy. They found that:

- The SLR was highly sensitive (pooled estimate 0.92, 95% CI: 0.87 to 0.95) with a wide range for specificity

(0.10 to 1.00, pooled estimate 0.28, 95% CI: 0.18 to 0.40) in *surgically confirmed* radiculopathy. Sensitivity was poorer for the SLR in *imaging confirmed* radiculopathy.

- The crossed SLR demonstrated high specificity (pooled estimate 0.90, 95% CI: 0.85 to 0.94) but consistently low sensitivity (pooled estimate 0.28, 95% CI: 0.22 to 0.35).
- Combining positive test results increased the specificity of physical tests, but few studies presented data on test combinations.

In a study<sup>56</sup> comparing leg-related complaints that were radicular versus stenosis-related in a senior group of participants, patients with herniation more often had positive nerve root tension signs with either or both straight-leg raising and femoral stretch signs positive in 58% of participants. Also, trunk flexion was more limited as compared to those with stenosis-related leg pain. Nerve root tension signs were found infrequently positive (8%). Patients with stenosis were more likely to have diminished Achilles reflexes. **Exhibit 6-7** demonstrates averaged likelihood ratios for some of the common orthopaedic and neurological examination findings to estimate the probability of lumbar radiculopathy.

Facets are often challenged through compression or stretch. In the supine patient, indirect pressure at the facets may occur with flexing the heel toward the buttocks, increasing the lordosis and consequently loading the facets. Another approach is the seated or standing Kemp's maneuver. While seated, the patient is taken passively into extension and rotation to each side in an attempt to determine whether local or radiating pain is reproduced (**Figure 6-6**). Local pain suggests a facet cause, whereas radiating pain into the leg is more suggestive of nerve root irritation, especially if the pain is below the knee. The

standing Kemp's test is a less specific test because it involves an active attempt by the patient to bend back, running the contralateral hand down the opposite leg. Therefore, muscle activation may cause spasm that is unrelated to a neural compressive or stretch effect.

### **Exhibit 6-7 Likelihood Patient Has a Lumbar Radiculopathy Approximating Probability**

The likelihood ratios (LRs) in this graphical representation represent estimates of probability based on the aggregate of multiple reviews of each test finding. They are only approximations and only reliable indicators of a change in the context of a patient having an intermediate pre-test probability of between 20% to 80%. If the pre-test probability is very high or very low, the LR has little effect on changing the probability.

A recent study evaluated the intra- and interrater reliability of visual assessment of cervical and lumbar lordosis (without the use of a measurement instrument).<sup>83</sup> This study included chiropractors, physical therapists, physiatrists, rheumatologists, and orthopaedic surgeons. Subjects were divided into those with back pain and those without. Raters were asked to rate photographs placed in a PowerPoint presentation. Lateral views of relaxed individuals' cervical and lumbar curves were rated as

normal, increased, or decreased. Interestingly, there was no difference in rating between those with or without back pain. The intrarater reliability was statistically fair ( $\kappa = 0.50$ ) and the interrater reliability was poor ( $\kappa = 0.16$ ).

Because leg length discrepancy has been often suspected as a biomechanical cause of LBP and other complaints, it is important to consider the reliability and validity of measurement of leg length in the physical examination. The reliability is good if the patient is measured supine and the difference in measurement allowed for agreement among examiners is extended to 12.5 mm, with the mean value of two measurements included.<sup>84</sup> Estimation through palpation of the iliac crests in the standing position is considered unreliable.<sup>85</sup> Leg length measurement is also used as an indicator and outcome measure for successful correction of biomechanical or neurologic dysfunction. Although some studies have indicated good reliability, others question the statistical analysis used in the studies, not to mention the design, which may include telling the examiners which is the short leg side.<sup>86</sup> More research is needed.

**Figure 6-6** Kemp's test. Kemp's test may be performed with the patient seated or standing. While seated, the examiner applies pressure at the lumbar spine while extending and rotating the patient to one side and then the other.

Motion palpation testing of the lumbar spine is commonly used in the evaluation of LBP. Studies have shown poor interexaminer reliability in some parts of the spine; however, Boline et al.<sup>87</sup> found interrater reliability at T12-L1 and L3-L4 and Mootz<sup>88</sup> found intrarater reliability at L4-L5.

Range of motion (ROM) may be evaluated through several procedures; however, there are problems with the reliability of all approaches.<sup>89,90</sup> Also, the correlation between ROM and functional impairment has been questioned.<sup>91,92</sup> Common methods are the modified (or modified-modified) Schober (**Figure 6-7A**) and the inclinometer method (**Figure 6-7**, B and C).<sup>93</sup> The inclinometer approach uses either a single or double inclinometer; however, the principles are the same. Placing the inclinometers at the T12-L1 area and the sacrum, they are "zeroed out." The patient is then asked to flex, and the new readings are recorded. The same may be done with other movements. The bottom inclinometer readings are subtracted from the

top inclinometer readings to obtain “true” lumbar participation (subtracting out the pelvic component). The modified Schober method uses a marking 5 cm and 10 cm above the lumbosacral junction (**Figure 6-7A**). With a tape measure held to the back, the patient is asked to flex. The difference is measured and recorded. The modified-modified Schober method involves connecting a line between the inferior margins of the posterior superior iliac spine and using a second skin marking 15 cm above the iliac line. The same procedure is then used to measure distance increases, using the closest millimeter. It is interesting to note that the old standard of measurement, the finger-to-floor method, is considered unreliable. A recent study<sup>94</sup> indicated that the change in the finger-to-floor results after the first month was a valid predictor of the change in self-reported disability using the Roland-Morris Disability Questionnaire over one year, outperforming the straight leg raise test as a measure of change in disability.

There are several commonly used approaches to functional testing of the low back. It is beyond the scope of this short discussion to cover all of these in any detail; however, the reader is encouraged to follow the references at the end of this chapter for more depth. The McKenzie approach to evaluation of LBP is to determine whether the patient has a postural problem, dysfunctional problem, or internal derangement.<sup>95</sup> This is accomplished by determining the position or movement that causes pain or relief. Patients who have no pain during, for example, flexion or extension (according to McKenzie) have a “postural” problem. This implies that the patient holds a particular posture during the day that needs to be interrupted to prevent the pain associated with holding any position for too long. The dysfunctional pattern is found when there is pain at end-range testing positions. McKenzie theorizes that this is due to shortened tissue. His solution is to stretch into the painful direction. The final category is the derangement

syndrome. This patient has pain going through a movement pattern. More important, when the prone patient is asked to lift the trunk off the table by pushing up with the hands and keeping the pelvis on the table, pain down the leg is increased (**Figure 6-8**). This is referred to as *peripheralization*. If the same maneuver is repeated after moving the pelvis to either side and the pain is felt more in the back (centralization), then a position of relief has been determined that is used as the main form of therapy for the patient. One study indicated poor intertester reliability for classification of these syndrome types in patients with LBP.<sup>96</sup> The interexaminer reliability of the McKenzie approach to evaluation of mechanical LBP has been questioned, yet a recent study<sup>97</sup> indicated that with a standardized protocol, the interexaminer reliability was high with the exception of identification of lateral shift.

**Figure 6-7** (A) Modified Schober Method. The modified Schober method measures the skin distraction with a tape measure. The modification of the Schober method test includes an additional third mark 5 cm below the lumbosacral junction. (B) and (C) Inclinator Method. Lumbar spine range of motion is best measured with two inclinometers.

Especially for patients with chronic LBP or for those interested in prevention, several functional approaches are helpful in determining exercise and stretching prescription. The Lewit/Janda approach is to search for “patterns” of muscle tightness and weakness and for dysfunctional patterns of movement.<sup>98-100</sup> These researchers focus on several patterns that seem to appear in layers. For the low back specifically, tight hip flexors and paraspinals associated with weak abdominals and gluteals are a

common pattern. Function is also investigated by watching the timing of recruitment with specific movement patterns. For example, with active hip extension in the prone position, there is a sequential recruitment of hamstring, gluteals, and paraspinals. If the hamstrings and gluteals are dysfunctional requiring the paraspinals to contract early, facet impingement may occur as a result of the increase in lordosis.

**Figure 6-8** Prone extension is performed by asking the patient to lift the chest off the table by pushing up from the elbows first, if possible, then the hands. The examiner stabilizes the pelvis on the table.

Other approaches assess the patient's ability to perform predetermined exercises, rate the patient, and use the perceived weaknesses to prescribe an exercise program. Other testing involves expensive, sophisticated machines in an attempt to isolate certain muscle groups or to determine the patient's ability to lift.

## Sacroiliac Tests

Palpatory tenderness over the posterior superior iliac spine (PSIS) has some degree of inter- and intraexaminer reliability.<sup>101</sup> Determination of iliac crest and PSIS heights as well as a sitting flexion test demonstrated only poor to fair

intra- and interreliability concordance. Two tests that appear to be reliable for SI involvement are the iliac gapping test (**Figure 6-9**) and the compression test (**Figure 6-10**).<sup>102</sup> These tests require a patient response. Other tests that may be valuable are the distraction (SI stretch) test (not shown), Gaenslen's test (**Figure 6-11**), hip extension test (**Figure 6-12**), and Patrick-Fabere's test (not shown; see [Chapter 11](#)). The latter tests act as compression tests and require that the hip be considered as a possible contributor to a positive response. Localization of the patient's response coupled with ROM of the hip may help localize the cause. In other words, if the pain is felt anteriorly and/or there is associated painful ROM in the hip, SI involvement is less likely. A common testing procedure used by manipulators is the Gillet or step test (**Figure 6-13**, A and B). Herzog et al.<sup>103</sup> reported that the test was reliable and a valuable indicator of the need for SI manipulation. A study by Mior et al.,<sup>104</sup> however, indicated poor kappa values. Furthermore, researchers in a study designed to test the interexaminer and intraexaminer reliability of the Gillet test for the SI joint found it to be unreliable.<sup>105</sup>

**Figure 6-9** The Gapping test.

**Figure 6-10** The sacroiliac compression (approximation) test.

**Figure 6-11** Gaenslen's test. The patient draws one leg up to the chest while the examiner distracts the opposite leg off the side of the examination, causing SI compression on the examiner's side.

**Figure 6-12** Passive hip extension may localize pain to the SI joint or lumbar facets.

**Figure 6-13** Testing for sacroiliac fixation. (A) The examiner palpates the sacral spine and the posterior superior iliac spine (PSIS). The patient then lifts the leg. If the joint is fixed, the PSIS will rise on that side. (B) The examiner palpates the sacral spine and the ischial tuberosity. With normal movement, the ischial tuberosity will move out laterally when the leg is lifted. If it moves upward, the joint is presumed fixed.

## Nonorganic Signs

When a patient is a chronic LBP sufferer, has potential loss of job or family breakup, or is involved in litigation, it is important to consider the history with the clinical findings. In patients in whom there is a mismatch or an apparent overreaction is perceived, nonorganic testing should be included. Waddell et al.<sup>106</sup> originally designed these tests. They consist of five categories of inappropriate responses to various testing maneuvers, which included the strategies of distraction, simulation, and evaluation of tenderness, regional disturbances, and overreaction. Finding three or more of these positive findings would indicate that the patient is somatizing or malingering. McCombe et al.<sup>70</sup> and Fishbaine et al.<sup>107</sup> found that the regional disturbance category (abnormal regional sensory or motor disturbance such as the whole leg or overlapping dermatomal sensory complaints) and superficial tenderness (tenderness to light touch in a wide area) were unreliable. Part of the reason for less focus on regional disturbances is that it is possible for patients to have less discrete sensory or motor complaints with single nerve lesions, and it is always possible that they have a spinal stenosis, which often can present with unusual regional disturbances. Malingering or nonorganic testing maneuvers include axial loading in the standing patient, passive flexion of the hip with the knee flexed, rotational twisting of the trunk, and forward bending in the seated position, among others.

## **Screening for Risk Due to Strength/Endurance Weakness**

A protocol based on studies by Reger,<sup>108</sup> Rissanen,<sup>109</sup> Alaranta,<sup>110</sup> Schellenberg,<sup>111</sup> and others,<sup>112,113</sup> is in common use as a screening approach to evaluating strength and endurance. The observation from these studies is that simple in-office testing has some predictive value and, in place of more expensive isokinetic testing, provides a level

of evidence for screening patients to determine specific weakness in either endurance or strength that can be used to prescribe rehabilitative exercises. Age- and gender-based normative data is then used to place the patient into one of five categories with five being excellent, four: good, three: moderate, two: poor, and one: extremely poor.

The four screening exercises are:

- Repetitive arch-up test—performed supine off the edge of a high table with stability provided by examiner; maximum of 50.
- Repetitive sit-up test—performed on a high table with foot support provided by examiner; maximum of 50.
- Repetitive squatting test—patient performs with hand support next to table; maximum of 50.
- Static back endurance test—same position as arch-up test. However, patient holds as an isometric with the trunk parallel to the floor for as long as possible; maximum of 240 seconds.

A more recent modified version of this prescreening for risk based on endurance includes (see **Figure 6-14**):

**Figure 6-14** Strength/endurance screening for low back pain, (A) side-bridge, (B) arch-up, (C) back endurance (extension), (D) flexion (sit-up).

- Side-bridge (right and left)—patient supports himself on one side with a flexed elbow and crossed feet (support at ankles). Generally should be held for about 1 to 1½ minutes in healthy young individuals.
- Flexion—patient is supine and supported by a jig or other device at 55° with hips and knees flexed to 90°. With the support removed, the patient is asked to hold the position for as long as possible. The average is about two minutes in healthy young individuals.
- Extension (same as static back endurance test above)—patient is supported at the ankles or lower legs in a prone position with the trunk suspended off of a high table. Patient is asked to hold a horizontal position to the ground with the arms crossed over the chest for as

long as possible. The average length of time for healthy young individuals is about 2½ to 3 minutes.

One of the most commonly prescribed approaches to prevent low back pain is core stabilization. The principle is to provide “core” strengthening of the abdominal muscles, back extensors, and quadriceps.<sup>112,113</sup>

McGill,<sup>114</sup> in a series of experiments, has demonstrated that the typical “hollowing” approach used by some training methods is actually potentially dangerous because it causes some muscles to relax thereby decreasing stability. Stiffening is the recommended approach to abdominal support for spinal stability. McGill also cautions that the psoas muscle is used to create hip flexion torque and is minimally linked to the spine. However, he states that substantial spinal compression is caused by psoas contraction which may lead to injury. He recommends standard screening but includes provocative tests, stability, McKenzie, and endurance tests based on the type of patient and his or her specific life demands.

---

## **Radiography and Special Imaging Plain Films**

The use of plain film evaluation of the patient with LBP is dictated by several factors:

- Does the patient have either a history or physical examination findings of a “high risk”?
- To what degree does the information gained alter the treatment?
- What are the relative risk and cost for the patient?

If the intention is to search for contraindications to adjusting or need for referral, it is usually clear from the history or examination when radiographs are necessary. If there are indications of cancer, infection, abdominal aneurysm, or fracture, radiographs are often the first

screening test because of their high sensitivity.<sup>115</sup> Significant damage must occur, however, before these pathologic lesions are evident. When there are no high-risk indicators, the next need felt by many chiropractors is a biomechanical evaluation of the patient from both a gross and a segmental level. In other words, what are the relative imbalances with regard to symmetry? From a segmental perspective, static or active examination is used to search for restricted or excessive movement at a segmental level. The validity of this approach has been questioned; however, it may represent a potential source of information that may change the approach to the patient if used honestly. It is important to note that studies indicating poor reliability have had some methodological flaws. One study tested the reliability of chiropractors identifying common findings that may influence adjusting procedures such as disc degeneration, osteophytes, and spondylolisthesis, among others. Also included were a small sample of tumors.<sup>116</sup> While the kappas and percentage agreement were acceptable for most pathologies, they were not excellent. In particular, the identification of facet arthrosis was poor. Another study<sup>117</sup> emphasizes the need for radiologists' (chiropractic or medical) evaluation with questionable findings. Researchers recently conducted a comparative study evaluating examiners' ability to agree (interobserver agreement) and to detect abnormalities that would be possible contraindications to chiropractic treatment of the low back. These "contraindications" included infections, malignancies, inflammatory spondylitis, and spondylolysis-lithesis. The observers (examiners) were five chiropractors, three chiropractic radiologists, and five medical radiologists. The kappa values for chiropractors were a little less than for the specialists. Most importantly, the sensitivity and specificity for interpretation of pathologies were similar among all three groups, with the medical radiologists being more specific. The conclusion by the researchers is that for most

radiographic indicators of contraindications to care, chiropractors might well be experienced enough to detect without the aid of a specialist.<sup>118</sup>

Numerous lines of mensuration are used to evaluate mainly facet loading, abnormal curve, or shear stresses to the spine. Gratings of spondylolisthesis and of central canal stenosis are also possible. Following is a limited description of some of these radiographic markings:

- Central canal stenosis. Two methods are used: (1) Beuler and (2) Eisenstein.<sup>119</sup> A magnification factor of 0.77 is used to compensate for the magnification effect of the radiograph. Both are relatively accurate. The Beuler method is more accurate at the L3 level. The normal sagittal diameter is approximately 15 mm or more. A diameter of 12 mm is considered relative stenosis; 10 mm or less is considered absolute. On the anteroposterior (AP) view, the interperpendicular distance can be measured. An AP diameter of 11.5 mm and an interperpendicular distance of less than 16 mm are considered diagnostic for spinal canal stenosis.<sup>120</sup>
- Facet syndrome. Several lines of mensuration are used to determine vertebral inclination on lateral films in an effort to uncover excessive weight distribution to the facets. The lumbar IVD disc angle varies at each level; however, any measurement greater than 15° is likely to indicate facet syndrome in those patients with correlated clinical symptoms. This is also true of the lumbosacral disc angle. The lumbosacral angle demonstrates wide variation of normal (26° to 57°) and is probably generally not helpful. The use of McNab's line is also not helpful because of the high incidence of abnormal findings in asymptomatic persons. Hadley's S curve is designed to indicate facet subluxation; however, displacements of 3 mm may not be visible. Although patients with LBP with a history of

trauma have more severe facet degenerative signs on radiography than patients without a history of trauma, there appear to be no differences in pain and disability.<sup>121</sup>

- Spondylolisthesis: Meyerding's grading system is the standard for measuring the degree of spondylolisthesis. The superior surface of the base of the sacrum is divided into fourths (this can be performed with the segment below for higher spondylolisthesis). The degree of slippage is then measured and graded 1 through 4.

Some chiropractors feel that the identification of anomalies is an important reason for screening all patients with LBP. However, studies have not found a higher incidence of LBP in patients with facet tropism, transitional vertebrae, spina bifida, or Schmorl's nodes.<sup>122,123</sup> However, the identification of a transitional vertebra or facet tropism may alter the positioning of the adjustment (manipulation) or cause the doctor to choose a different manipulative approach. This has yet to be researched.

When pathology is suspected, it is important to begin with a limited series, including AP and lateral views. Lytic, blastic, and degenerative processes are usually well visualized on routine views. In addition, a calcified aortic aneurysm is visible on a lateral view. Special views should be reserved for specific concerns. For example, if the patient is seen to have a spondylolisthesis on the lateral film, oblique films may allow visualization of pars interarticularis discontinuity. If the SI joint is suspected of having a sclerotic focus (e.g., seronegative arthritides), angled spot-views may provide a clearer picture.

## Computed Tomography

CT is usually reserved for suspected cases of fracture or stenosis. It may also be useful in imaging infection, tumor, the cause of pain in postoperative spines (recurrent disc herniation and fusion), and herniated discs in general. Because of the increased radiation exposure, MRI is often chosen as an alternative (also see [Table 1-4](#)).

## **Magnetic Resonance Imaging**

MRI has the advantage of no ionizing radiation, yet it has a slightly higher cost. Soft tissue is well visualized. MRI is particularly valuable in evaluating disc pathology, the extent of tumor or infection invasion, and abnormalities involving the nerve root, thecal sac, or subarachnoid space. In differentiating between recurrent disc herniation or postsurgical fibrosis, MRI with gadolinium (injected) is often helpful (see also [Table 1-4](#)).

## **Bone Scan**

Bone scan is quite sensitive to bone changes and is valuable in the detection of spinal metastasis and activity of a spondylolisthesis. However, it is not specific for the cause of the increased uptake pattern. In other words, any bony inflammatory condition may cause an increased uptake. The extent of damage is also not well visualized.

## **Discography and Pain Provocation/Relief Studies**

For patients who have equivocal imaging studies or for patients with known pathology who are unresponsive to conservative care, various minimally invasive medical approaches have been suggested. These include

discography, selective nerve root blocks, epidural blocks, sympathetic nerve blocks, and facet neurotomy (medial branch rhizotomy). **Table 6-2** summarizes each procedure, when it is most appropriate, and generally how it is performed.<sup>32,124</sup> Some authors question the use of selective nerve blocks, citing little validation in randomized controlled trials.<sup>125</sup>

**Table 6-2** Selected Nonsurgical Diagnostic and Therapeutic Procedures for the Discs, Nerve Roots, and Facet Joints

Procedure/Definition	Procedure	Expected Results
<b>Discography: A diagnostic test used to view and assess the internal structure of a disc and determine if it is the source of a patient's complaint.</b>	Under fluoroscopic guidance, a needle is advanced into the disc. Provocation discography attempts to identify a specific disc as the cause of a patient's complaint through injection of saline and radiopaque dye; analgesic discography attempts to relieve pain through injection of a local anesthetic into the suspected disc; computed tomography (CT) discography attempts to identify abnormal internal morphology and is used on the disc identified as the source of a patient's complaint.	The sedated patient is able to identify when his or her specific complaint is reproduced thereby identifying the disc causing the pain. Sometimes the procedure is quite painful. It should be used only when an anatomic diagnosis is needed.
<b>Translaminar and Transforaminal Epidurals: A</b>	A local anesthetic is given. Then a spinal	The procedure takes about 30 minutes

<p><b>procedure in which epidural steroids are injected into the space outside the thecal sac (which contains the nerve roots) in an attempt to decrease any inflammatory process in that area. An anesthetic is used to block the pain muscle spasm cycle.</b></p>	<p>needle is introduced into the epidural space through either an interlaminar space (just lateral to the interspinous ligament) or a selected neuroforamen. An anesthetic and steroid are then injected.</p>	<p>with 45 minutes recovery. The expected result is relief of pain. Complications are less for the transforaminal than the translaminar. There is more risk of needle-related trauma such as bleeding and intrathecal puncture with translaminar techniques.</p>
<p><b>Facet Block: A “block” is an anesthetic injection into the facet joint or capsule to determine if it is the source of a patient’s complaint.</b></p>	<p>The patient is given a local anesthetic. A needle is guided to the facet joint or capsule under fluoroscopy. An anesthetic and steroid are injected into the area.</p>	<p>The procedure takes about 30 minutes. The patient should experience relief of pain. Patients who are either older than 65 years; have pain that is not worsened by either coughing, hyperextension, forward flexion, rising from flexion, extension with rotation; or relieved by recumbency have a high success rate with this procedure (92% initial pain relief).</p>
<p><b>Sympathetic Nerve Block: This test is primarily used to determine damage to the sympathetic nerve chain.</b></p>	<p>A local skin anesthetic is given, then a needle under fluoroscopic guidance is advanced next to the vertebral body. An anesthetic medication is then injected.</p>	<p>The procedure takes about 30 minutes with another 1 ½ hours for recovery. During the procedure the patient may experience redness and a feeling of warmth in the lower extremity.</p>
<p><b>Facet Neurotomy (Medial</b></p>	<p>The prone patient is</p>	<p>If the facet is the</p>

<b>Branch Rhizotomy): This procedure involves denervation of the facet joint nerve supply by a radiofrequency probe. The two small medial branches are heated in an effort to interrupt nerve supply to the facet joint.</b>	given a local anesthetic. Using fluoroscopy, the radiofrequency needle is directed to the base of the selected transverse process. The needle is heated to 80° C for 90 seconds. Two branches are treated.	source of pain, there is a 60% chance of pain relief until the nerves grow back (3 months to 1 ½ years). Risks are several days or weeks of increased pain and destabilization of the facet joint treated.

## Thermography

There is much controversy with regard to the use of thermography. In general, thermography can be sensitive; however, it is nonspecific as to the cause of a patient's complaint. There are generally two types: (1) infrared, and (2) liquid crystal thermography. Electronic infrared thermography is more sensitive than liquid crystal; however, the cost and need for standardization of the testing environment make it relatively unavailable. In addition, thermography is between 78% and 94% sensitive for radiculopathy; however, it is nonspecific (20% to 44%).

## Electrodiagnostic Studies

Electrodiagnostic studies (EDS) are used when there is a question as to the cause of a patient's low back and leg complaints. EDS consists of the following:

- Electromyography (EMG) is used to differentiate between nerve root causes, myelopathy, and myopathy. EMG does not become positive for three to four weeks following denervation. Positive findings

include electrical hypersensitivity reactions such as fibrillation potentials and positive sharp waves.

- Nerve conduction velocity (NCV) is used to differentiate between entrapment neuropathies and radiculopathies; late responses such as the H-reflex are the electrodiagnostic equivalent of a decreased Achilles reflex and are found 90% of the time with S1 dysfunction.
- Sensory-evoked potentials (SEPs) are used to measure the sensory component of a patient's complaint in an attempt to localize the site of the pathologic lesion; dermatomal sensory-evoked potentials (DSEPs) may be useful in the assessment of patients with spinal stenosis.

The Council on Chiropractic Guidelines and Practice Parameters (CCGPP) has published a series of best-practices documents online. The low back chapter is available at [www.ccgpp.com](http://www.ccgpp.com). It focuses primarily on management. Many of the conclusions and recommendations are similar to other published summaries.

Clinical guidelines<sup>126</sup> published by the American College of Physicians and the American Pain Society are consistent with current recommendations by similar groups including the National Council on Quality Assurance. The guidelines make seven recommendations, which are summarized as follows:

- 1.** A focused history and examination should be performed to place patients in one of three broad categories: (a) nonspecific low back pain, (b) back pain associated with radiculopathy or spinal stenosis, or (c) back pain due to other specific causes. Also, the history should assess possible psychological risk factors.

2. Avoid routine imaging for patients with nonspecific LBP.
3. Perform diagnostic imaging for severe or progressive neurologic deficits, or when serious underlying conditions are suspected.
4. For patients with persistent LBP or signs of radiculopathy or stenosis, MRI or CT should be ordered only if they are potential candidates for surgery or epidural steroid injection.
5. Provide patients with evidence-based information on LBP with regard to natural history and activity, and provide information about self-care options.
6. Prescribing physicians should consider the use of medications with proven effect in conjunction with back- and self-care information.
7. For patients who do not improve with self-care options, consider the addition of nonpharmacological therapy including manipulation (for both acute and chronic LBP) and a host of other approaches including exercise, massage therapy, yoga, cognitive behavioral therapy, or progressive relaxation (less evidence than for manipulation).

It is interesting that no intervention had Grade A evidence (good quality evidence of substantial effect) for either acute or chronic LBP.

In 2006, the European Guidelines for Low Back Pain were published in the *European Spine Journal*. A summary of recommendations for acute nonspecific low back pain includes:<sup>23</sup>

- Give appropriate information and reassure the patient while being careful not to prescribe bed rest as a treatment.
- Advise patients to stay active and suggest working if possible.

- Pain medication may be necessary starting with NSAIDs, and then muscle relaxants for only short course prescription.
- Refer for spinal manipulation for patients failing to return to normal activities.
- Consider multidisciplinary treatment programs for those with subacute LBP and sick leave for more than four to eight weeks.

A series of articles appeared in a 2008 full issue of the *Spine Journal* devoted to evidence-informed management of chronic low back pain (CLBP). The intention was to bring together experts in various treatment strategy approaches who would summarize the existing literature and conclude with some statements about what is known and how well it is supported. Recommendations for further research were also included. A summary of those evidence-informed treatment conclusions is presented in **Table 6-3**.

**Table 6-3** Evidence-Informed Summaries for Various Management Approaches to Chronic Low Back Pain (CLBP)

*(Please note that these summaries are based on evidence-based criteria of the existing literature. Having no literature support for or against a given approach does not indicate that it is ineffective.)*

*\*Listed alphabetically*

<b>Tx Approach</b>	<b>Summary of Conclusions by Expert Panels for Chronic Low Back Pain</b>
Acupuncture <sup>127</sup>	<ul style="list-style-type: none"> <li>• Some evidence that acupuncture is effective immediately after a series of treatments for pain and functional improvement.</li> <li>• Evidence suggests that acupuncture is no more effective than other treatment methods.</li> </ul>

	<ul style="list-style-type: none"> <li>• The most consistent evidence suggests that the addition of acupuncture to other therapies improves outcomes.</li> <li>• Moderate evidence that acupuncture may be better than massage, especially if combined with exercise.</li> <li>• Inconclusive evidence for the effectiveness of acupuncture when compared to sham acupuncture.</li> </ul>
Adjunctive analgesics <sup>128</sup>	<ul style="list-style-type: none"> <li>• Evidence supporting the use of adjunctive analgesics is limited.</li> <li>• The panel suggests that it is reasonable to use tricyclic antidepressants (TCA) at low dosage for painful radicular syndromes when acetaminophen and NSAIDs have not helped.</li> </ul>
Back school, brief education, fear avoidance <sup>129</sup>	<p>Back School</p> <ul style="list-style-type: none"> <li>• Conflicting evidence about the effectiveness for back schools in reducing recurrences of LBP compared to usual care or no intervention.</li> <li>• Limited evidence that back schools are less effective than exercise.</li> <li>• Moderate evidence that back schools are not better than waiting, any intervention, placebo, or exercise for reduction of pain. However, there is conflicting evidence for the reduction of disability compared to the same interventions.</li> <li>• Limited evidence that back school is better than usual care or a cognitive behavioral-based back school.</li> <li>• Conflicting evidence that back schools are better than a waiting list, no intervention, or usual care for return to work.</li> </ul> <p>Brief Education</p> <ul style="list-style-type: none"> <li>• Limited evidence that brief education in the clinical setting (back book, pamphlet, etc.) is not more effective than usual care for reduction of pain but was more effective than usual care for return to work.</li> <li>• Conflicting evidence that brief education is more effective than usual care in reducing disability.</li> <li>• Limited evidence brief education is not as effective as yoga, massage, and exercise, but is more effective than a waiting list for pain reduction.</li> </ul>

	<ul style="list-style-type: none"> <li>• Limited evidence brief education is more effective than massage and no intervention, and less effective than yoga with massage for reduction of disability.</li> <li>• Panel recommended brief education in the clinical setting for return to work but not a back book or Internet discussion as an alternative to other treatments.</li> </ul> <p>Fear Avoidance Training</p> <ul style="list-style-type: none"> <li>• Moderate evidence that fear avoidance training emphasizing exposure to provocative maneuvers is more effective than graded activity for fear avoidance, pain, and disability.</li> <li>• Limited to moderate evidence that rehabilitation incorporating exposure to physical activities labeled “not recommended” is not different from spinal fusion with regard to pain, disability, and return to work.</li> <li>• The panel recommended fear avoidance training in a rehabilitative program as an alternative to spinal fusion and to include exposure as an important element of the training.</li> </ul>
Cognitive behavioral training <sup>130</sup>	<ul style="list-style-type: none"> <li>• Some evidence that cognitive behavioral therapy (CBT) is effective for chronic pain; generally helping with the pain experience, pain behavior and activity, cognitive coping and appraisal, and social functioning.</li> <li>• The recommendation is that the biopsychosocial approach to chronic pain is likely a multitherapy (interdisciplinary) approach that should include CBT.</li> </ul>
Epidural steroid injection <sup>131</sup>	<ul style="list-style-type: none"> <li>• For discogenic pain there are no well-designed studies that assess the efficacy of transforaminal epidural steroid injections (ESI).</li> <li>• Nonspecific ESIs have been demonstrated to have some short-term benefit. It appears that one to three appear effective.</li> </ul>
Extensor exercises <sup>132</sup>	<ul style="list-style-type: none"> <li>• Lumbar extensor strengthening exercise (LESE), alone or with co-interventions, is more effective than passive modalities in improving pain and disability for CLBP. However, it has no clear benefit over other exercise programs.</li> <li>• The long-term benefits for LESE over other interventions is lost over time.</li> </ul>

	<ul style="list-style-type: none"> <li>• Hyperextension does not appear to offer additional benefit.</li> <li>• LESE alone or with co-intervention is more effective than stabilization exercise or home exercise in improving cross-sectional area of the paraspinal muscles.</li> <li>• LESE is more effective than no treatment and passive modalities in improving lumbar paraspinal muscle strength and endurance. However, there is no benefit compared to other exercise programs.</li> <li>• High-intensity lumbar strengthening appears to be more effective to low-intensity for improving strength and endurance.</li> <li>• Many methods of performing dynamic LSES. Panel did not recommend floor, stability ball, and free weight exercises. It felt that Roman chairs and benches are viable, although lumbar dynamometer machines appear to be the best option.</li> </ul>
Facet injections and radiofrequency neurotomy <sup>133</sup>	<ul style="list-style-type: none"> <li>• Some evidence that controlled lumbar medial branch blocks are the best diagnostic test for Z joint (facet) involvement.</li> <li>• Limited studies on medial branch neurotomy that indicate the majority of patients have pain relief lasting one year.</li> <li>• Controlled studies have shown that intra-articular injection of steroids is no more effective than placebo.</li> </ul>
Functional restoration <sup>134</sup>	<p>Functional restoration is a broad based approach drawing a team of multidisciplinary individuals together for formal quantification of physical deficits to guide an individualized approach. This includes psychosocial and socioeconomic components, multimodal disability management using cognitive behavioral training, and psychopharmacological use (for those in need) complemented by ongoing outcome assessment and communication among all involved.</p> <ul style="list-style-type: none"> <li>• Panel concludes that there is strong evidence that functional restoration reduces pain and improves function more than less intensive programs or usual care.</li> </ul>
Herbs, vitamins, homeopathy <sup>135</sup>	<ul style="list-style-type: none"> <li>• Strong evidence for 50 mg harpagoside per dose in aqueous extract of <i>H. procumbens</i> per day better than placebo.</li> </ul>

	<ul style="list-style-type: none"> <li>• Moderate evidence that 60 mg harpagoside is equal to 12.5 mg of rofecoxib.</li> <li>• Moderate evidence for 240 mg of salicin (extract of <i>S. alba</i>) per day is better than placebo.</li> <li>• Moderate evidence for intramuscular B12 when compared to placebo for pain reduction.</li> <li>• Moderate evidence that there is no difference in pain reduction among Spiroflor SRL, Cremor Capsici Compositus FNA, the capsici oleoresin gel.</li> <li>• Limited evidence for topical <i>C. frutescens</i> (Rado-Salil cream or Capsicum plaster), lavender, vitamin C, and manganese in addition to prolotherapy, and for homeopathy equivalent to physiotherapy.</li> </ul>
IDET <sup>136</sup>	<ul style="list-style-type: none"> <li>• Intradiscal electrothermal therapy (IDET) is a minimally invasive technique producing modest pain relief rather than functional improvement.</li> <li>• For patients with less functional impairment, well maintained disc height, and discogenic pain from annular tears or protrusions less than 3–4 mm IDET may be indicated as an alternative without the expectation of returning to demanding manual labor.</li> <li>• Success reported varies widely dependent on the type of study from only 14 (randomized) to 63% (nonrandomized studies).</li> </ul>
Lumbar stabilization exercises (LSE) <sup>137</sup>	<ul style="list-style-type: none"> <li>• Moderate evidence that LSE are effective in improving pain and function in a heterogeneous group of patients with CLBP.</li> <li>• Strong evidence that LSE is no more effective than less specific, general exercise programs.</li> <li>• Strong evidence that LSEs are no more effective than manual therapy in the same population.</li> <li>• Caveat is that the few studies that qualified were comprised of heterogeneous patients. Suggestion for further research on homogeneous groups to determine any patient-specific effect.</li> </ul>
Manipulation/mobilization <sup>24</sup>	<ul style="list-style-type: none"> <li>• Moderate evidence that spinal manipulative therapy (SMT) with strengthening exercise is similar in effect to prescription NSAIDs with exercise in both the short and long term.</li> </ul>

	<ul style="list-style-type: none"> <li>• Moderate evidence that flexion-distraction mobilization is superior to exercise in the short term and superior/similar in the long term.</li> <li>• Moderate evidence that a high-dose SMT regimen is superior to low-dose SMT in the very short term.</li> <li>• There is limited to moderate evidence that SMT is as good or better than chemonucleolysis for disc herniation in the short and long term.</li> <li>• There is limited evidence that mobilization is inferior to back exercise after disc herniation surgery.</li> </ul>
Massage <sup>138</sup>	<ul style="list-style-type: none"> <li>• Strong evidence that massage is effective for non-specific CLBP.</li> <li>• Moderate evidence that massage provides short- and long-term relief of symptoms.</li> <li>• Standard massage has the same effects as traditional Thai massage.</li> </ul>
McKenzie method <sup>139</sup>	<ul style="list-style-type: none"> <li>• The McKenzie method is primarily a system of assessment and classification.</li> <li>• Intervention studies have demonstrated that the McKenzie method produces better short-term outcomes than nonspecific, guideline-based care and equal or marginally better outcomes than stabilization or strengthening exercises for patients with CLBP.</li> </ul>
Medicine-assisted manipulation <sup>140</sup>	<ul style="list-style-type: none"> <li>• Generalizing medicine-assisted manipulation (MAM) is difficult because there are a variety of techniques which include manipulation under anesthesia (MUA), manipulation under joint anesthesia, and manipulation under epidural steroid injection.</li> </ul> <p>However, all studies to date have shown positive results regardless of specific technique used.</p> <ul style="list-style-type: none"> <li>• No recommendation can be made for a specific technique for MAM.</li> <li>• Generally the evidence for MAM is weak and consists mainly of observational studies.</li> </ul>
NSAIDs, muscle relaxants, analgesics <sup>141</sup>	<ul style="list-style-type: none"> <li>• No one drug or medication has been shown to be more effective than another.</li> <li>• No trials were available to compare the effectiveness of antispasmodic drugs to placebo or other treatments.</li> <li>• It is unpredictable which patient will respond to which medication and therefore it is</li> </ul>

	recommended to apply a trial period of three to four days based on patient preference.
Nuclear decompression <sup>142</sup>	<ul style="list-style-type: none"> <li>• Little evidence at this point in time; however, some indications that about 40% of patients obtain relief.</li> <li>• This procedure is suggested only for patients with disc protrusions less than 4–6 mm, minimal stenosis, and well-maintained disc height.</li> </ul>
Opioid analgesics <sup>143</sup>	<ul style="list-style-type: none"> <li>• Some evidence that opioid analgesics are effective in the short term compared to placebo.</li> <li>• Withdrawal rates are high due to side effects, however, among the remaining group, 1/3 respond well, 1/3 have a fair response, and 1/3 are nonresponders.</li> <li>• Improvement in pain is more substantiated than function.</li> <li>• No evidence of superiority among the opioids; addiction seems rare.</li> </ul>
Physical activity, smoking cessation, weight loss <sup>144</sup>	<ul style="list-style-type: none"> <li>• Moderate evidence that physical activity with general aerobic and strengthening exercise or aquafitness was more effective than nonactive controls for long-term reduction of disability and limited evidence for improvements in worst pain, medication use, work status, and mood.</li> <li>• Moderate evidence that different types of physical activity programs were equally effective.</li> <li>• No evidence yet for the efficacy of smoking cessation or nonoperative weight loss; however, there are few trials available.</li> </ul>

## Management

Prior to a discussion of the plethora of approaches to low back pain, a popular approach developed and tested by Murphy et al.<sup>145</sup> attempts to connect the examination to the management approach based on a diagnosis-based clinical decision rule (DBCDR). They are careful to point out that the DBCDR is not a clinical prediction rule but is an attempt to identify issues regarding the need for referral and when

management is attempted, to consider factors related to the perpetuation of pain and the risk for disability so that all factors that affect patient recovery can be addressed. The sequence and focus of this approach is predicated on determining a cross-section of information including the answers to the following primary questions:

- 1.** Are the symptoms with which the patient is presenting reflective of a visceral disorder or a serious or potentially life-threatening disease? Red-flag indicators would warrant referral.
- 2.** From where is the patient's pain arising? The attempt is to use diagnostic clues to categorize patients into one of the following groups with different management approaches:
  - Centralization dominance—implying disc derangement possibly responsive to a McKenzie approach
  - Segmental pain—suggesting facet-related (subluxation) pain amenable to manipulation
  - Neurodynamic cause—implying a radiculopathy which may respond to manipulation or “neural” techniques
  - Myofascial/trigger point-related—potentially responsive to myofascial treatment approaches
- 3.** What has gone wrong with this person as a whole that would cause the pain experience to develop and persist? The attempt is to determine factors that contribute to chronicity and recurrence including underlying dynamic instability (impaired motor control), central-mediated pain, fear avoidance of activity and catastrophizing behavior, and related, passive coping and depression.

## **Injections**

Injection therapy for LBP takes many forms based on the underlying suspected cause. Trigger point injection, facet injection, and epidural injections are the most common. For radicular pain or for spinal stenosis, epidural injections are frequently recommended prior to surgery. Epidural injections involve anesthetics, steroids, or a combination of the two. Epidural steroid injections (ESI) are classified by type: (1) caudal, (2) interlaminar (also called translaminar), and (3) transforaminal (also known as a selective nerve root block). Caudal and interlaminar are referred to as nonspecific conducted without fluoroscopic guidance (i.e., a blind approach). Transforaminal ESIs are directed through fluoroscopic guidance. Recent studies indicate that the success of ESIs is based partly on the type and the location. A study<sup>151</sup> published in 2013 demonstrated a high response rate for lumbar ESI compared to caudal. Response rates for facet joints and the SI joint were substantially less. Also, a review<sup>152</sup> published in 2012 concluded that although limited for axial pain and pain secondary to surgery, transforaminal ESIs have good evidence for effectiveness for radiculitis secondary to disc herniation and fair evidence for effectiveness with spinal stenosis. Looked at another way, if ESIs are used not as a curative but to either allow other therapy such as manipulation or to prevent surgery, the statistics seem more favorable. A review<sup>153</sup> published in 2006 demonstrated that 71% of patients with a transforaminal ESI avoided surgery even at a five-year follow-up. What is not compared is the percentage of those who did not receive an ESI. Regarding safety, there was an unfortunate contamination event from a single compounding company (unregulated compared to normal pharmaceutical companies) in which 55 deaths occurred due to fungal infection. This isolated event is related to the production of the medication. A review by Epstein<sup>154</sup> in 2013 examined the risks related to adverse events in the literature. The most common were positional headache,

adhesive arachnoiditis, allergic reactions, and spinal fluid leaks (which were less with transforaminal injections).

## Surgery

Lumbar discectomy is performed over 480,000 times in the United States annually. Hospital costs for complex spine fusions can reach up to \$80,000 per patient. The United States has the highest rate of low back surgery and these rates have increased by 55% from 1979 to 1990, with now 21 per 100,000 Medicare beneficiaries having a spine fusion annually.<sup>155</sup>

There are basically two types of spine surgery; decompression and fusion. Both may be utilized together in some procedures. Decompression may occur through discectomy or laminectomy/otomy or a combination of the two. The surgical techniques used are divided into two types: open and microscopic. By combining the two categorizations, different spine surgeries are named. Further differentiation is based on whether the surgery is instrumented or non-instrumented. Instrumented means the addition of screws, hooks, cable, cages, and so on. Noninstrumented implies that stabilization is primarily through bone, which is divided into autograph (also called autologous or autogenous), meaning from the patient or allograph, meaning from a donor.

One of the most common types of fusion surgeries is minimally invasive transforaminal lumbar interbody fusion (TLIF). Minimally invasive TLIF has been shown to be superior to the traditional open procedure in terms of postoperative back pain, total blood loss, need for transfusion, time to ambulation, soft-tissue injury, and functional recovery.

Under fluoroscopy in the anteroposterior and lateral views, a spinal needle is used to locate the level of lesion.

Unilateral pedicle screws are placed percutaneously over a guide wire and then a laminectomy and TLIF are performed via a 21-mm nonexpandable tube. The advantage is the minimally invasive approach that preserves the midline muscular and ligamentous structures. Patients are usually released within 24 hours following the surgery, and are able to return to their daily routines and work within two to three weeks. Compared to the traditional four-hour procedure, this surgery takes only 45 to 60 minutes with minimal blood loss. There is also less pain because of the smaller incision

More recently, McMorland et al.<sup>156</sup> studied patients who were randomized to either microdiscectomy or manipulation. Microdiscectomy is a procedure where 1- to 2-cm incisions are made over midline at the level of the herniated disc. Laminotomies are performed as needed to allow visualization. Retraction of nerve roots is then used to allow access to the herniated disc. Both sequestrectomy and intra-annular discectomy are performed. Patients remained in the hospital for one to two days. Sixty percent of patients failing medical management for disc herniation-related sciatica demonstrated some benefit with side-posture manipulation equal to those who underwent microdiscectomy. Patients who failed to benefit from side-posture manipulation received benefit from subsequent surgical management. However, those patients failing to receive benefit from surgery did not benefit from subsequent management with manipulation. Based on this study, there is an implied care pathway that indicates that patients have no risk and possible benefit from manipulation and that those who fail to obtain relief have the option of microdiscectomy.

The older open surgeries require large incisions in the back or abdomen. For anterior approaches, vascular surgeons perform this portion of the surgery often requiring complicated dissection of muscles, nerves, and even organs so that the surgeon can gain access to the affected area.

This preliminary process can take hours even before a spine surgeon begins. Patients are at a much higher risk for greater blood loss as well as nerve and muscle injury. Some surgeons still use this approach in select patients.

Obviously, one of the largest concerns about lumbar spine surgery other than cost is adverse events (AE) and complications. A past review<sup>157</sup> of complication rates for lumbar spine surgery included 11 studies with an overall mortality rate of <1%, but a complication rate of 3.7% to 12.8%. An adverse event is defined as any unexpected or undesirable event occurring as a result of spinal surgery, whereas a complication is defined as a disease or disorder that is a consequence of a surgical procedure. In one prospective observational study, this distinction was used and the researchers reported an overall AE rate of 14% and an overall complication rate of 3.2%. In the review by Street et al.<sup>158</sup> published in the *Spine Journal* in 2012, the first prospective approach to studying morbidity and mortality for spine surgery was conducted. There was an overall intraoperative AE rate of 12%. In the previous year, chart review retrospectively identified an intraoperative rate of 9.8% in 918 patients. The researchers also concluded that postoperative events appear to be grossly under-recorded by traditional methods.

The four most common intraoperative AEs were

- Dural tear (42 cases, 4.45%)
- Anesthetic related (32 cases, 3.4%)
- Blood loss, > 2 L (21 cases, 2.2%)
- Hardware malposition requiring revision (18 cases, 1.9%)

The total incidence of intraoperative AEs for the elective group was 14.65% compared with 9.3% for the emergency group (p. 01). The incidence of iatrogenic dural tear in the elective degenerative group was 12%, significantly higher to

the incidence in all other groups. The incidence of infection for elective surgery was approximately 3%, similar to a recent previous publication by the Scoliosis Research Society, where they reported on 10,329 patients undergoing surgery for spinal stenosis with an overall complication rate of 7%, a mortality rate of 0.13%, a 3% dural tear rate, and a 2% infection rate.

In a recent publication about the incidence and mortality of thromboembolic events in lumbar spine surgery, we are reminded that when one thinks of spine surgery, it is easy to forget that in addition to local damage, other adverse events such as infection and vascular accidents occur. In this study<sup>159</sup> published in *Spine* in 2013, the researchers studied the incidence of deep vein thrombosis and pulmonary embolism as complications of lumbar spine surgery. They found an incidence for DVT of 2.4 per 1,000 cases for lumbar decompression surgery and an incidence of 4.3 per 1,000 cases for lumbar fusion. For pulmonary embolism the incidence for lumbar decompression was 1 out of 1,000 and 2.5 per 1,000 for lumbar fusion. These patients had higher preoperative pulmonary circulation disorders, coagulopathies, fluid-electrolyte disorders, anemia, and obesity. Also the rate was higher for large teaching hospitals.

A Cochrane review published in 2012 by Jacobs et al.<sup>160</sup> examined the effectiveness of total disc replacement for chronic discogenic low back pain. It was believed that artificial discs could act as low-friction devices allowing more spinal mobility. Articulating surfaces are either metal-on-polyethylene or metal-on-metal. Although such devices allow controlled motion, they do not replicate the elasticity of the normal human intervertebral disc. The researchers concluded that the reviewed studies indicated that compared to total disc replacement and traditional surgery, the effectiveness based on differences in the outcome measures used demonstrated very small advantages and

that these differences did not exceed clinical relevance and/or the quality of evidence was low. For these reasons and the potential harm and complications that they suggest may occur years later, they warn the spine surgery community to be prudent about adapting this approach and to use it sparingly on select patients.

Although many studies examine the ability to predict chronicity following an acute episode of LBP, there are few that address prediction of lumbar spine surgery following occupational injury. In a study published in 2012 by Keeney et al.<sup>161</sup> among workers in Washington state with compensation for temporary total disability for occupational back injury, 9.2% underwent lumbar spine surgery within three years. Higher Roland-Morris Disability Questionnaire scores, greater injury severity, and first seeing a surgeon for the injury significantly increased the odds of having spine surgery. Forty-two percent of workers who first saw a surgeon had surgery. Participants younger than 35 years, females, Hispanics, and participants whose first visit for the injury was to a chiropractor had lower odds of surgery; only 1.5% of those who saw a chiropractor first had surgery. No other factors in the employment-related, health behavior, or psychological domains were significant. The odds of surgery were highest for workers with reflex, sensory, or motor abnormalities but odds were also high for workers with symptomatic radiculopathy without such abnormalities.

A quickly advancing field is the use of biologics in spine surgery. Biologics is based on the introduction of autologous or allogeneic stem cells or progenitor cells. Important characteristics of stem cells include the ability to (1) regenerate, and (2) differentiate into a variety of cell types. Generally, stem cells can be categorized several ways. Certainly, one obvious category is adult versus embryogenic. The advantage of embryologic stem cells (ESC) is their ability to differentiate into all three germ layer types of the mesoderm, endoderm, and ectoderm. However,

ethical issues and the potential for the development of teratomas likely will restrict their usage in spinal surgery with perhaps the exception of treating spinal cord injury.

A specific type of adult, or somatic, stem cells called mesenchymal stem cells (MSCs) is more likely the group of cells of importance to standard spine surgery due to their limited potential to differentiate. The potentials include differentiation and development of bone, cartilage, muscle, and fat. The source of these cells is primarily from bone marrow and adipose tissue, and they are specifically referred to as mesenchymal progenitor cells (MPCs). Potential uses might include:<sup>162</sup>

- For fusion surgery and disc regenerative therapies based on MPCs' ability to differentiate into bone and disc.
- For stability postsurgically because MPCs secrete multiple bioactive factors such as multiple bone morphogenetic proteins (BMPs), which have a strong osteogenesis potential.
- For the treatment of both myelopathy and radiculopathy due to MPCs' production of immune modulatory factors, anti-inflammatory agents, and anti-fibrotic substances.

Direct culturing of existing spine tissue is already occurring. Cells from the nucleus pulposas (NP) and annulus fibrosis (AF) have been cultured from explanted tissue. A variety of stimulatory agents are used to cause growth; experiments have been conducted to test different bio-scaffolding for growth, including the use of three-dimensional printing devices. Interestingly, even cells from damaged discs retain the potential for activation. Cells cultured with total explanted discs retain more of the functional structure of the real disc. One study<sup>163</sup> in Europe specifically investigated regenerating the disc following

microdiscectomy by extracting cells, expanding through culturing and stimulation, and replacing them through injection in a second procedure. The patients experienced a decrease in back pain in this study. The drawback is the need for two procedures. These techniques will likely require many years of testing and perfecting prior to use on humans on a regular basis.

## Manipulation

Important screening questions or findings with regard to possible contraindication to manipulation of a specific area include the following:<sup>164</sup>

- use of anticoagulants
- recent back surgery (unstable spine)
- spinal infection
- spinal cancer
- severe osteoporosis
- signs of acute myelopathy or cauda equina syndrome
- acute inflammatory arthritis

In two separate reviews, Bronfort et al.,<sup>165</sup> found moderate evidence that for acute LBP, spinal manipulative therapy/mobilization is effective in the short term. For chronic LBP moderate evidence was shown again in the short term as compared to standard care, and in the long term as compared to physical therapy.

The evidence for manipulation is rather strong for acute LBP without radiation, but little research has been done to determine the effects on patients with “sciatica” or radiating pain into the leg below the knee. Two interesting studies have set the stage for further research based on their positive outcomes. One study by Santilli et al.<sup>166</sup> randomized patients with acute back pain and “sciatica” into either a

true chiropractic manipulation group or a sham manipulation group. A total of 102 patients were treated with either true manipulation or sham manipulation for five days per week. Depending on pain relief, a “rapid thrust technique” similar to a diversified or Gonstead-like, side-posture treatment was applied for a maximum of 20 times. Standard outcome measures including visual analog scale, quality of life, use of medication, and psychosocial findings were checked at 15, 30, 45, and 90 days. Manipulation was judged as more effective based on the percentage of pain-free cases. Interestingly, though, there were no significant differences in quality of life and psychosocial scores.

More recently, several studies indicate both safety and effectiveness for spinal manipulative therapy (SMT) in the management of lumbar radiculopathy. Regarding the conservative management of sciatica with clinical indicators of neurological dysfunction, a study<sup>167</sup> utilizing either the McKenzie approach or sham exercise demonstrated that although 65% of participants had three or four positive nerve root compression signs and would be considered by many medical physicians as surgical candidates, only 3% had symptoms so severe that they were referred to a neurosurgeon. At the end of the treatment period, 89% of patients reported being better or much better and at one-year follow-up, 91% of patients, surpassing the results indicated in the literature for surgical interventions.

In evaluating these studies, it is important that the patient population has an actual radiculopathy and not another cause of radiating leg pain.

As mentioned above in the discussion of surgery, in a study<sup>156</sup> published in 2010, patients who had failed usual medical care for LBP and sciatica were randomized to either microdiscectomy or SMT. At the end of the study, 60% of patients randomized to SMT demonstrated some benefit with side-posture manipulation equal to those who underwent microdiscectomy. Patients who failed to benefit

from side-posture manipulation received benefit from subsequent surgical management. Those patients failing to receive benefit from surgery did not benefit from subsequent management with manipulation.

In 2011 a publication<sup>168</sup> in *Spine* compared the management of patients with sciatica through randomization to the McKenzie approach using directional exercise or manipulation. The McKenzie treatment method was “superior” to “manipulation” based on the number of patients who reported success following treatment (71%: McKenzie versus 59%: manipulation; odds ratio 0.58, 95% (CI) 0.36 to 0.91, P=0.018). The researchers concede though that the differences are statistically significant but unlikely to represent any clinically significant difference. There were some differences in response based on whether patients were categorized as centralizers, meaning their pain moved from the leg more toward the back versus peripheralizers who tended to have their pain radiate more into the leg with provoking maneuvers. Seventy percent of the centralizers had success in the McKenzie group (105/151) whereas 59% of the centralizers had success in the manipulation group (92/156). And 67% of the peripheralizers had success in the McKenzie group (16/24) versus 37% of the peripheralizers who had success in the manipulation group (7/19). At one-year follow-up, of the original patients on sick leave, only 13% of patients in the manipulation group were still on sick leave compared to 21% of patients in the McKenzie group who were still on sick leave. We do not know whether or not the radiation in these patients was radicular.

For studies evaluating the effect of therapy for radiculopathy, it is important that the diagnosis of disc herniation and the level and type of herniation are documented for all participants using MRI. These MRI findings must match the clinical findings and correlate with the same nerve root and disc level. The following study was

Careful to exclude those that did not meet this inclusion factor.

A prospective study<sup>169</sup> performed in Switzerland, compared patients treated with nerve root injection (NRI) versus high-velocity, low-amplitude (HVLA) adjusting with a push move used for foraminal herniations and a pull move used for paramedian herniations. Improvement in the SMT group was 76.5% (39/51) compared with 62.7% (32/51) of the NRI group. Both treatment groups had significant decreases in their NRS scores at one month ( $P = 0.0001$ ) with a 60% reduction for the SMT cohort and a 53% reduction for the NRI group. The cost effectiveness measured in both Swiss francs and U.S. dollars demonstrated an advantage for SMT over injection.

In 2014, for the first time in a major guideline recommendation, the North American Spine Society in their evidence-based guidelines for the management of LBP, stated that based on the literature evidence, spinal manipulation is an option for the relief of pain for patients with lumbar radiculopathy.<sup>170</sup>

For CLBP, Haas et al.<sup>171</sup> designed a study to evaluate the dose response of high-velocity, low-amplitude manipulation. Patients were randomized into several groups based on frequency. One group was manipulated one time per week, another group three times per week, and another group five times per week. At one month, the data suggest that there was a substantial linear effect of visits favoring a larger number of visits. More recently, Haas et al.<sup>172</sup> conducted a much larger study that included 400 patients with CLBP. One hundred patients were randomized into four groups based on frequency, which included either 0, 6, 12, or 18 sessions of SMT delivered as HVLA manipulation. All participants were assigned 18 treatment visits, three per week for six weeks. So the range was from no real spinal manipulation in one group to as many as 18 treatments of SMT in another. The control was a light massage performed on the non-SMT

visits. There was little real difference among groups but a modest effect for more treatments, with an optimal balance being 12 visits. It is common practice for chiropractors to recommend “maintenance” treatments for their patients with spinal pain including LBP. A survey by Rupert<sup>173</sup> indicated that approximately 95% of clinicians believe that maintenance treatments reduce the recurrence and exacerbation of symptoms. A preliminary study by Descarreaux et al.<sup>174</sup> evaluated the efficacy of preventive spinal manipulation for patients with CLBP. Both the treatment group and control group were given a high-intensity regimen of 12 visits over a one-month period. There was a one-month “washout period” for both groups. Following that period, the treatment group received maintenance spinal manipulation at three-week intervals for nine months while the other group did not. Although both groups had similar success with the initial high-intensity treatments and pain scores at the follow-up period, only the group with the maintenance spinal manipulations maintained their postintensive treatment disability scores. The control group reverted to their pretreatment levels.

For patients presenting with LBP, several studies suggest that some prediction can be made related to response to manipulation. Although many of these studies are small and are not randomized controlled studies, some common observations occur with most of them. One of these studies by Flynn et al.<sup>175</sup> suggests that if a patient presents with four out of five variables, the success rate approaches 95%. However, patients presenting with three or less of these same variables had a 50% or less chance of recovery. These variables are:

- 1.** Segmental dysfunction/pain with springing palpation over the lumbar facets
- 2.** Acute onset of pain < 16 days
- 3.** No pain distal to the knee

4. Limited hip internal rotation
5. Low fear avoidance belief score

It is important to note that manipulation was performed by physical therapists in this study and therefore extrapolation to a chiropractic setting may not be similar.

Another report by Axen et al.<sup>176</sup> suggested that by the fourth visit the chance for recovery was only 30% if all of the following were present:

- No immediate improvement after first visit
- Pain was not decreased at second visit
- No decrease in disability reported at the second visit
- A reaction, such as local pain or fatigue, lasting more than 24 hours, new radiating pain, or other reactions to the first treatment

In a recent summary, Liebenson,<sup>177</sup> drawing on previous reports of predictability for LBP management, suggested the following approach to types of patients with chronic pain:

- Acute patients at risk of not responding to chiropractic care—Advise that gradually resuming activity, rather than prolonged rest, hastens recovery. Manipulate and mobilize other areas in addition to the low back, including hips or thoracic spine, and prescribe exercises, such as McKenzie or stabilization types, including instruction on how to perform them safely. Approximately 30% of patients may not respond to this approach.<sup>178</sup>
- Subacute patients at risk of not responding to chiropractic care—Assure patients that hurt does not mean harm and that pain is not the consequence of irreversible damage. In addition to the approach for acute patients, adding graded exposure to feared stimuli and following cognitive behavioral principles

may be helpful. Linton<sup>179</sup> also suggests an emphasis on applied relaxation and promotion of a healthy lifestyle, including positive coping skills, controlling stress at home and work, good communication skills, assertiveness, and developing a plan for adherence.

- Chronic patients at risk of not responding to chiropractic care—Adding to the above approaches, advise the patient that pain is usually due to a central nervous system sensitization of pain due to lowered pain thresholds and tolerance. Also, consider involvement of a multidisciplinary team for comanagement, including a pain psychologist.

Cautions for the practitioner include:

- Passive treatment can be iatrogenic.
- Reinforcement of avoidance may occur if the focus is on pain relief prior to activation (return to activity).
- Psychosocial factors are an important and often ignored component.
- Job dissatisfaction is a significant predictor as to whether back injury and chronic disabling pain is reported.
- More success occurs with proactive policies that facilitate a return to work prior to total pain resolution.

Researchers in an interesting study comparing the psychological effects of spinal manipulation versus either physical treatment or verbal interventions used a meta-analysis of existing studies to compare psychological outcomes.<sup>180</sup> There appears to be some evidence that spinal manipulation improves psychological outcomes as compared with verbal interventions.

More studies must be performed to determine whether there is a global effect rather than effects that are segment-specific. The broader issues of passive and active care are

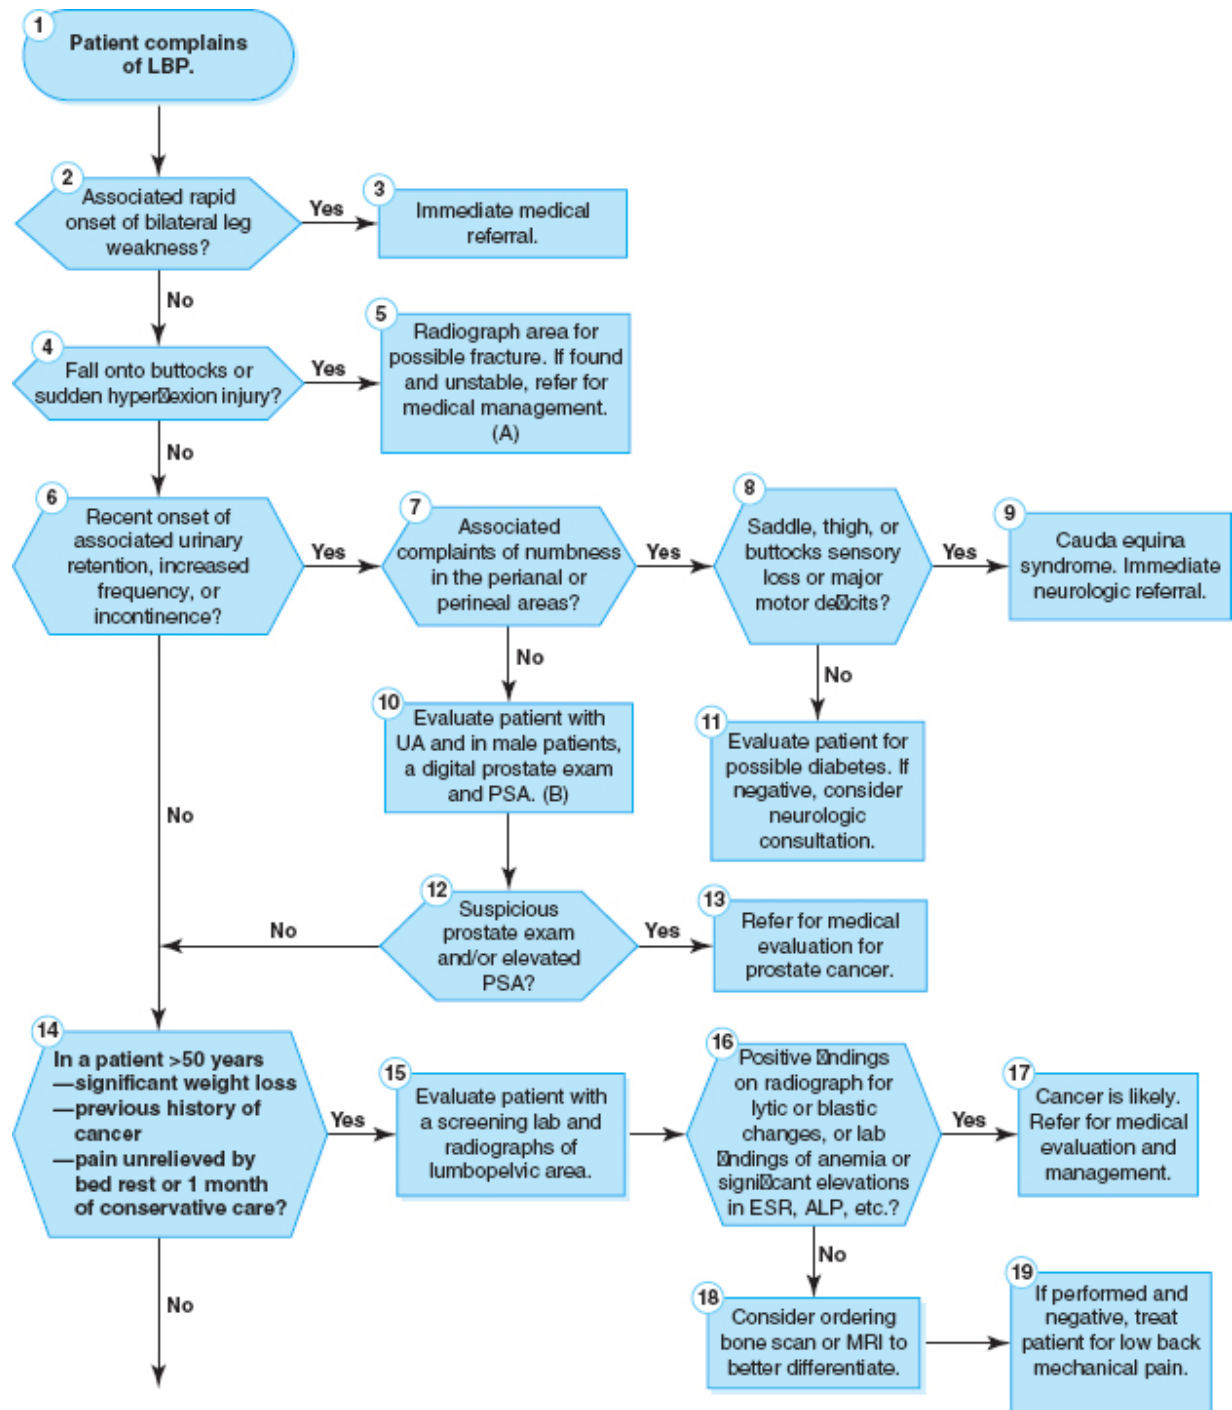

applicable to any approach chosen by the chiropractor. Algorithms for these areas are given in [Chapter 1](#). Algorithms for LBP screening and mechanical LBP are presented in [Figures 6-15](#) and [6-16](#).

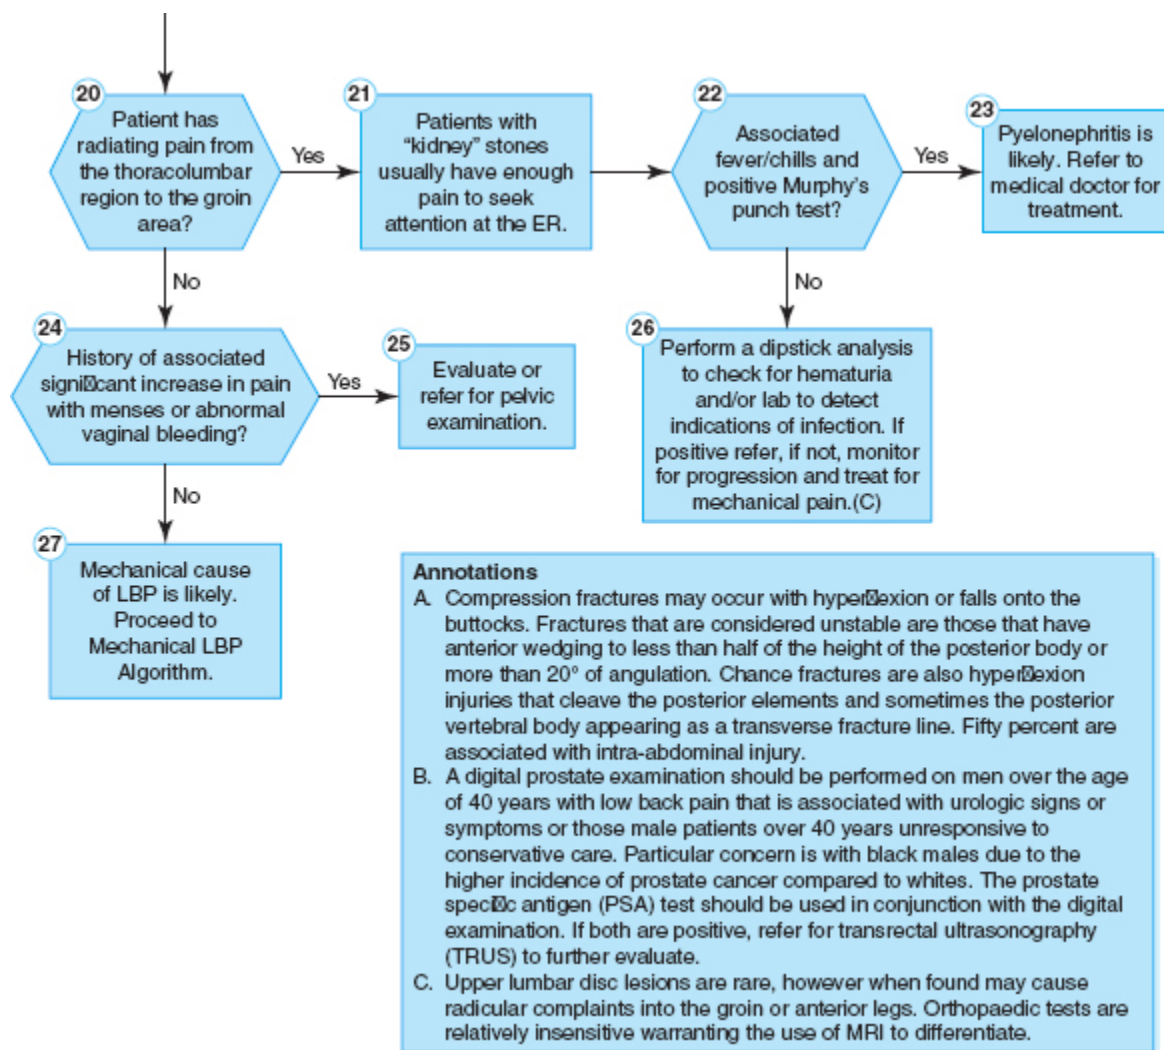

## Mechanical Traction

There are a number of approaches to mechanical traction for LBP. The evidence for superiority of one type over another has not yet been demonstrated. A small study<sup>181</sup> published in 2009 identified some potential predictors of the likelihood of improvement using supine mechanical traction. The prediction rule includes the following four variables:

- 1.** Fear Avoidance Belief Questionnaire – Work subscale < 21
- 2.** No neurological deficits
- 3.** > 30 years of age
- 4.** Nonmanual work job status

If all four items were present, there was a LR of 9.4 that supine traction over three sessions would provide at least a 50% improvement in pain. The protocol included supine, intermittent traction applied with the patient's knees and hips flexed 90° and supported. The traction intensity was at 30% to 40% of the patient's body weight. Fifteen minutes of intermittent traction with a 30-second hold and a 10-second relaxation phase was utilized. Out of all study participants, only 20% met the four criteria that predicted success.

**Figure 6-15** Low Back Pain Screening—Algorithm

A small study<sup>182</sup> published in 2007 compared the results of prone lumbar mechanical traction for patients with signs of nerve root compression. This preliminary study identified two predictors that, when both were present, discriminated between those who would and those who would not respond to traction. For those meeting the two variables of peripheralization with repeated lumbar extension and a positive crossed SLR there was a differentiation that identified 84% who responded to traction versus only 49% who recovered without traction. The protocol included the following:

- Static traction was applied in the prone position.
- The patient was positioned to maximize centralization of symptoms.
- 40% to 60% of body weight was utilized.
- If not initially in extension after three minutes of traction, there was a repositioning within patient comfort to acquire a more neutral or extended position.
- The patient remained at rest for two minutes after the treatment session and performed 10 press-ups prior to standing.
- Treatment was for two weeks only.

Even though there were no differences between groups at six weeks, it is notable that there were significant differences in favor of the tractioned group at two weeks, implying that these patients were able to function earlier than those without traction. More studies are needed.

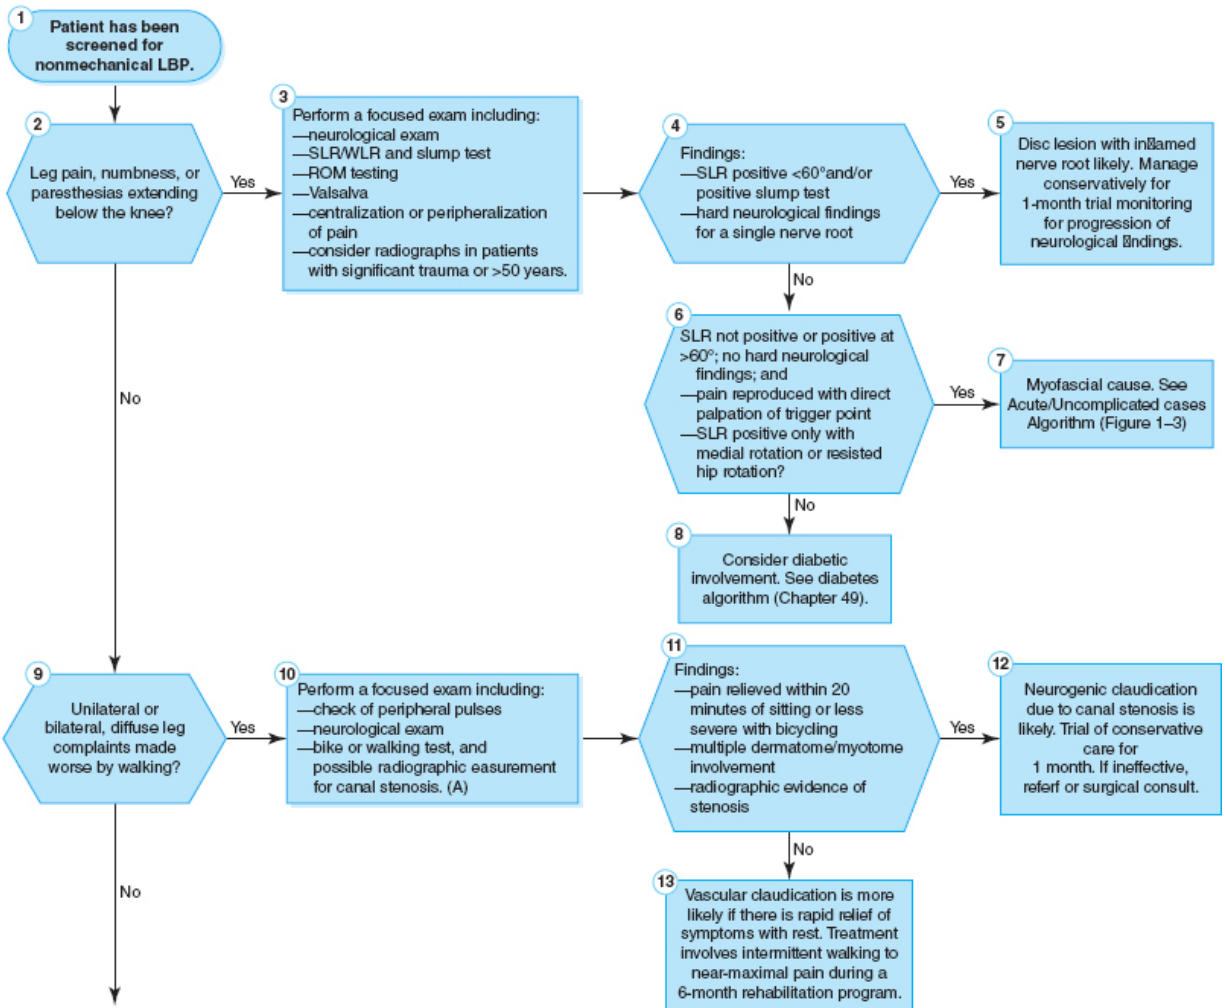

## Yoga

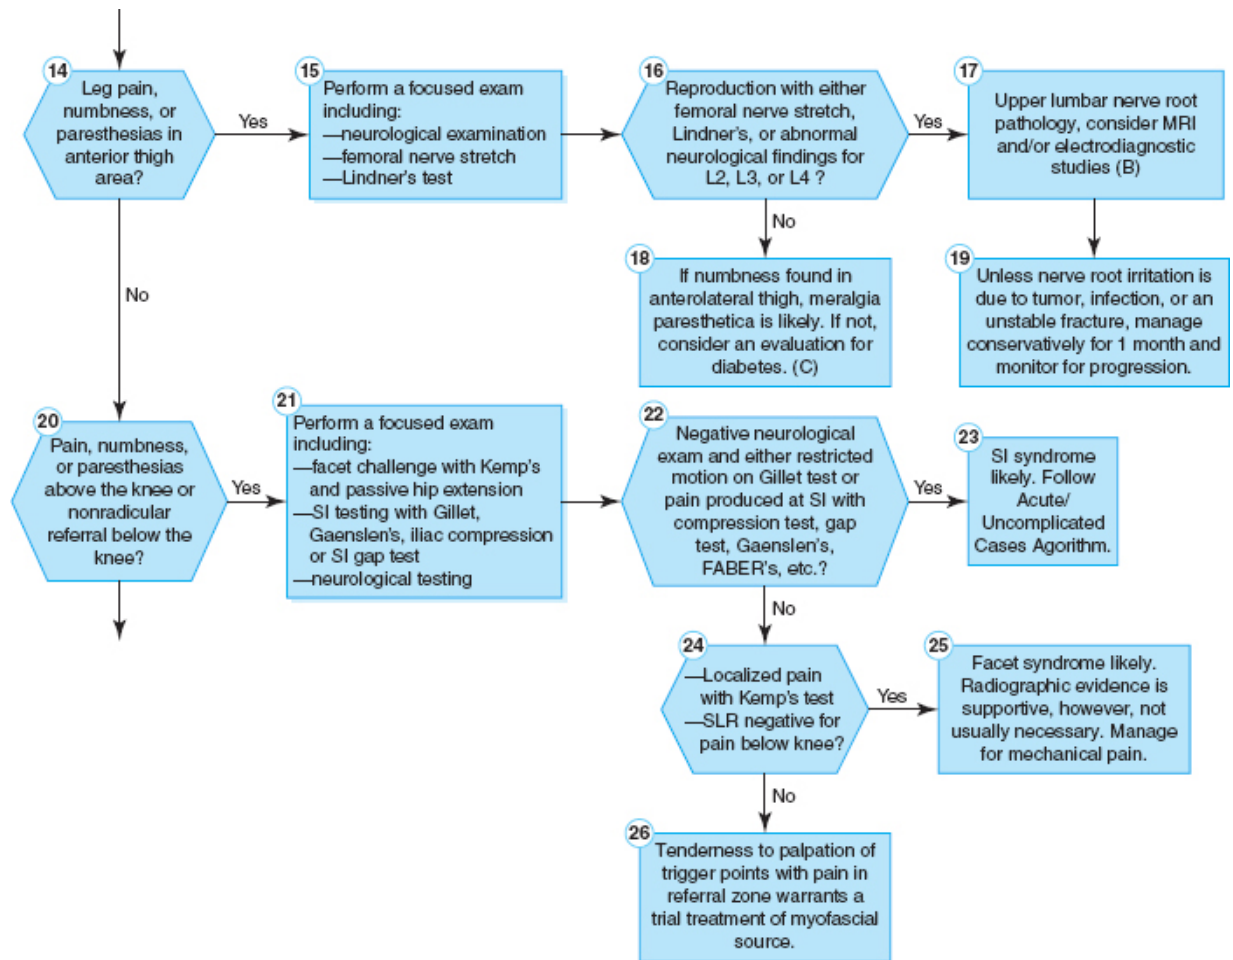

The evidence for yoga as an approach to LBP is still minimal. A study<sup>183</sup> published in 2011 demonstrated that there was no difference in back pain and general health between a usual care group and a group assigned to a 12-week yoga program for patients with CLBP. However, a systematic review<sup>184</sup> published in 2013 found short-term effectiveness and moderate evidence for long-term effectiveness for CLBP.

## Exercise

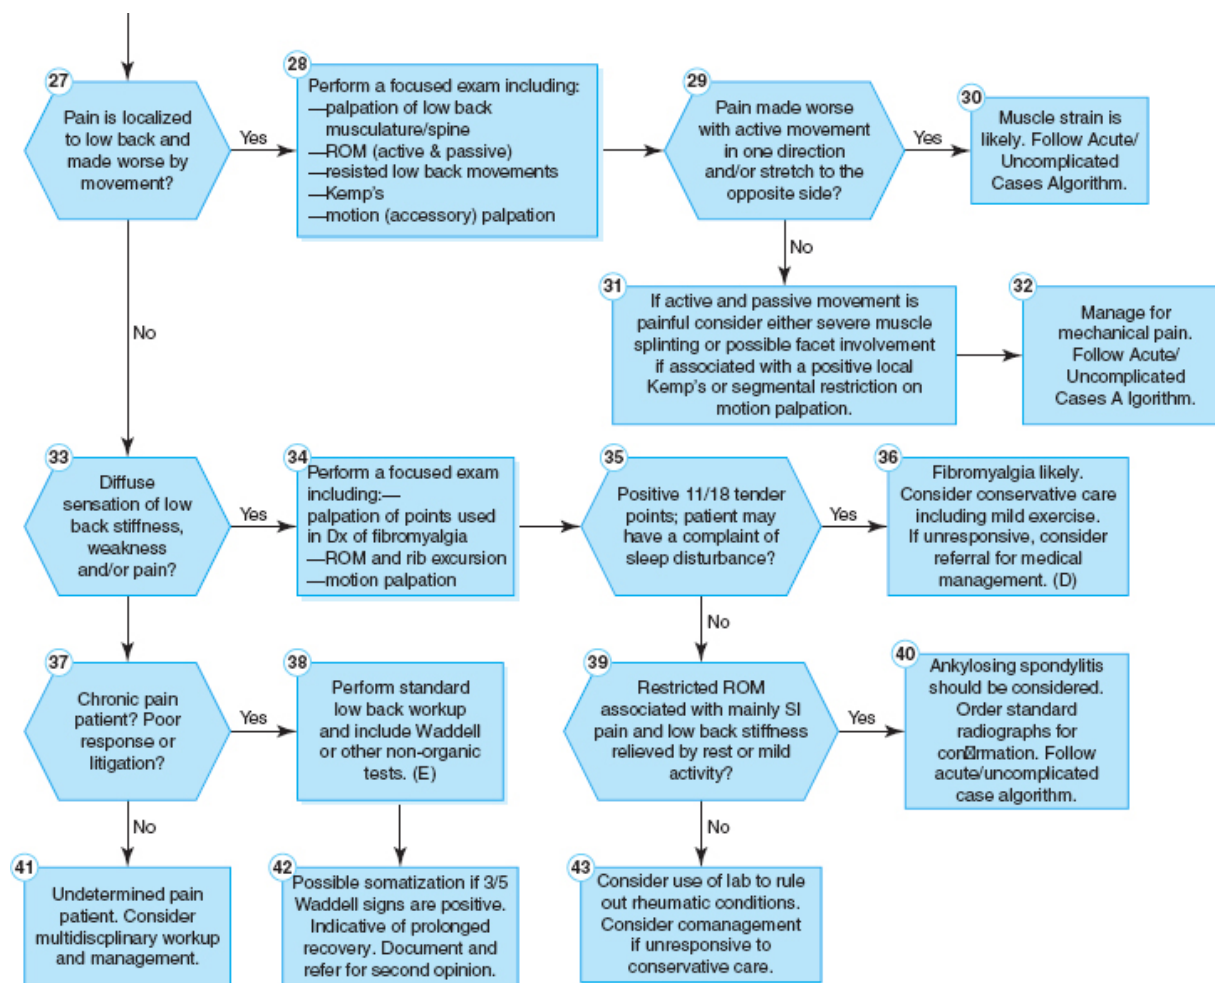

Most exercise recommendations involve either prevention or rehabilitation after acute low back pain has subsided or for chronic low back pain patients. In a Cochrane review<sup>185</sup>

evaluating the effect of exercise for the prevention of recurrences of LBP, it was found that at two to five years, the recurrence rate was 72% with an average of two recurrences over that time period. The researchers made an attempt to stratify exercises based on type but finding this difficult, divided exercise into a during-treatment type and a post-treatment intervention type. Based on their review, there was no difference in the number of recurrences when exercise was given during treatment. However, the use of post-treatment exercises led to a reduced number of sick days and greater time between occurrences.

### Annotations

- A. Central canal stenosis may be estimated on a lateral lumbar radiograph using either Beuler's or Eisenstein's measurements. A normal canal is 15 mm; 12 mm is considered relative stenosis; 10 mm or less is considered absolute.
- B. Upper lumbar disc lesions are rare, however, when they do occur, they often affect more than upper lumbar nerve roots. Therefore, the Achilles reflex may be affected and the patient may have some posterior leg pain.
- C. Diabetes may cause distal sensory disturbances or cause unilateral peripheral nerve palsies such as in amyotrophy. With diabetic amyotrophy, involvement of the femoral nerve is most common with weakness and atrophy of the quadriceps.
- D. Fibromyalgia is a more generalized, symmetric distribution of myofascitis. The American College of Rheumatology has set criteria for the diagnosis: pain in 11 of 18 tender sites in a patient with pain for at least 3 months. These bilateral points include suboccipital, lower cervical spine, trapezius, supraspinatus, second rib, lateral epicondyle, gluteals, greater trochanter, and medial fat pad of the knee.
- E. Waddell's non-organic signs include generalized or non-anatomic tenderness, positive responses to simulated orthopaedic testing (axial loading, trunk rotation), distracted SLR (hip test), regional weakness and sensory abnormalities that are nonmyotomal and nondermatomal, and overreaction to testing.

**Figure 6-16** Neruological and Mechanical Low Back Pain—Algorithm

In a study by Bronfort et al.<sup>186</sup> published in *The Spine Journal*, patients with LBP were randomized into one of the following groups:

1. High-dose, supervised, low-tech trunk exercise
2. Spinal manipulative therapy
3. A short course of home exercise and self-care advice

The specifics for the supervised exercise group included an emphasis on trunk muscle endurance and trunk stability. There were approximately 20 one-hour sessions (about two per week) which included two to three sets of 15–20 repetitions for each exercise. Also included was a five-minute warm-up and six stretches including lumbar, gluteals, and hamstrings. Core strengthening included trunk extensions, leg extensions, and abdominal exercises. High-velocity, low-amplitude manipulation was performed on those patients in the spinal manipulative therapy group.

About 50% of patients in all groups experienced a 50% reduction in pain. About 60% of patients on average experienced a 50% gain in their global improvement. About 50% experienced a 75% gain in their global improvement. There were no significant differences in outcomes among the three approaches in this study. All groups did demonstrate an improvement; however, improvement to the point of a 75% reduction in pain was seen in only 30% of patients, on average, for all three groups of patients in the long term. Consistently, patient satisfaction was higher in the supervised exercise therapy group.

## **McKenzie or Directional Preference Approach**

One exception to the approach of waiting until pain has subsided is “directional preference” (DP) exercises, which are a primary diagnostic and management approach of the McKenzie technique. A study by Long et al.<sup>187</sup> was designed as a randomized controlled study involving 312 acute, subacute, and chronic low back pain patients. In this particular study 74% of patients had a DP. Those who performed the DP versus the opposite direction of DP had immediate improvement in the outcomes measured, which included pain intensity, disability, and medication use, among others. DP is a particular position or repeated end-range movement that either centralizes a patient’s radiating pain or eliminates or decreases lumbar spine pain. These motions include side-gliding/rotation or repeated end-range lumbar flexion or extension. The classic approach used by many practitioners is patient-performed prone-extension to determine if radiating pain centralizes to the low back or, if not, attempting side-shifting of the pelvis and repeating the position to determine effectiveness. The interrater reliability for identifying DP has been reported as high (kappa values between 0.79 and 1.00).

In a comparative study<sup>188</sup> published in 2012, patients with sciatica and some with clinical signs of radiculopathy were randomized to either a directional-exercise approach (i.e., McKenzie technique) or sham exercise. Participants in this study had, on average, severe pain with radicular findings. Over 50% had motor deficits or asymmetrical DTRs and 80% had sensory deficits. Sixty-five percent of them had three or four positive nerve root compression signs and 30% had two positive signs. Therefore, many medical physicians would classify most patients in this study as surgical candidates. A clinically significant change was set at a threshold of 30% change in the baseline Roland-Morris Disability Questionnaire and a 2-point decrease in a 10-point numerical pain score. At the end of the two-month treatment period, 89% of participants reported feeling

better or much better and at a one-year follow-up, 91% of participants reported feeling better or much better. At the end of the treatment period, 74% of the symptom-guided group was back to work and 60% in the sham-exercise group had returned to work. There were no significant differences between groups for pain or RMDQ scores; however, with the exception of DTRs, there was a greater improvement in both motor deficits and sensory deficits after treatment and at one-year follow-up in the Symptom-Guided Exercise group that was statistically significant. In general, neurological findings improved significantly more in the symptom-guided exercise group versus the sham exercise group. The conclusion that is drawn for the participants in this study is that an active treatment approach results in significant improvement over eight weeks and these changes were sustained and improved over a one-year period for patients with acute, subacute, or chronic radicular pain.

A similar approach to determining a position of relief is proposed by Mulligan.<sup>189</sup> This dynamic approach to positionally based relief is based on assisting the vertebrae or sacrum into a position of accessory movement that may be blocked, and repeating a painful movement to determine if the pain is reduced or eliminated. For example, if a patient has pain on forward flexion, the examiner contacts below the spinous process of a suspected segment and/or the articular pillar unilaterally. With pressure in an anterior superior direction, the patient is asked to flex forward to determine if decrease or relief of pain has occurred. Other positional stresses can be applied to the spinous processes pushing right or left. For the sacrum, pushing downward may relieve pain on flexion. The findings may help determine the spinal level to be adjusted.

Passive care involves procedures that are performed on the patient with the patient providing no more than cooperation. These include physical therapy modalities,

passive ROM, massage/trigger point massage, mobilization, and manipulation. Criteria for passive care include a history of recent trauma, an acute or inflammatory condition, or dependency behavior. The primary goal is to control inflammation and pain. The frequency of manual therapy visits during the first 10 to 14 days may range from three to five visits per week dependent on the severity of the pain and disability. The patient should be reevaluated to determine whether therapy is effective. If not effective, a second two-week trial using a different treatment approach is warranted. If this is not successful, further evaluation with special imaging or comanagement with a medical doctor is recommended. Use of the New Zealand screening tool for psychosocial yellow flag indicators may help direct management for those at high risk for chronic pain and disability. Generally, if the patient has a preconsultation duration of symptoms greater than eight days or has severe pain, more than four previous episodes, or preexisting structural or pathologic conditions, the anticipated recovery time is often doubled.<sup>190</sup>

There is still and will continue to be some debate as to the appropriateness of side-posture manipulation in the treatment of disc herniations. The review of the literature by Cassidy et al.<sup>191</sup> supports the cautious application of this form of treatment. However, Slosberg's<sup>49</sup> review of the same literature points out some possible factors that may warrant a more cautious approach. Both reviews agree that low-grade mobilization attempts to determine the patient's response are a good screening procedure prior to the application of a thrust. In other words, if mild mobilization is applied at the involved segment, an increase in pain or reproduction of leg pain may be a caution against side-posture manipulation at that time.

Trigger point injection is advocated by some as a conservative alternative to surgery. Results indicate possible benefits for patients with chronic LBP.<sup>192</sup> A relatively new

approach to chronic LBP is the use of connective tissue proliferants using injections of dextrose-glycerin-phenol and other substances (prolotherapy). Currently the literature is limited with regard to the effectiveness of this approach. The literature that does exist is mixed regarding prolotherapy's long-term efficacy.<sup>193,194</sup>

## Medication

Through a systematic review of randomized, double-blind controlled trials, the Cochrane Collaboration Back Review Group evaluated the effectiveness of NSAIDs in the management of LBP.<sup>195</sup> The researchers also compared medications to determine whether one had demonstrable superior effectiveness. In a review of 51 studies, the group found that NSAIDs are effective for short-term symptomatic relief, but that no specific type of NSAID was clearly more effective. The group also stated that there was insufficient evidence to support the use of NSAIDs for chronic LBP.

## Acupuncture

A systematic review<sup>197</sup> published in 2013 concluded that real acupuncture was slightly better than sham acupuncture for the treatment of acute LBP. The review of 11 randomized trials also indicated that acupuncture was as effective as medication for acute LBP. Another study<sup>198</sup> published in 2013 comparing acupuncture and sham acupuncture in the management of chronic LBP demonstrated that using the Oswestry Disability Index, the Beck Depression Inventory, and Short Form-36 scores, both groups improved without group difference. And yet another systematic review<sup>199</sup> published in 2013 evaluating the effectiveness of acupuncture in the management of nonspecific, chronic LBP

concluded that acupuncture produced a clinically meaningful reduction in self-reported pain and improved function when compared to sham acupuncture or no treatment immediately post-intervention. It appeared that there was benefit to adding acupuncture to usual medical care but no significant differences between usual medical care and acupuncture alone.

## **Active Care and Prevention**

Active care involves the patient in determining goals and objectives. Exercises and stretches, modification of diet or other lifestyle changes, and modification of work or recreational environment or performance are among the targeted areas. Exercise takes into account the fitness level of the patient, pain-free ROM, strength, facilities, and motivation. In general, mild isometrics can be performed within pain-free ranges in an attempt to facilitate muscle activity and prevent atrophy. These are followed by various strategies involving isotonic exercises. The primary focus with the low back is strengthening abdominals and stretching the paraspinals. Information gained from a functional evaluation as discussed above can then lead to a more sophisticated approach at strengthening weak areas and stretching shortened areas. Although it is suggested that exercise is appropriate and helpful for subacute and chronic low back pain, the type of exercise that produces the best results has not surfaced in the literature.<sup>187,200</sup> Examples include core stabilization approaches,<sup>112,113</sup> Pilates,<sup>201</sup> and expensive equipment approaches such as MedEx. It would appear that results may be dependent on the patients and their individual needs for function. Following a strengthening phase, endurance and functional movement patterns are emphasized. Coupled with this approach is an attempt at proprioceptive stimulation

through the use of balance exercises. For the low back, giant balance (Swiss) ball exercise protocols have been developed. A significant effect for exercise and acute low back pain compared to natural history has not been demonstrated.<sup>202</sup> The beneficial effects of exercise for chronic low back pain patients have been demonstrated.<sup>203</sup> A recent study<sup>204</sup> indicated that the success of three different active therapies for chronic low back pain did not differ; however, the cost of application did differ significantly. One of these active therapies was low-impact aerobics, which is associated with a very low cost when compared with muscle training devices or active physiotherapy.

Proper lifting is essential to avoid injury or reinjury. The primary focus is to maintain a slight lordosis when lifting. When possible, the patient should be instructed to lift lower objects by bending the knees first and lifting from the legs. To reduce the effect of increasing the extensor movement, the load should be kept as close to the body as possible. Twisting should be avoided while lifting. The spine is most vulnerable to lifting injury after holding a prolonged flexed position or after prolonged recumbency (in the morning). Finally, all lifting should be accompanied by co-contraction of the back and abdominal muscles. One controlled trial<sup>205</sup> failed to demonstrate any long-term benefit for an educational program designed to prevent work-associated low back injury.

Although it may seem counterintuitive, a systematic review by Martimo et al.<sup>206</sup> has concluded that there is no evidence to support the use of advice or training in working techniques with or without lifting equipment to prevent back pain and resulting disability. Additionally, in a recent study by Martimo et al.,<sup>207</sup> strong evidence was found that manual material handling advice or lifting assistant devices do not prevent low back injury.

The seated position causes significantly higher disc pressure than standing. When seated, the chair should be stable with a seat-backrest angle of 95° to 105°. <sup>208</sup> A lumbar support may help maintain a slight lordosis. A slightly forward-sloped seat may also be helpful. Too low a seat shifts more weight onto the ischial tuberosities. Proper desk height is considered about 27–30 cm higher than the seat, allowing the arms to rest with the elbows bent 90° with the hand relaxed on the desk surface. <sup>209</sup>

An active lifestyle provides many health benefits that are primarily regarded as cardiovascular and musculoskeletal, yet a study <sup>210</sup> published in 2007 indicates that seniors aged 70 years to 100 years who exercised vigorously were rewarded with a protective effect against LBP. Increasing levels of strenuous activity translated to an increasing magnitude of protection against LBP. Although no specific exercise or program could be determined from this study, intensity and frequency were the determinants of success.

A 2008 Cochrane review by Engers et al. <sup>211</sup> evaluated the literature for the effectiveness of individual patient education for LBP. This extensive review led the authors to conclude that there is strong evidence that an individual 2.5-hour oral educational session is more effective for short- and long-term return to work as compared to no intervention at all. Also, less educational time was not effective. This approach appears to be effective for acute and subacute LBP in improving long-term pain, as well as global improvement when compared to noneducational interventions. No specific type of individual education seemed to stand out as being more effective.

A Cochrane review <sup>212</sup> published in 2007 evaluated the effectiveness of herbal medicine for LBP. Three herbs were represented in the literature as having an effect greater than placebo, and in some cases equal to drug therapy. These were:

- 1.** *H. procumbens* (Devil's Claw)—standardized daily dosage of 100 mg harpagoside.
- 2.** *S. alba* (White Willow)—extract of *S. alba* at a standardized dosage of 120 mg of Salix per day.
- 3.** Topical *C. frutescens* (Cayenne)—plaster application.

# Selected Disorders of the Low Back

## Disc Lesion with Radiculopathy

### Classic Presentation

The patient complains of low back and leg pain below the knee, often of sudden onset from a bending and/or twisting maneuver. There is often a past history of several bouts of LBP that resolved.

### Cause

Although in the past it was believed that all leg pain that was radicular was due to compression of a nerve root by a herniated nucleus pulposus, current thinking is that the nerve root is inflamed, but not always compressed.<sup>213</sup> Currently, it is theorized that herniated disc material causes the release of irritating substances or initiates an autoimmune inflammatory reaction. The disc, the corresponding inflamed nerve root, or compression of the nerve root by the disc may be the source of pain. When there is leg pain without objective neurologic evidence, the pain is often referred. When the nerve root is compressed, frank neurologic signs usually become evident. Only about 1% of LBP patients have frank neurologic findings.

### Evaluation

Given that 98% of all disc lesions are at L4-L5 or L5-S1, the neurologic examination is focused to these areas. Although there are conflicting findings in systematic reviews regarding the value of the orthopaedic and neurologic evaluation for lumbar radiculopathy, the following might be considered a reasonable approach based on the literature. Use the SLR and the slump test as sensitive tests and the crossed-SLR as a more specific test. Combinations of orthopaedic findings with neurological testing may be helpful. An L5-S1 disc rupture is 86% probable if all three S1 signs are found: (1) pain projection into the S1 area, (2) a pathologic Achilles reflex, and (3) a sensory defect in the S1 dermatome.<sup>69</sup> Localization to the L4-L5 disc is 87% probable with all three L5 signs: (1) extensor hallucis (EH) weakness, (2) pain projection into the L5 area, and (3) a sensory defect in the L5 dermatome. It is important to note though that the patient's report of pain is *nondermatomal* in 64.1% of

cases of lumbar radiculopathy according to the Murphy et al. study.<sup>214</sup> Also important to note is that in subjects with electrodiagnostic evidence of radiculopathy, 31% will have no weakness on examination and 33%–45% will have no sensory abnormalities.<sup>215</sup> And, although 64%–75% will have weakness on examination, only 15%–34% will complain of weakness.

Confirmation of nerve root involvement may be physiologic with electrodiagnostic studies or anatomic with MRI. These studies are rarely used during the first four weeks of a complaint unless severe, unremitting pain or progressive neurologic signs are present.

## Management

Given the nucleus pulposus is avascular, when it is exposed to the body's normal defense mechanisms it is perceived as "foreign" and an immunological response is set in play to eliminate the disc material. As a result, it is likely in most cases of extrusion that many are "reabsorbed" over several months leading to a natural history of resolution.<sup>216</sup> This reabsorption process requires matrix metalloproteinases (MMPs). Previously these were called collagenases, gelatinase, stromelysin, and elastase. Now these are termed MMP-1, MMP-2, MMP-3, and MMP-12 respectively. This process is terminated by tissue inhibitors of metalloproteinases (TIMPs). MMP/TIMP balance is essential for resolution.

There is some debate as to whether side-posture adjusting should be used in the treatment of disc herniations.<sup>49</sup> The primary concern is the rotary component. If the patient is adjusted in a slightly extended side-lying position, the facets will more likely provide protection. If the rotary component is minimized and the patient is pretested with mild mobilization at the segment to determine aggravation of the leg complaint, cautious side-posture adjusting is a possible alternative.<sup>190</sup> In fact, in 2014, the North American Spine Society stated that manipulation was an option for patients with lumbar radiculopathy. Other studies listed above in the Management section of this chapter detail the evidence for which these conclusions were based. Manipulation under anesthesia is gaining support as an extension of the standard clinical approach in-office. Guidelines released in 2014 help advise the practitioner in patient selection. Practitioners also opt for "softer" approaches that involve no rotation, such as flexion-distraction, blocking, and activator adjusting.

In the event that nonsurgical management is ineffective, there are some middle-of-the-road medical approaches that involve either medication or injections. For example, many chiropractors refer their nonresponsive patients for a Medrol Dosepak prescription. A Medrol Dosepak is a medication card with twenty-one 4 mg pills. The medication is methylprednisolone (similar to prednisone). The patient starts with six pills (24 mg) and takes one less pill each day until finished. The pills are taken orally with a full glass of water before breakfast, after lunch, and after dinner.

Epidural injections are another approach. See the earlier discussion of epidural injections for the literature support and recommendations regarding this approach.

Surgery is rarely needed; however, when suggested, a number of procedures are used. **Table 6-4** summarizes the most common approaches. A new technique is currently being researched that attempts to heat and “shrink” the disc in patients who have discogenic pain.<sup>217</sup> This technique is called *intradiscal electrothermal annuloplasty* (IEA) and *intradiscal electrothermal therapy* (IDET). Using a radiofrequency probe, annular tissue is heated to 85° C for a mean duration of 14 minutes. The preliminary results are promising; however, further studies are needed. Data do not demonstrate a superior outcome for restored neurologic function for operative intervention compared to nonoperative over time. Yet, some authors still suggest that if there is a motor deficit after six months, operative intervention should be considered.<sup>218</sup> It is important to remember that with appropriate triage, the percentage of patients meeting the indications for surgical intervention is only between 2% and 4%.<sup>219</sup> A recent report from the Maine Lumbar Spine Study<sup>220</sup> presented data that suggested the five-year outcome for patients with sciatica secondary to lumbar disc herniation treated surgically was better for a larger percentage (70%) compared to those managed nonsurgically (56%). The researchers also reported that the patients treated surgically more commonly received disability compensation, and the relative benefit of surgery decreased over the five-year period. Macro and microdiscectomy have a reported success rate of 80% to 96%.<sup>130</sup> Comparisons between the outcomes of operative versus nonoperative medical management for lumbar disc herniation are difficult. Researchers<sup>222,223</sup> have attempted to determine long-term results but due to large numbers of crossover patients and the intention-to-treat analysis, conclusions were not possible. Generally speaking, both groups improve. However, there may be some slight benefit to surgical treatment. This was emphasized in a study by Mariconda et al.<sup>224</sup> who followed up on patients with an average of 27.8 post-surgery (discectomy) for their LBP and compared them to those who had not had surgery. There was a high satisfaction rate for those with surgery and a slight difference regarding pain, favoring those who had surgery over those who had not. The question is, if there is only a small difference, is the risk and cost of surgery worth it? The answer to this question will likely always depend to some extent on patient context and preference.

A new approach to the management of discogenic pain is being tested. This involves the use of an artificial lumbar disc. A two-year, follow-up, randomized trial<sup>225</sup> indicates good results for those that have failed other approaches. The concern, as was the case with early knee and hip replacements, is migration of the device. This approach may be an alternative for younger patients with less degeneration and is not a good option for those with considerable degeneration and poor bone quality. At this time, if surgery is considered, most surgeons would still recommend fusion for the majority of cases.

**Table 6-4** Selected Surgical Procedures for Disc Lesions

<b>Procedure</b>	<b>Comments</b>
Intradiscal electrothermal therapy (IDET) or intradiscal electrothermal annuloplasty (IEA)	Using normal discographic technique, a catheter is inserted anteriorly into either the annulus or nucleus via a 17-gauge introducer. The active tip of this radiofrequency probe generates electrothermal heat starting at 65°C increasing in a stepwise process to 85°C for about 14 minutes. The intention is to shrink discal material and relieve discogenic pain.
Percutaneous/arthroscopic mechanical discectomy	A discoscope is used in either a biportal or single portal approach. Fluoroscopic monitoring is essential. On patients meeting selected criteria, the success rate is in the 90th percentile if those with increased mobility and reduced medication are included. However, only 66% had returned to work.
Percutaneous laser discectomy	Laser ablation for disc removal is a questionable technique due to the high cost of laser equipment and the potential for inadvertently injuring adjacent tissues such as the vertebral end-plate or spinal nerve, leading to chronic low back pain.
Percutaneous suction discectomy	Also called automated percutaneous lumbar discectomy, the nucleus pulposus is removed with a rotary cutting device attached to an aspiration probe. Studies have not shown consistent long-term results, and it is less cost-effective than microdiscectomy.
Open limited discectomy	A limited laminotomy with disc excision (also called microdiscectomy) is considered the

	treatment of choice by many surgeons.
Anterior discectomy and fusion	Anterior surgery is considered unnecessary given the less invasive limited laminotomy and fragment excision techniques available.

## Fact Syndrome

## Classic Presentation

The patient often will complain of well-localized LBP with some hip/buttock or leg pain above the knee. The onset is often sudden after a simple misjudged movement or arising from a flexed position.

## Cause

The facet and its capsule may be the source of pain. Each facet receives innervation from two spinal levels, specifically from the medial branch of the posterior primary rami. Synovial folds (meniscoids) may become entrapped or pinched and cause pain. The synovium and capsule have specific substance P-sensitive nerves in addition to small-diameter nociceptors.<sup>226</sup> Another process that may predispose to facet-mediated pain is degeneration, seen more often in middle-aged and older adults.

## Evaluation

Although there is often difficulty in distinguishing facet from disc/nerve root irritation, there is usually a cluster of findings that help support the differentiation. For facet syndrome, these include absence of neurologic deficits, absence of nerve root tension signs/tests, pain that is rather localized with Kemp's maneuver (extension and rotation; [Figure 6-5](#)), and when reproduced with an SLR does not extend below the knee. Radiographic evidence may include signs of facet imbrication using the lumbar or lumbosacral disc angle, or Hadley's S curve. The variability of normal findings in asymptomatic patients makes the use of these markings questionable. In general, any disc angle greater than 15° is strong evidence of facet imbrication.

## Management

In a recent study<sup>227</sup> researchers measured the anterior to posterior position of the lumbar zygapophyseal joints using MRI scans taken before and after side-posture adjusting and before and after side-posture positioning. Spinal adjusting was demonstrated to produce increased gapping of the Z joints. Interestingly, side-posture positioning also produced some gapping, although less than the adjustment.

Facet syndrome appears to be particularly responsive to adjustment (manipulation). The mechanism is still not clear; however, two major proposals are that either the adjustment frees an entrapped meniscoid tab or large-fiber input causes reflex changes, reducing muscle spasm and reflex-mediated pain.

Medical approaches such as radiofrequency facet denervation and facet injections are often advocated. Facet denervation shows some promise for selected chronic low back pain sufferers.<sup>228</sup> Facet injection has mixed support in the literature.<sup>229</sup>

## **Canal Stenosis**

# **Classic Presentation**

Patients often are aged 50 years or older. They complain of back and leg pain. The pain can be unilateral and bilateral and often is diffuse. Patients may complain of the onset of leg complaints with walking (claudication) and relief after resting 15 to 20 minutes or by maintaining a flexed posture.

## **Cause**

It is estimated that approximately 13% to 14% of patients with LBP seeking specialty physician consultation and 3% to 4% of those seeking general practitioner consultation have lumbar spinal stenosis.<sup>230,231</sup>

Stenosis may be central or lateral, caused by bony or soft tissue encroachment, and congenital or acquired. As a result, the signs and symptoms vary widely. For leg complaints to occur, it is usually true that there are multiple levels of stenosis. Congenitally, a trefoil shape of the spinal canal leads to central canal and lateral stenosis. Pedicogenic stenosis is due to anatomically short pedicles. Acquired stenosis is due to bony outgrowths from the facets, laminae, or pedicles, degenerative spondylolisthesis, or hypertrophied and/or calcified ligamentum flavum. Postoperative stenosis may also be a consequence of decompressive surgeries (e.g., laminectomies).

## **Evaluation**

Neurologic deficits may be apparent, yet cross dermatomal and other nerve root boundaries. In an older patient with multilevel findings, stenosis should be considered. Often used is the bicycle or walking test to differentiate between neurogenic and vascular claudication. Patients with neurogenic claudication often find it possible to bicycle or walk farther when flexed. This theoretically opens up the canal and intervertebral foramina, taking pressure off the neural structures. One study<sup>232</sup> indicated that these tests may not be able to differentiate clearly between the two types of claudication. Although reasonably insensitive (0.60), improvement with flexion points strongly to canal stenosis. Central canal stenosis may be estimated on a lateral lumbar film using either the Eisenstein or Beuler method. A normal canal is 15 mm or greater; 12 mm is considered relative stenosis; 10 mm is considered absolute. CT scan is often used when bony canal stenosis is suspected. MRI is more valuable with soft tissue encroachment. Electrodiagnostic studies are often used when multiple nerve root levels appear to be affected. EMG is less valuable than dermatomal sensory-evoked potentials (DSEPs).<sup>233</sup>

## Management

Treatment is based on the underlying type and cause of the stenosis. The natural history seems to suggest that many patients with stenosis may improve or remain stable (90%) without treatment.<sup>234</sup> If manipulative therapy is tried, caution should be used because of the possibility of increasing compression, causing an exacerbation or worsening of symptoms. The response to manipulative treatment is less predictable than for other causes of LBP. The positive response rate is approximately 36% according to a study by Cassidy et al.<sup>17</sup> If the patient has severe neurologic deficit or fails to respond to conservative management, surgical consultation is warranted for possible decompression of the area or areas. In one study,<sup>235</sup> a significant number of patients with spinal stenosis avoided surgery with aggressive therapies including exercise, analgesics, and epidural steroid injections. In a review comparing the four-year outcomes for surgical and nonsurgical management of lumbar spinal stenosis, it appears that both groups improve; however, 70% of the surgically treated group were free of their leg or back pain whereas only 52% of the nonsurgically managed group reported relief.<sup>236</sup> Those who went to surgery were at baseline reporting more severe symptoms and worse functional status. Therefore, it appears that those patients with the worst symptoms may be better candidates. It has been reported that patients who have surgery for lumbar stenosis have very good initial results but these are lost over one to two years so that they are comparable to conservative management. A study by Malmivaara et al.<sup>237</sup> indicates that although the effects decrease, disability, leg pain, and back pain are still more improved after two years compared with conservative management. A study by Weinstein et al.<sup>238</sup> published in 2008 concludes that there is significantly more improvement in all primary outcomes for those treated surgically

compared to those treated non-surgically. For those who have radiographic evidence of stenosis yet do not have severe enough signs and symptoms to warrant surgical intervention, the evidence is unclear. One study<sup>239</sup> indicated that depression, cardiovascular comorbidity, dysfunction with walking (i.e., leg pain with walking), and scoliosis predicted poorer subjective outcome with surgery. It did appear that the more severe the stenosis, the more likely there would be a positive subjective outcome with surgery. There are some encouraging results from a randomized control study comparing two physical therapy approaches for lumbar spinal stenosis.<sup>240</sup> The data indicate that a six-week program including manual therapy, exercise, and bodyweight-supported treadmill walking resulted in recovery for 79% of patients.

## **Spondylolisthesis**

### **Classic Presentation**

There are several types of spondylolisthesis; however, the most common are isthmic, occurring in the young, and degenerative, occurring in the older patient. Patients may be asymptomatic or have LBP made worse with extension. In older patients, the degenerative spondylolisthesis may cause signs of stenosis.

### **Cause**

Although congenital types and destructive (e.g., tuberculosis or cancer) types are possible, they are rare. The isthmic type is due to either a stress fracture of the pars interarticularis (spondylolysis) or an elongated pars; 90% of spondylotic spondylolisthesis occurs at L5.<sup>241</sup> The spondylolysis type is more likely to become symptomatic in children more than 5 years old. Although slippage is more common in girls, the isthmic type is one half as common as it is in boys. Sports such as gymnastics, which require repetitive hyperextension, are more likely to cause problems. There is a high incidence in Alaskan Eskimos. (Also see [Chapter 53](#).) Degenerative spondylolisthesis was found to be associated with increased BMI, age, and angle of lordosis in women but not in men.<sup>242</sup>

### **Evaluation**

Spondylolisthesis is primarily a radiographic diagnosis seen best on a lateral film. However, some patients may have increased back or leg pain with a one-legged balance test. The patient is asked to balance on one leg and hyperextend at the lumbar region. Palpation may reveal a prominent spinous

process at the involved level with a steep sacral base angle. The radiographic grading of spondylolisthesis is based on dividing the sacrum (if L5) or the vertebrae below (if above L5) into fourths. Each slip of one fourth the length of the anterior to posterior body is considered a grade. Therefore, slippage of three fourths the AP length would be classified as a grade 3. The sacral table angle (STA) is one of several radiographic measures taken from a lateral radiograph to determine the biomechanical status of the sacrum and spine.<sup>243</sup> The STA is the angle in the sagittal plane subtended by a line on the anterior aspect of the superior end-plate of the sacrum to the posterior edge, and a line that starts from that point drawn down the posterior midline to the caudal end-plate of the sacrum. There is a strong association between a lower STA and the occurrence of pars defects that appears to be causative.

Developmental spondylolisthesis is in part due to the pelvic shape and support, which is radiographically measured by the pelvic incidence angle. A greater angle is found in those who develop a listhesis. Individuals also have a greater pelvic slope, sacral slope, and lumbar lordosis, while the thoracic kyphosis is reduced.<sup>244</sup> The pelvic incidence angle is measured on a lateral x-ray and is subtended by a line drawn through femoral head to the midline of sacral end-plate and a line drawn perpendicular to the sacral endplate. Oblique radiographs may be used to assess the pars interarticularis integrity. Stability of the spondylolisthesis can be evaluated with a traction radiograph (the patient hangs from a bar) or a compression stress radiograph (20-kg rucksack on the shoulders). Another method involves using a measure referred to as the sagittal pelvic tilt index. This gives the examiner an objective measure quantifying the relationship between S2, the center of the hip, and L5. A decrease in the sagittal pelvic tilt index correlates with slip progression and risk of conservative treatment failure.<sup>245</sup> Single-photon emission tomography (SPECT) is often used to distinguish athletic patients who require an antilordotic brace and rest from those who do not have an “active” lesion.

## Management

Most grade 1 spondylolistheses are asymptomatic and stable. Progressive slippage is rare, occurring in only 2% to 3% of patients.<sup>246</sup> The majority of slippage occurs in children under age 10 years. In adults with degenerative spondylolisthesis, progression is rarely greater than 18% anterior displacement. Grade 2 spondylolistheses may be symptomatic but are considered stable. Cassidy et al.<sup>247</sup> indicate a good response to manipulative management. Only when grade 3 or 4 spondylolistheses are discovered is there a need for surgical consultation. Patients with a hot SPECT bone scan are placed in a brace for several weeks. Follow-up scans should be performed in several weeks.

## Sacroiliac Sprain and Subluxation

# Classic Presentation

The patient presents with pain over one SI joint after straightening up from a stooped position, often lifting an object. The pain may radiate down the back of the leg. With a sprain the pain is often sharp and stabbing and is relieved somewhat by sitting or lying. The pain is less often affected by posture with an SI subluxation.

## Cause

Although not often recognized in the medical literature as a source of LBP, two systematic reviews by McKenzie-Brown et al.<sup>248</sup> and by Hansen et al.<sup>249</sup> indicated that the prevalence of SI joint pain is between 10% to 19% of low back pain patients. The SI ligamentous support is strong; however, in younger patients, pregnant patients, or those with degenerative disease, prolonged or sudden lifting or bending may cause a sprain or subluxation. Movement at the SI joint is small but existent in younger patients. The movement is primarily an anteroposterior rotary movement around a transverse axis. This is an accessory movement (involuntary) occurring mainly when attaining a standing position. The sacral promontory moves forward approximately 3 to 6 mm.<sup>250</sup>

## Evaluation

Either direct compression ([Figure 6-9](#)) or distraction (gapping; [Figure 6-8](#)) at the joint may increase the pain or in some cases decrease the pain. Other tests include Gaenslen's test ([Figure 6-10](#)) whereby the supine patient draws the uninvolved leg to the chest while the examiner extends the involved-side leg off the side of the table. An increase in posterior pain suggests SI involvement.

The Gillet test ([Figure 6-12](#)) is essentially a motion test of the SI joints in an attempt to determine restricted movement. Although the sensitivity of these tests is questioned, the combination of patient presentation, history, and SI tests will usually help define the problem. Evaluation of the patient should include signs of seronegative arthritides (i.e., AS, Reiter's, or psoriatic). This would include a search for skin lesions, eye irritation, or heel/foot pain. A prior history of painful urination or eye pain suggests Reiter's syndrome. Marked decreases in forward flexion without significant pain suggest AS; extensor or scalp skin lesions suggest psoriatic arthritis. Radiographic discrimination is usually possible.

## Management

Acute SI sprains are best managed with an SI support (brace). Adjusting of the SI joint should be performed cautiously, avoiding increased stretch to the ligaments. Patients with SI subluxation usually have dramatic pain relief with manipulation. One interesting study<sup>251</sup> found that isolated contraction of the transverse abdominals was effective at stabilization of the SI joint in those individuals found to have laxity and resulting pain. This contraction was through a “drawing-in” of the abdominal wall versus a “brace” pattern that incorporated all of the abdominal muscles. The McKenzie-Brown review concluded that evidence for the diagnostic value of SI joint injections was moderate, having a 20% false positive rate. Therapeutically, both reviews concluded that there is moderate evidence for short-term and limited evidence for long-term relief with intra-articular SI joint injections. They felt the evidence for the use of radiofrequency neurotomy was limited or inconclusive.

## **Piriformis Syndrome**

### **Classic Presentation**

The patient often complains of buttock and posterior leg pain with a nontraumatic onset.

### **Cause**

The sciatic nerve may be compressed by the piriformis muscle. In most patients, the sciatic nerve runs under the muscle; however, in approximately 15% of the population, there are two muscle bellies with the sciatic nerve coursing between them.<sup>252</sup>

### **Evaluation**

Either resisted external rotation of the hip or passive medial rotation of the hip may increase the pain. Some practitioners use an SLR test with internal rotation to distinguish between nerve root or piriformis involvement. This should be interpreted cautiously because nerve root irritation also may cause pain increase with this maneuver. Direct palpation of the piriformis may cause a referred pattern down the back of the leg. Predisposition to piriformis syndrome may be an anatomically short leg, pronation, or pelvic rotation.

### **Management**

Postisometric relaxation techniques or myofascial release techniques are often helpful. In the acute stage, it may be necessary to use adjunctive physical therapy pain modalities. In rare cases, injection of the piriformis trigger point may be needed.

## **Ankylosing Spondylitis**

### **Classic Presentation**

The patient is usually a young man presenting with a complaint of chronic low back pain and stiffness with occasional radiation of pain into the buttocks, anterior, or posterior thighs. The patient feels the stiffness upon rising and has some relief of complaints with mild to moderate activity.

### **Cause**

AS is an inflammatory arthritis that usually affects the SI joints with progressive spinal ankylosing. It is characterized by enthesopathy (inflammation at the site of ligamentous insertions). It affects about 1% of whites and 0.25% of blacks. Men are affected three times more often than women. Women are less likely to have disease as severe. In general, the earlier the onset, the more progressive the disease is. With progression there is gradual stiffening, loss of the lumbar lordosis, increase in the thoracic kyphosis, and decrease in chest expansion due to costotransverse joint involvement. Heart involvement may lead to atrioventricular conduction defects and aortic insufficiency in approximately 3% to 5% of patients with chronic, severe disease. Peripheral joint involvement occurs 50% of the time, with permanent changes occurring 25% of the time. The joints most affected are the hips, shoulders, and knees.

### **Evaluation**

There are several formalized consensus criteria used to determine whether a patient has AS; some are specific to AS (i.e., Rome criteria and modified New York criteria) and some are more generalized as criteria used for the determination of spondyloarthropathies (Amor criteria and European Spondyloarthropathy Study Group [ESSG]).<sup>253</sup> Two validated outcome measures used in the evaluation and prognosis for AS patients are the Bath Ankylosing Spondylitis Radiology Index (BASRI) and the Bath Ankylosing Spondylitis Functional Index (BASFI).<sup>254-257</sup> In a recent study, researchers in search of long-term outcome predictors for patients with AS came to the following conclusions: 80% of the variations in radiological status and 50% of

the variations in the functional capacities of AS patients are unknown.<sup>258</sup> These findings led the researchers to conclude that genetic factors are more important than environmental factors. Some of the standard predictors for a poor outcome—including age, early age of onset, lower socioeconomic status, positive family history, and associated inflammatory bowel disease—were not associated with a poorer outcome in this study. For patients who smoke, are male, have had iritis, hip involvement, and higher disease activity scores, the prognosis for a worse outcome is increased. Fatigue was a common complaint in patients with AS. In patients with advanced disease, osteopenia is a risk factor for compression fractures.

AS is suspected when a patient with chronic back pain and stiffness has a global decrease in ROM of the lumbopelvic area. This is best measured with an inclinometer (Figure 6–6, B and C) or with a tape measure using the Schober method (Figure 6–6A). Orthopaedic and neurologic tests are normal. Chest expansion may be decreased with chronic involvement. In approximately 15% to 20% of patients, an anterior uveitis is found. Although lab testing will reveal elevations in erythrocyte sedimentation rate (ESR) in 85% of cases and HLA-B27 in 90% of cases (compared with 6% to 8% of asymptomatic individuals) and a negative rheumatoid factor, these tests are nonspecific and not diagnostic. AS is primarily a radiographic diagnosis.<sup>259</sup> Early changes are seen at the SI joint with “pseudowidening,” erosions, and sclerosis. In the spine, early changes include marginal sclerosis and erosion of the superior/inferior margins of the vertebral bodies, causing a “squaring” appearance on a lateral view. Calcification of spinal ligaments and the annulus fibrosus creates a “trolley track” sign and eventual fusion with a characteristic bamboo spine appearance. Peripheral joint involvement causes a periosteal reaction at ligament/tendon insertion points of the iliac crest, Achilles, and plantar fascia insertion points. Given that radiographic changes may not be visible for four to six years after the onset of symptoms, the use of HLA-B27 may be an early but nonspecific indicator. Elevated ESR has moderate sensitivity and specificity for AS; however, an elevated level is present in only 34% to 64% of patients with severe disease when radiographic changes are already evident.<sup>260</sup>

## Management

AS, like other rheumatoid and rheumatoid-variant diseases, has an unpredictable course of remission and relapses.<sup>261</sup> Management includes manipulation to keep the spine flexible, stretching, and postural and breathing exercises. Manipulation should be as gentle as possible considering the inflammatory nature of this disease. In the early stages, the calcification present on the radiograph represents a “soft” ankylosing that allows for some intersegmental movement. With severe progression, monitoring for cardiac and pulmonary involvement should be performed. It is important that patients avoid long-term use of pain medication if possible because of the gastric and renal consequences. There are a few case study reports on the management

of AS patients chiropractically.<sup>262,263</sup> These reports indicate varied responses and treatment approaches; therefore, no generalized statements can be made at this time regarding an agreed-upon approach. In a 2006 study,<sup>264</sup> a multimodal exercise program for AS patients was tested against a control group who did not perform any exercise. The program included aerobic exercise, stretching, and pulmonary exercises. Exercise was performed three times a week for three months. Physical work capacity and vital capacity values improved in the exercise group but decreased in the control group. This small study of 90 patients indicates that a multimodal approach may be of benefit to AS patients. The specifics of this program included:

- Prior to the step (aerobic) exercise, the target heart rates were calculated.
- A 10-minute warm-up of step exercises (using aerobic step device) was followed by 5 minutes of stretching, 20 minutes of step exercises, and 10 minutes of pulmonary exercise.
- The pulmonary exercises included twice the normal rate of respiration (inspiration through the nose; expiration through the mouth) and the use of deep breathing.

## Reiter's Syndrome

### Classic Presentation

A young male patient presents with a complaint of LBP that began after the onset of urethritis (burning on urination), conjunctivitis (eye pain), and skin lesions on the soles or palms.

### Cause

Reiter's is a seronegative (negative for rheumatoid factor) arthropathy that follows an infection. *Chlamydia*, *Campylobacter*, *Salmonella*, and *Yersinia* have all been implicated. It appears that the HLA-B27 marker may indicate those individuals prone to a reactive arthritis following bacterial infection.

### Evaluation

The diagnostic tetrad includes: (1) conjunctivitis that usually resolves in a day or two, (2) mucocutaneous lesions on the tongue, palate, and penis or plantar keratogenous lesions of the foot, (3) urethritis (often one of the first symptoms and often unresponsive to antibiotics), and (4) arthritis affecting the knees and ankles asymmetrically, but the SI joint is the most common symptomatic joint. Mechanical testing of the SI joint will usually increase pain.

Laboratory testing may demonstrate increases in ESR and HLA-B271, but be negative for rheumatoid factor. Radiographic changes may be subtle at the SI joint in the early stages. Unilateral involvement with joint space narrowing, erosive changes, and eburnation of subchondral bone may be seen. "Sausage" fingers or toes due to marked swelling and ankylosis may also be seen.

## **Management**

Antibiotics are ineffective. Management is primarily symptomatic. It must be remembered that this is an inflammatory disease, and manipulation of the SI joint may aggravate the patient's symptoms. Most of the nonarticular complaints resolve over days or weeks. Joint involvement may be progressive and permanent, however, especially in patients who have recurrent infection.

## **Multiple Myeloma**

### **Classic Presentation**

The patient is older (> 50 years) and complains of persistent back pain that is unrelieved by rest. The pain seems worse at night. There may be associated rib pain.

### **Cause**

Multiple myeloma (MM) is a malignant disease characterized by proliferation of plasma cells with replacement of bone marrow, which results in osteoporosis, hypercalcemia, anemia, renal disease, and infection (often pneumonia) due to suppression of normal immunoglobulins.

### **Evaluation**

In older patients with unexplained LBP, laboratory and radiographic evaluation may reveal signs of MM. Laboratory findings include anemia with normal erythrocyte morphology but increased rouleau formation, hypercalcemia, hyperuricemia, and increased globulins. A 24-hour urine test may reveal the presence of Bence-Jones protein (light chain). Electrophoresis will reveal a monoclonal spiking; immunoelectrophoresis usually demonstrates elevated immunoglobulin G (IgG). The definitive diagnosis is a bone marrow aspirate showing more than 20% plasma cells. Radiographic findings demonstrate osteopenia followed by widespread lytic lesions in the

spine, ribs, and skull (punched out or rat-bite lesions). Unlike metastasis to the spine, MM does not usually affect the posterior elements such as the pedicles.

## Management

Treatment is primarily palliative. Chemotherapy or radiation therapy is used primarily to relieve bone pain. Bone marrow transplant is curative, but the patient must be under age 55 years and therefore few patients with MM qualify. The survival rate is variable; however, some degree of prediction is based on the degree of IgG spiking on immunoelectrophoresis, anemia, and hypercalcemia. In general, patients with IgG less than 5 g/dL and no evidence of anemia, renal disease, or lytic lesions have a survival rate of 5 to 6 years.<sup>265</sup>

## Metastatic Carcinoma

### Classic Presentation

The patient is usually over age 50 years and complains of insidious onset of pain that is persistent, worse at night, and not mechanically affected. There is often a history of weight loss and fatigue. (*Note:* The patient may remain asymptomatic until late in the course of the disease or may become symptomatic after trauma because of the pathologic weakness of the vertebrae.)

### Cause

Metastatic involvement of the spine accounts for only 1% of LBP. The most common metastases are from the breast, prostate, lung, and kidney. Prostate cancer spreads through Batson's plexus to the vertebrae. Metastasis from the above cancers may involve the vertebral bodies, pedicles, and, less commonly, the neural arches. The sequence of changes is usually replacement of fatty bone marrow with nonfatty tumor cells, followed by either destruction of the trabeculae with a periosteal response when a lytic metastasis is involved, or osteoblastic or sclerotic response such as with prostate cancer.

### Evaluation

A history of prior cancer, unexplained weight loss, or unresponsiveness to conservative care for one month is highly suggestive of cancer, especially in patients older than 50 years of age. Radiographically, metastatic cancer may appear as an osteolytic process (such as the missing or one-eyed pedicle seen with breast cancer) or osteoblastic (such as the ivory vertebrae seen with prostate cancer). Compression fracture of the vertebrae with posterior collapse is highly suggestive of a cancer-induced pathologic fracture. Osteolytic processes may increase the serum calcium levels, whereas the osteoblastic process may increase the alkaline phosphatase levels. Determination of total and free prostate specific antigen (PSA) with a digital rectal examination should be performed in males suspected of prostate cancer. Bone scans may help determine the degree of spinal involvement with regard to location; MRI can determine the volume of involvement at any individual site. (For a list of spinal cord tumors, see [Table 6-5](#).)

## Management

Referral for an oncologic consult is necessary. Comanagement issues can then be discussed.

## Infectious Spondylitis

## Classic Presentation

Although there is no consistency regarding a typical patient and whether fever is present, the following is a presentation not to be missed: The patient presents with a complaint of deep back pain. There is a history of a recent respiratory or urinary tract infection (or intravenous drug use or diabetes). The patient is antalgic and complains of a fever and difficulty sleeping because of the pain.

**Table 6-5** Malignancies of the Spine and CNS

Type	Summary Information
Astrocytomas	<p>75% in cervical and thoracic areas  20% in distal cord; 5% in the filum terminale  Occur most frequently in ages thirties to forties  50%–70% present with back, neck, or leg pain; 20%–30% have spasticity and stiffness of legs</p>

	Survival period is from 1 to 8 years
Ependymoma	<p>Slow-growing, benign tumors arising from ependymal cells in central canal (intramedullary), filum terminale, sacral area (extradural/extraspinal)</p> <p>Represent 60%-70% of spinal cord tumors</p> <p>60% occur in the conus, filum, or cauda equina</p>
Hemangioblastoma	<p>Benign tumor composed of dense network of capillary and sinus channels</p> <p>Usually intramedullary; may be intradural/extramedullary involving posterior roots of cauda equina</p> <p>Solitary or multiple; when multiple, associated with von Hippel-Lindau disease; patients develop renal cell carcinoma</p>
Intradural lipomas	<p>Benign neoplasms composed of fat cells</p> <p>Three types:</p> <ol style="list-style-type: none"> <li>1. filum terminale</li> <li>2. intradural</li> <li>3. lipomyelomeningocele</li> </ol> <p>Most common in thoracic spine; males more commonly affected</p> <p>The intradural type are not commonly a cause of radicular pain, unlike filum terminale lipoma</p>
Intramedullary spinal cord metastasis	<p>Found in only 1%-3% of tumor patients</p> <p>Lung and breast cancer most common</p> <p>Other non-CNS processes such as melanoma, leukemia, and lymphoma may metastasize to the cord</p> <p>CNS tumors that may involve cord are glioblastoma, ependymoma, and medulloblastoma</p>
Extramedullary tumors: meningiomas	<p>Meningiomas account for 25% of intraspinal tumors</p> <p>Occur from ages 20-60 years; peak in forties; female predominant (4:1)</p> <p>Predominance at exits of spinal nerves from dural sleeves</p> <p>Most common in T spine, they compress but do not invade spinal nerves or cord</p>
Extramedullary tumors: neurinoma	<p>Most common extramedullary (29%)</p> <p>Originate from sensory nerve roots; usually in C and T spine; however, 40% occur in L spine</p>

Peak incidence in fifties; male predominant Generally singular; when multiple, associated with von Recklinghausen's disease
--

## Cause

Infection involving both the disc and the vertebral body is referred to as infectious spondylitis. This is more common in adults with a prior history of urinary tract infection, intravenous drug abuse, recent use of an indwelling catheter postsurgery, or skin infection. Children are more prone to discitis (usually benign) without vertebral body involvement. Infection is spread via the arterial system, Batson's venous plexus, and direct inoculation through surgery. There are generally two types: (1) pyogenic and (2) nonpyogenic. The pyogenic type is usually due to *Staphylococcus*, *Streptococcus*, and gram-negative organisms. The nonpyogenic type is usually due to tuberculosis; however, *Brucella* or fungi may be the cause.

## Evaluation

Adults will usually have a deep pain made worse with pressure or percussion of the spinous process. Fever is often present. Although not particularly sensitive, it is relatively specific.<sup>53</sup> Radiographic indications often take three to four weeks to become evident. Pyogenic causes involve more than one vertebra, often leaving the disc unaffected. Bony lysis is followed by sclerosis in the vertebral bodies. Posterior elements are rarely affected. Nonpyogenic spondylitis centers around L1. On occasion, the posterior elements are involved. Laboratory findings include an increase in ESR, and occasionally changes are evident in leukocyte response.

## Management

Refer for orthopaedic consultation and determination of course of care.

### Abdominal Aneurysm

## Classic Presentation

Most abdominal aneurysms are asymptomatic until rupture. The symptomatic patient may present with mild to severe middle abdominal or low back pain.

There may be an associated complaint of leg pain with exertion (claudication).

## Cause

Atherosclerotic aneurysms (weakening with dilation) occur primarily below the renal arteries (95% of the time). The incidence is between 2% and 4% with a 5:1 male predominance. It has become clear that smoking is an important risk factor for abdominal aneurysm.<sup>265</sup> In fact, the Agency for Healthcare Research and Quality has listed smoking as a screening question for men at risk for abdominal aneurysm.<sup>266</sup>

## Evaluation

In asymptomatic patients the most common finding is a pulsatile mid- or upper abdominal mass. Palpation is most sensitive for abdominal aneurysms greater than 3.0 cm (50% for 3.0 to 3.9 cm and 76% for those > 5.0 cm) with an overall positive predictive value of 43%.<sup>267</sup> Auscultation may reveal a bruit. Peripheral pulses may be prominent (due to a reactive arteriomegaly). Lateral lumbar radiographs may reveal an enlarged calcific margin of the aorta, usually between L2 and L4. A diameter exceeding 3.8 cm is considered an aneurysm.<sup>268</sup> Other indirect findings may include erosion of the anterior vertebral bodies behind the aneurysm.

## Management

Referral for abdominal ultrasonography is warranted to demonstrate the size and extent of involvement. Those patients with a documented diameter of 4–6 cm should have a surgical consultation. If not excised and grafted, most aneurysms will go on to rupture. However, one study<sup>269</sup> indicated that in patients 65 to 80 years old with aneurysms less than 6 cm, surgery was not necessary unless the aneurysm expanded more than 1 cm. Patients with acute rupture usually have a searing/tearing pain warranting immediate emergency management. Patients whose aneurysm proceeds to rupture have only a 10% to 20% survival rate.<sup>270</sup>

---

## The Evidence—Lumbopelvic

<h3>Translation Into Practice Summary (TIPS)</h3>
---

The physical examination combined with the history is reasonably good at identifying disc disruption and/or lumbar radiculopathy, and stenosis. Neurologic testing in isolation is not as valuable as combined testing for numbness, weakness, and deep tendon reflex loss.

The literature on evaluation of the sacroiliac and pelvic regions is extensive but inconclusive. Pain provocation tests have been studied extensively and have been found individually to be poor, but as a group may rise to the level of value in ruling in sacroiliac involvement.

### **The Literature-Based Clinical Core**

- The patient history is not good for identifying lumbar radiculopathy compared to other sources of radiating pain.
- The neurological examination consisting of sensation testing, muscle testing (myotome), and deep tendon reflex (DTR) testing is not good at identifying disc herniation and/or radiculopathy if used alone. The L5 reflex is unreliable and is not necessary to perform. The reliability of the DTR is best for L3/L4 spinal levels (i.e., patellar reflex), which is far less commonly involved than L4/L5 and L5/S1. The value of DTR findings is best for ruling in but not ruling out radiculopathy.
- Even with myotomal weakness, dermatomal numbness, a decreased or absent DTR, and a positive SLR, the positive LR is good but not great at identifying radiculopathy.
- The identification of a radiculopathy is increased when orthopaedic findings are combined with neurological findings. The combination of a positive slump test with findings of calf-wasting, a positive SLR and a crossed SLR when positive as a group is good at ruling in radiculopathy.

- The reliability of leg-discrepancy testing is good and although there are no studies to indicate the validity for differentiating SI involvement, it may serve as an indicator of checking for SI involvement.
- Dermatomal radiation is inconsistent (i.e., radiation more often described as nondermatomal by patients) and is typical only for S1 involvement (although high-lumbar disc involvement does overlap sometimes with an S1 dermatomal patch).
- There are good indicators of spinal stenosis in the history including “no pain while seated.” Decreases in sensation (vibration and pin-prick), decreased or absent DTRs, or weak muscle tests have only fair + LR. Rombergs and/or a two-stage treadmill exam may be of value for detecting stenosis.
- The centralization phenomenon is good at identifying painful lumbar discs. The classification system for McKenzie has variable kappa values.
- Spinal instability may be detected with a combination of testing procedures, yet the value in determining management is still to be determined.
- The only valuable history indicator for sacroiliac (SI) involvement is pain relieved by standing, which has a good positive LR.
- Single pain-provocation tests are poor at either identifying or specifying SI involvement.
- Grouping a cluster of four or five tests including distraction, thigh thrust, sacral thrust, and compression after a repeated McKenzie approach is good at identifying SI involvement.
- Motion and static palpation tests demonstrate poor reliability.
- There are a number of orthopaedic tests designed to distinguish between SI versus lumbar involvement, but, there is no literature support for this function.

## **The Expert-Opinion-Based Clinical Core**

- With radiculopathy, the area of numbness is patchy and does not extend throughout the radiation of pain pattern.
- Myotome weakness is painless weakness.
- There are no reliable tests for spondylolisthesis although the balance test is often used.
- Patients with insidious onset of SI pain should be evaluated radiographically for sero-negative arthritides given there are no orthopaedic tests that can discriminate these from other causes of SI pain.

## CHAPTER 7

# Shoulder Girdle Complaints

### Context

Shoulder pain in the general population has been reported to be as high as 50% in some countries.<sup>1</sup> The range is between 20%–50%. Chronic shoulder pain appears to be common. At six months following initial evaluation 34% to 79% of patients report still having shoulder symptoms<sup>2–6</sup> with 24% to 61% reporting pain 6 to 18 months beyond the initial six-month follow-up. Most disturbing is that only about half of the elderly who reported having shoulder symptoms sought treatment. Poor recovery from shoulder pain was associated with increasing age, severe or recurrent symptoms, restricted range of passive abduction, or with concomitant neck pain.<sup>7</sup> The presentation of mild trauma or overuse occurring before the onset of shoulder pain, acute onset, and early presentation to a caregiver indicated a favorable outcome.

The shoulder provides a unique diagnostic challenge. The shoulder's dependency on an integrated, position-dependent system of ligaments, muscles, and tendons for stability, coupled with the need for coordinated interaction of a number of joints, makes it a complex region to assess. When a single-event trauma occurs, soft tissue or bony damage is usually discovered by challenge on physical examination and/or radiographs. When trauma is not evident, however, it often becomes difficult to isolate a

specific structure or cause. Many shoulder problems are, in fact, multidimensional. In other words, a patient with instability may develop an impingement phenomenon, or a patient with tendinitis or restricted mobility may overload the compensatory capacity of other structures, leading to further soft tissue involvement.

The unique design of the shoulder provides a great degree of mobility; however, as a result it cannot always provide substantial stability, especially at higher levels of elevation and/or extreme abduction. Therefore, local shoulder pain that occurs with these extremes of position is due to excessive demands on the stabilizing function of the muscles, ligaments, and capsule of the shoulder. In addition, mechanical or structural predisposition may narrow the variable space through which some tendons travel, resulting in an impingement phenomenon. These structures are rarely challenged in individuals whose work or play requires only minimal elevation.

Shoulder complaints are common in sports such as weight lifting, swimming, and throwing, or in an occupational setting requiring overhead work. In that context, injury, when not due to a single trauma, is often due to repetitive activity or overuse. These problems can often be linked to specific positional demands. Finally, the shoulder may be the site of injury when a fall onto an extended arm transforms the shoulder into a weight-bearing joint. Fracture, dislocation, tendon, or labrum damage must be considered.

The shoulder may be the site of pain originating or caused by a variety of sources, including the following:

- Referred pain from a variety of musculoskeletal sites such as cervical or thoracic spine facet joints or trigger points
- Referred pain from visceral sources such as the diaphragm, gallbladder, lungs, or heart

- Radicular pain from cervical nerve root compression
- Peripheral nerve and brachial plexus entrapments
- Local causes of pain
  - trauma (e.g., fracture, dislocation, tendon rupture)
  - overuse (e.g., tendinitis, capsular sprain, bursitis)
  - arthritide (e.g., osteoarthritis, rheumatoid arthritis, rheumatoid variants)
  - other (e.g., tumor or infection)

Although this list may seem overwhelming, the primary causes of shoulder complaints generally fall into several categories with some overlap, including the following:

- instability (traumatic or nontraumatic)
- impingement syndrome (anteromedial [subcoracoid]—subscapularis; anterolateral [subacromial]—biceps tendon, supraspinatus tendon, and subacromial bursa; posterolateral—posterior labrum and infraspinatus/teres minor tendons)
- tendinitis/bursitis
- osteoarthritis
- adhesive capsulitis
- acromioclavicular (AC) separations
- referred pain from the cervical spine

In the context of the chiropractic office setting, a common complaint is neck and shoulder/arm pain. With this presentation it is important to differentiate between neural referral versus radiculopathy. This differentiation requires a search for objective neurologic deficits. When not present, a mechanical or referral association is more likely. When the shoulder is part of a neck and arm complaint it is also important to consider brachial plexus involvement through overstretch (stinger) or compression (thoracic outlet syndrome) and a double-crush phenomenon.

Like all joints, the shoulder is susceptible to traumatic sequelae such as fracture, dislocation, and ligament or tendon rupture. When these are suspected, thorough radiographic and orthopaedic evaluations are necessary. If fracture or ligament/tendon rupture is found, an orthopaedic consultation is necessary. For most other conditions many practitioners<sup>8</sup> now recommend a conservative approach for at least six months.

In the elderly population, the accumulation of years of wear and tear leads to an end-stage of chronic irritation that results in osteoarthritis that may cycle into an impingement phenomenon. Degenerative labrum tears and rotator cuff tears are not uncommon in the senior, often becoming symptomatic with little or no trauma. The other common problem in the senior population is stiffening of the shoulder, sometimes due to adhesive capsulitis. Differentiating between the effects of osteoarthritis and adhesive capsulitis is an important element in approaching the stiffened senior shoulder.

Trauma, including surgery, may predispose the shoulder to early degenerative changes. Osteoarthritis may be more common than previously recognized.<sup>9</sup> Even when not evident radiographically, osteoarthritis has been demonstrated histologically. Therefore, osteoarthritis should be considered in the senior or posttraumatic patient. Arthritides that commonly affect the shoulder are ankylosing spondylitis and rheumatoid arthritis. Advanced rheumatoid arthritis often leads to rupture of the supraspinatus tendon. The shoulder may be a site of infection, although infrequently.

## **General Strategy**

## **History**

- Determine whether the patient's complaint is one of pain, stiffness, instability, weakness, numbness, or tingling.
- Localize the complaint to anterior, posterior, lateral, inferior, or superior.
- Determine whether there was a traumatic onset; if so, determine the mechanism and the need for immediate radiographic assessment before proceeding (possible fracture or dislocation).
- Determine any relationship to activity, with focus on position, degree of restriction, and amount of repetition (overhead position suggests possible impingement).
- Consider an acute calcific bursitis or the early phase of adhesive capsulitis if pain is the primary complaint with no history of trauma and all ranges of motion are painful. Also, Parsonage-Turner syndrome (i.e., brachial neuritis) may present with sudden, non-traumatic shoulder pain often following a respiratory infection.
- Determine whether there is a past injury if stiffness is the complaint; for specific ranges of restriction determine whether there was an antecedent period of moderate to severe pain that has gradually been replaced by stiffness (suggests adhesive capsulitis).
- If weakness is the complaint, determine whether the weakness is painless (suggests instability) or painful (inhibitory effect).
- Determine whether the patient has a history suggestive of damaged structures (i.e., anterior dislocation) or if the patient has a bilateral, multidirectional looseness indicative of generalized capsular laxity (nontraumatic) if instability is suspected.
- Determine the degree of functional impairment within the context of patient usage. Is the patient a high-end

user, such as an athlete, or a low-end user such as a sedentary office worker?

## Evaluation

- Perform a focus-based examination; however, begin with an evaluation of stability, given instability may be the cause of or contributor to other problems.
- Check for labrum damage, in particular, when instability or looseness is found or there is a history of trauma.
- Evaluate for impingement.
- Evaluate for specific muscle/tension involvement with palpation, muscle tests, and lag signs.
- Use findings to determine the need for further evaluation with regard to radiographic or special imaging, referral to a specialist, or initial management.

## Management

- Dislocations should be relocated, preferably by an experienced individual; postreduction radiographs should be taken to determine whether an associated fracture is evident; rehabilitation of the shoulder is important to avoid recurrence.
- Infections, fractures, and tumors should be referred for orthopaedic consultation. Also, if the patient is in so much pain that it is interfering with the ability to sleep and is unaffected by over-the-counter medications, referral for prescribed pain medication should be made. This is most common with an acute subacromial bursitis and an early phase of adhesive capsulitis.
- All other shoulder disorders should be managed for six months with conservative approaches; if unresolved,

consideration for special imaging should be given.

## **Relevant Anatomy and Biomechanics**

The shoulder is capable of extreme mobility for the purpose of placing the upper limb in an almost infinite number of positions. For this mobility, a price is paid. From a bony support perspective, the shoulder is essentially unstable. As a result, the demand for constant integrated function is high for soft tissue structures delegated the job of providing that stability. This inherent instability becomes even more evident at higher degrees of shoulder elevation, making unusually high demands on coordinated muscular function. Damage to any of these soft tissue stabilizers results in increasing demands on the residual support structures. Add to this a repetitive demand from a sport or occupational perspective and the shoulder's ability to cope may be compromised (or overextended).

Depending on arm position and underlying pathologic processes, different aspects of the general capsular system are called into play. With the arm at the side, much of the support is ligamentous (superior glenohumeral ligament), with some contributions from a precarious glenoid ledge. Any relative abduction will cause an increased capsular and muscular contribution. A reciprocal contribution is most evident in the capsular structures, where stress is sequentially shared by the various capsular ligaments. With the arm at rest, the superior capsule contributes most. As the arm is elevated, the support management is shifted to the inferior capsular complex. This reciprocity also occurs with rotation. With the arm elevated, a hammock-like inferior capsule protects against inferior stress as well as anterior or posterior stress. With external rotation added to

90° abduction, the broad aspect of the capsule rotates in front of the humeral head while the posterior band of the complex supports posteriorly. The opposite occurs with internal rotation as posterior support is provided by the broad aspect of the inferior capsular complex and anterior support is provided by the cord-like anterior aspect of the complex. Another component of capsular control of movement is through a tension-dependent role in accessory movement of the humeral head. It has been found that capsular tightness contributes to an obligatory translation in the opposite direction of tension.<sup>10</sup> For example, in a normally functioning shoulder, the position of abduction with external rotation causes tension on the anterior capsule. In turn, this causes a posterior translation of the humeral head by approximately 4 mm.<sup>11</sup> This is also true with abduction, where tension in the inferior capsule and pull from the deltoid/supraspinatus couple cause a superior migration of the humeral head of approximately 3 to 6 mm. More is discussed under relevant clinical scenarios.

Additional support is provided passively by the fit of the humeral head into the glenoid. It is affected by the contact area, angle of the glenoid, and degree of adhesion or lack thereof. Active support is provided directly through the capsular integration of rotator cuff attachment. The biceps tendon also plays a crucial role in stability due to its position anteriorly as a mechanical block and its attachment to the superior labrum. The labrum is a fibrocartilaginous structure, analogous to the meniscus in the knee, which serves a primary function in stabilizing the shoulder, deepening the concavity within which the humeral head resides. Tears of the inferior labrum are common with dislocation. Tears of the superior labrum are classified based on type and cause. A specific type of superior labrum tear is referred to as superior labrum anterior to posterior (SLAP). There are four types of labrum tears: Type I lesions have primarily degeneration and fraying without instability. Type II

SLAP lesions are by far the most common and demonstrate detachment of the superior labrum off the glenoid. Type III SLAP lesions are bucket-handle tears of the superior labrum; however, the remainder of the labrum is firmly attached to the glenoid. Type IV SLAP lesions have a bucket-handle tear that extends to the biceps tendon. Indirectly, movement of the scapula provides a stable platform upon which the humeral head can function at higher elevations. This is accomplished by an exquisite cooperation between the rotator cuff and the scapular muscles. A major player in this interaction is the serratus anterior muscle. The properly functioning scapula serves several roles, including:

- 1. Stabilization:** Maintains the proper position to allow the instant center of rotation to be maintained within an optimum physiological range.
- 2. Retraction and protraction against the thoracic wall:** Allows a greater range of shoulder/arm movement while maintaining a stabilized platform for the humeral head.
- 3. Elevation of the acromion:** Allows for a greater range of abduction.
- 4. Serves as a base for muscle attachment:** Connects the rib cage, upper extremity, and spine.

The shoulder is part of a complex of joints that function together to provide smooth movement of the upper extremity. This complex is composed of the sternoclavicular joint, the AC joint, the glenohumeral joint, and also the pseudojoint of the scapulothoracic articulation. The SC joint has a long axis superior to inferior and a short axis anterior to posterior. The joint faces slightly posterior, outward and upward. It is not totally congruent, requiring an intra-articular disk (meniscus) similar to the AC joint. Although the joint axis indicates anterior to posterior and superior to inferior translation, 30° of axial rotation also occurs.

Ankylosis at the SC severely limits elevation to only 90° of shoulder elevation. Through a series of levers and supports, the shoulder is allowed to function in many planes. The contribution of muscles may be categorized on the basis of several roles. First are the protectors. These are the inherently smaller rotator cuff muscles that act to compress the humeral head into the glenoid. Second are the pivoters. These are the scapular muscles that serve to pivot the scapula under the humeral head during elevation of the arm for proper muscle/tendon alignment and tension. The primary pivoters are the various fiber orientations of the trapezius and serratus anterior muscles. Next are the positioners. These act to position the shoulder in varying degrees of elevation. The deltoid complex and supraspinatus muscle play the major role. For purposes of strength or propulsion, there are the propellers. These are the much larger adductor/internal rotator muscles consisting mainly of the pectoralis and latissimus dorsi muscles.<sup>12</sup> There is a natural imbalance between the stronger internal rotators/adductors and weaker external rotators/abductors. This imbalance is often made worse by occupational posture and overdevelopment of the larger muscles.

The subscapularis, pectoralis, teres major, and latissimus dorsi are internal rotators (**Figure 7-1**). The external rotators include the infraspinatus, teres minor, and posterior deltoid. The abductors include the supraspinatus and deltoid group (**Figure 7-2**). Adduction is a large muscle movement accomplished by the pectoralis and latissimus dorsi. As stated previously, the rotator cuff musculature, in addition to a dynamic movement role, also serves to stabilize the shoulder through insertion into the capsule providing a tightening effect upon contraction. The need for stabilization increases with arm elevation. In an effort to determine which muscles contribute to stability, researchers conducted a cadaveric study with simulation.<sup>13</sup> In the midrange of motion, the supraspinatus and subscapularis provided the

highest degree of stabilization. With the arm in external rotation and abduction, the cadaver shoulders were taken to end-range. In this end-range position (considered the most stressful for the anterior capsule of the shoulder), the subscapularis, infraspinatus, and teres minor provided more stability than the supraspinatus. The deltoid muscle takes on an increasingly important role, especially the middle deltoid, as the shoulder becomes increasingly unstable.<sup>14</sup>

**Figure 7-1** (A) The rotator cuff (anterior view); (B) the muscles of the rotator cuff (posterior view).

One of the more important anatomic or structural concepts with regard to efficient shoulder function has to do with the plane of the scapula. It is evident that the glenoid of the scapula does not face directly lateral. It faces between 30° and 45° forward because of the curved fit of the scapula on the bony thorax. The result is that more efficient muscle tension relationships exist in this plane.<sup>15</sup> This is often apparent in the patient with a painful shoulder who unconsciously selects this scapular plane as his or her elevation plane of choice.

Several significant observations must be made with regard to shoulder elevation. The first is that with abduction of the arm with internal rotation, the arm can be abducted

to only about 75° (if you eliminate scapular rotation or “shrugging” effects). With external rotation, the 45° angle between the axis of the humeral head and that of the axis of the shaft is moved out of the coronal plane automatically straightening the angle and adding the 45° angulation to the existing 75°, accomplishing a sleight of hand. In other words, it appears that the arm has been elevated to 120° of abduction when in fact it is due to the elimination of the angle between the humeral head and shaft. Jobe<sup>16</sup> also points out that to avoid impingement, the greater tuberosity must clear the glenoid rather than the acromion as more commonly believed. He feels that “impingement” may occur more as superior glenoid and labrum contact with the internal fibers of the rotator cuff and greater tuberosity. This occurs in shoulders with and without indicators of instability. Jobe describes four structures at risk of injury: (1) the internal fibers of the rotator cuff, (2) the superior labrum and biceps origin, (3) the greater tuberosity and posterosuperior glenoid, and (4) the inferior glenohumeral ligament and labrum complex (due to tension). It is also interesting to note that a similar theory is used to explain why patients experience relief with the relocation test (pain felt initially on a supine apprehension test). In other words, the anterior-to-posterior pressure used in the relocation test removes posterior impingement by repositioning the humeral head in relation to the glenoid.

## Evaluation

## History

A prognostic study by Thomas et al.<sup>17</sup> indicated that baseline characteristics, rather than treatment rendered, were a better predictor of outcome. Criteria that reduced the likelihood of recovery were: being female, reporting a gradual onset, or higher baseline disability scores. A study by Largacha et al.<sup>18</sup> attempted to determine, among other things, age at time of presentation for specific disorders. Those with instability seemed to present to a specialist around age 20–35 years. Patients with full-thickness tears present 15 years later than those with partial cuff tears. Those individuals with cuff tear arthropathy presented 13 years later than full-thickness tears. The conditions with greatest female prevalence were RA and adhesive capsulitis. All other conditions were male predominant, especially capsulorrhaphy arthropathy, degenerative joint

disease (DJD), and traumatic instability. A study by Miranda et al.<sup>19</sup> indicated there was also an association found between mental stress, obesity, and older age; as well as physically strenuous work and working with the trunk forward-flexed or with the hand above the shoulder level, and increased risk of shoulder pain. The more recent study by Leclerc et al.,<sup>20</sup> after adjustment for other risk factors, found that the presence of depressive symptoms was able to predict occurrence of shoulder pain. There was also an association between a low level of job control and shoulder pain. Men with repetitive tool use and women using vibrating tools and working with arms above shoulder level were also strong predictors of shoulder pain. All of these factors should be included, less for the diagnostic value, but for the predictive value of response to care or natural history.

In a systematic review of shoulder disability questionnaires, Bot et al. (2004)<sup>21</sup> evaluated 16 questionnaires focusing on those with the most evidence, which included the Disability of the Arm, Shoulder, and Hand Scale (DASH), the Shoulder Pain and Disability Index (SPADI), and the American Shoulder and Elbow Surgeons Standardized Shoulder Assessment Form (ASES). Properties scored included validity, reproducibility, responsiveness, interprobability, and practical burden. The results indicated that none of the questionnaires demonstrated satisfactory results for all properties. Only seven questionnaires showed adequate test/retest reliability (ICC > 0.70 with five questionnaires testing as inadequate). Most studies had small sample sizes ( $n < 43$ ) and none had information on the interpretation of test results. The DASH received the best ratings for clinimetric properties.

Careful questioning may point to the diagnosis (**Table 7-1**).

# Pain Localization

The following are possible causes of pain based on localization (see **Table 7-2** and **Figure 7-3**, A to C):

- Anterior
  - 1.** traumatic—fracture, dislocation, subacromial bursitis, capsular sprain, rupture of long head of biceps, labrum tear
  - 2.** nontraumatic or overuse—general impingement syndrome, subcoracoid impingement, biceps tendinitis, subacromial bursitis, subscapularis tendinitis, subluxation
- Lateral
  - 1.** traumatic—contusion, supraspinatus rupture, referral from cervical spine or brachial plexus injury
  - 2.** nontraumatic or overuse—impingement syndrome, deltoid strain, supraspinatus tear or rupture, referral from cervical spine problem
- Superior
  - 1.** traumatic—AC separation, distal clavicular fracture, shoulder pointer
  - 2.** nontraumatic or overuse—osteoarthritis of the AC joint, osteolysis of the distal clavicle
- Posterior
  - 1.** traumatic—scapular fracture, posterior dislocation
  - 2.** nontraumatic or overuse—posterior impingement, infraspinatus or teres minor strain or tendinitis, posterior deltoid strain, triceps strain, suprascapular nerve entrapment

**Table 7-1** History Questions for Shoulder Complaints

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Was there trauma? (Did you hurt your shoulder in an accident?)	Rule out fracture, subluxation, dislocation, separation, capsular or muscle tearing	Fall on an outstretched arm? Land on the top of your shoulder? Did you have your arm up and pulled back? Does your arm get stuck in certain positions that you can click back in place?	Clavicular fracture, posterior dislocation, supraspinatus, biceps, or labrum tear AC separation, distal clavicular fracture, shoulder pointer Anterior dislocation Glenoid labrum tear
Do you perform repetitive activities with your shoulder?	Impingement syndrome, capsular sprain, muscle strain, tendinitis	Do you work in overhead positions? Is it worse with lifting weights?	Impingement syndrome Osteolysis of distal clavicle with AC pain; labrum tear if mechanically locks or gives out, and muscle strain
Is there any associated neck pain?	Cervical spondylosis, disc lesion, referred facet pain	Trauma to the neck? Are the pains connected?	Whiplash, and the “lateral whiplash” of a cervical burner C5- C6 areas most commonly affected
Are there other problems that seemed to occur at the same time as your shoulder pain?	Arthritides, connective tissue disease, visceral referred pain	Any gastrointestinal symptoms (abdominal pain, etc.)? Any associated chest pain?	Gallbladder Cardiac referral
Is the complaint more of stiffness?	Adhesive capsulitis, subluxation, unrecognized posterior dislocation, arthritides	Past history of trauma? Did the stiffness get worse after a few weeks of pain?	Posterior directed force may have caused an unreduced posterior dislocation Adhesive capsulitis
Is there a sense of weakness or instability?	Capsular instability, glenoid labrum tear, neurologic weakness	Past history of trauma? Does it feel weak with your arm elevated?	Capsular, rotator cuff, or labrum damage Capsular looseness or damage
Have you ever been diagnosed with any kind of arthritis in the past?	Osteoarthritis uncommon unless previous surgery/trauma; RA, AS, pseudogout and others should be considered	Do you have other joint pains?	Finger joint pain might suggest RA, spine/S1 pain may suggest AS; knee/wrist pain may suggest pseudogout

## Traumatic and Overuse Injuries

With trauma, there are usually clear indicators of dislocation or separation. Fracture, too, may be implicated by the mechanism, magnitude of forces, and degree of pain. Common injury patterns for the shoulder include the following:

- Blow to the anterior shoulder—dislocation, subluxation, or contusion
- Fall onto top of shoulder—AC separation, distal clavicular fracture, shoulder pointer

- Fall on an outstretched arm (landing on hand with elbow extended)—AC separation, clavicular fracture, posterior dislocation, glenoid labrum or rotator cuff tear

**Table 7-2** Shoulder Pain Localization

#	Structures	Overt Trauma	Insidious or Overuse
1	Acromioclavicular (AC) joint	AC separation, shoulder pointer, distal clavicular fracture	Osteoarthritis of AC joint, osteolysis of the distal clavicle
2	Deltopectoral triangle	Subscapularis rupture	Subscapularis tendinitis, capsulitis
3	Clavicle	Clavicular fracture	Pectoralis clavicular strain
4	Coracoid process	Coracoid fracture or bursitis	Pectoralis minor tendinitis
5	Biceps tendon	Biceps tendinitis	Biceps tendinitis
6	Pectoralis major	Pectoralis major rupture	Pectoralis major strain
7	Deltoid insertion (deltoid tubercle)	Bruise at or slightly below, possibility of hematoma and myositis ossificans	Common referral area for many shoulder conditions and C5 nerve root or facet irritation, deltoid strain
8	Supraspinatus insertion, subacromial bursa	Supraspinatus rupture	Impingement syndrome, bursitis, supraspinatus tendinitis
9	Infraspinatus/teres minor tendons and insertion	Contusion	Infraspinatus or teres minor tendinitis
10	Teres minor tendon, long head of triceps tendon, posterior circumflex artery, axillary nerve	Contusion	Teres minor or triceps tendinitis, quadrilateral space syndrome
11	Infraspinatus muscle, scapula	Scapular fracture	Atrophy due to suprascapular nerve entrapment
12	Levator scapulae, superior-medial border of scapula	Radiation zone for cervical disc lesions	Levator scapulae syndrome

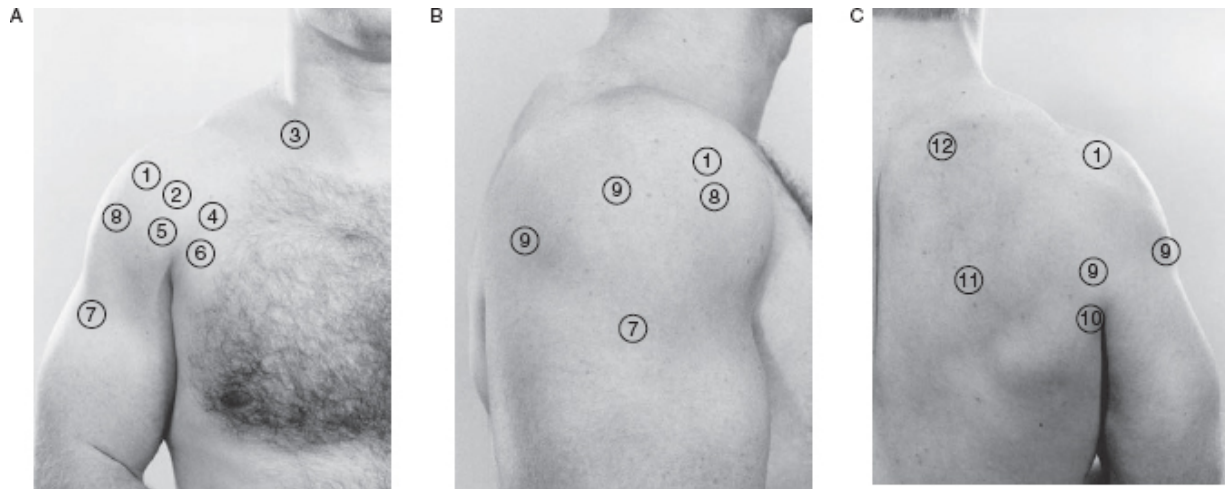

*Note:* See [Figure 7-3](#), A, B, and C, for localization of numbered areas.

- arm forced into external rotation and horizontal abduction with shoulder flexed to 90° or above— anterior dislocation, glenoid labrum tear
- sudden traction to the arm—medical subluxation or brachial plexus traction injury
- sudden pain with weight lifting (no apparent dislocation)—consider muscle/tendon rupture, labrum tear

With frank trauma excluded, the most fruitful approach is first to distinguish the patient's complaint. Have the patient categorize his or her complaint into mainly pain, stiffness,

instability, weakness, or numbness and/or tingling. Ascertain whether there are associated cervical or thoracic spine complaints. Although they are rare, determine whether there are any visceral complaints, in particular, right upper quadrant pain suggestive of biliary disease.

**Figure 7-3** (A) Anterior shoulder; (B) lateral shoulder; (C) posterior shoulder.

## Pain

When pain is the chief complaint, it is important to determine whether it is chronic or acute. An attempt to define a positional relationship is important. For example, patients who feel most of their pain while working in overhead positions may have an impingement problem. Patients who find it difficult to throw a ball or otherwise attain the cocking position of abduction/external rotation often will have instability. With acute pain that is severe with no trauma, the inability to move the arm in all ranges of motion without pain is highly suggestive of an acute bursitis. With chronic and insidious cases, it is important to determine the extent to which overuse or misuse is a culprit.

# Weakness

A sense of weakness or instability may be an isolated or associated complaint. It is important to discover past traumas, in particular dislocations or medical subluxations. If not rehabilitated, a progressive looseness of the capsule frequently develops. This may lead to concomitant damage to the labrum, resulting in a downward spiral. Another possibility is peripheral nerve damage such as suprascapular nerve involvement. Evidence is usually visually apparent with atrophy of the infraspinatus. When there is associated neck pain and painless weakness of the shoulder, consider and test for nerve root involvement. If there is no past trauma or surgery, consider the possibility of an inherent looseness of the shoulder capsule, which is likely a bilateral phenomenon. This is best determined with orthopaedic testing for instability.

# Restricted Movement

With a complaint of stiffness, it is important to determine the sequence of events leading to the sense of restriction. For example, a patient complaining of an acute, unprovoked episode of incapacitating shoulder pain that lasted for weeks before resolving into stiffness is likely to have adhesive capsulitis. A patient with a past traumatic history (especially a posteriorly directed force to the humerus) must be suspected of having a posterior dislocation. Those with a history of trauma or surgery might be expected to develop an early onset of osteoarthritic changes. In those with coexisting arthritides the shoulder may be a secondary area of involvement. In addition to osteoarthritis, the most common arthritides that involve the shoulder are rheumatoid arthritis and ankylosing spondylitis. All of the

above causes are likely to result in stiffness in many planes. A single movement plane of stiffness must be qualified. Restriction due to pain and weakness is likely caused by a mechanical block resulting from bone or labrum pathology. If there is overuse or trauma to muscle, subsequent scarring may lead to an obvious restriction in the direction of stretch.

## **Other Complaints**

Atrophy or deformity is sometimes the primary concern of patients. Atrophy of the infraspinatus is evident by a depression over the scapula. This is most often due to suprascapular nerve damage, not uncommon in overhead sports—in particular volleyball. If the patient complains of a mass in the distal arm, rupture of the long head of the biceps should be considered. The patient often will report an injury during which a pop was heard. Another cause of a mass in the arm is myositis ossificans. The patient will report having been struck on the arm, with subsequent swelling that never resolved. Radiographs will reveal the calcified muscle mass. Deformity at the top of the shoulder is often due to the instability of an AC separation or a distal clavicular fracture when trauma is reported. Without trauma and in an older individual, osteoarthritis of the AC joint is likely.

## **Examination**

There is strong evidence that clinical tests for the rotator cuff:

- Are able to rule out full tears.
- Have questionable value for partial tears.

- Have moderate sensitivity and specificity for instability and labrum tears, but the quality of studies is still questionable.
- Indicate moderate reliability for ROM.
- Suggest that use of Cyriax testing of the shoulder has not been shown to be reliable.

An examination of the shoulder can be problem (diagnosis) focused or generic. If the intent of the examination is to reproduce a diagnostic impression leading to further evaluation such as radiographs or special imaging, then a diagnosis-focused examination may be appropriate. This is more likely in the acute setting. With a chronic problem, two aspects of the examination become important: (1) the diagnostic impression and (2) the comprehensive evaluation of the patient's biomechanical status. In other words, what are the limitations in active, active-resistive, and passive ranges of motion? How is the scapula participating in this motion? If the patient has signs of impingement, is there any underlying instability or looseness? The generic approach is best when multiple factors are suggested.

With an acute injury, mechanism of injury coupled with observation of patient positioning and shoulder contour often suggest an underlying cause:

- If the patient either was injured by a direct blow to the shoulder or was suddenly overstretched into a position of external rotation/abduction or extension, anterior dislocation is likely; significant pain causes the patient to hold the arm in slight abduction and external rotation; associated observational findings are a visibly flat deltoid, prominent humeral head anteriorly, and a prominent acromion with a posterior depression underneath.

- If the patient fell on an outstretched arm or any mechanism of posterior force was applied to a flexed arm, a posterior dislocation is likely; the patient holds the arm slightly adducted and internally rotated (sling position); a prominent coracoid with anterior shoulder flattening is an associated observational sign best seen from a bird's-eye view (looking down at the shoulder of a seated patient).

Palpation of the shoulder may be revealing for many common shoulder complaints. Tenderness and deformity at the AC joint are often secondary to trauma and may represent a second- or third-degree separation or distal clavicular fracture. If there is no deformity, consider a shoulder pointer (contusion of the local muscles) or a first-degree separation of the AC joint. If there is no trauma but there is deformity, consider an old AC separation or, in an older individual, osteoarthritis; tenderness may or may not be elicited. Discrete tenderness at the AC joint in a serious weight lifter suggests osteolysis of the distal clavicle.<sup>22</sup>

Tender areas often correlate well to specific tissue involvement. This is often position-dependent:<sup>23</sup>

- The supraspinatus tendon insertion is most palpable with the patient seated and the arm held behind the back with the elbow flexed; the arm is internally rotated as much as possible and the elbow is lifted away from the back as far as possible (maximum extension of the shoulder); the supraspinatus tendon is then palpable directly anterior-inferior to the AC joint.
- The infraspinatus and teres minor tendons are most palpable with the patient seated or prone with the shoulder flexed to 90°, adducted 10°, and externally rotated 20°; the elbow is bent to about 90° during positioning; the tendons are then palpable directly inferior to the posterior acromion.

- The subscapularis tendon is palpated with the shoulder held in neutral at the patient's side; the tendon is palpable deep under the area of the clavicle just medial to the medial border of the deltoid in the deltopectoral triangle.
- The tendon of the long head of the biceps is palpated with the patient's arm internally rotated 20°; the tendon is palpable in the same deltopectoral triangle as the subscapularis; however, the internal rotation has placed the biceps tendon in an overlying position.

## Range of Motion

A small study by Hayes et al.<sup>24</sup> evaluated five methods including visual estimation, goniometry, still photography, "stand and reach," and hand-behind-back reach for six shoulder movements. For flexion, abduction, and external rotation, fair to good reliability was demonstrated for the interclass correlation coefficient (ICC) using visual, goniometry, and photography. The standard errors of measurement were between 14° and 25° (interrater) and 11° and 23° (intrarater). The hand-behind-back reach was the least reliable. While fair to good reliability was found for some approaches, the range of standard measurement errors indicates a large variation in precision.

Although active internal rotation of the shoulder is often tested with the patient being asked to reach behind the back and then to touch the highest point possible on the spine, this approach is fraught with misinterpretation. Both Wakabayashi et al.<sup>25</sup> and Ginn et al.<sup>26</sup> have determined that this is an inaccurate approach to measure, among other things, flexion of the elbow more than internal rotation of the shoulder. The contribution of internal rotation of the shoulder above the T12 vertebral level is very small.

Information from range of motion testing is often interpreted through a system developed by Cyriax sometimes referred to as a selective tension approach. Hayes et al.<sup>27</sup> performed a study on the reliability of resistive testing as proposed by Cyriax. The study included both the upper and lower extremities with the knee, shoulder, and elbow included. Examiners used maximum contraction testing and were unaware of previous testing results. The intrarater kappa values ranged from 0.44–0.82; the interrater kappa coefficients ranged from 0.00–0.46. A small number of patients who were classified as weak affected the kappa coefficients. In the intrarater evaluation percentages for the knee, evaluators averaged 91% of maximum kappa, while for the shoulder the average was 66.5%. For the interrater evaluation, the average was 60.4% of the maximum kappa for both the knee and the shoulder. The intrarater and interrater reliability were not acceptable for the shoulder.

Some characteristic movement pattern restrictions in range of motion (ROM) are as follows:

- Patients unable to perform most movements due to pain (and no history of trauma) are likely to have either an acute bursitis or the initial stage of adhesive capsulitis.
- If there is a history of trauma and the patient avoids any attempt at movement, consider dislocation and/or fracture.
- If there is a history of trauma and the patient is unable to lift the arm into flexion with a supinated arm, posterior dislocation should be considered.
- Pain in the midrange of abduction is referred to as a “painful arc.” The painful arc is between 70° and 110° (**Figure 7-4**). To qualify as a painful arc, the pain must be less above this range. When patients cannot actively move beyond this range, the examiner should

assist the patient to 120° and then ask the patient to continue if possible. In general, an active painful arc combined with a negative passive painful arc is suggestive of a contractile lesion (i.e., muscle/tendon). If a painful arc is felt on active and passive movement, the involved structures are less clear.

- Restriction in *both* active and passive ROM preferentially affecting external rotation, abduction, and then eventually extension and flexion suggests adhesive capsulitis.
- Pain felt at a discrete point with active ROM as a sharp pain is suggestive of a labrum tear, especially if it can be relieved by avoiding the specific position.
- Inability to lower from an abducted position (drop-arm test) is suggestive of a rotator cuff (specifically supraspinatus) tear.
- The use of body leaning or shoulder hunching is often visible when patients with adhesive capsulitis, rotator cuff tear, or osteoarthritis are compensating for weakness or loss of active movement.

**Figure 7-4** The painful arc is between 70° and 110°. The patient will feel more pain in this range and less on either side of this arc.

When the patient performs abduction maneuvers, it is important to palpate the scapula for a normal glenohumeral

to scapula ratio of movement. The ratio between humeral and scapular motion is often quoted as 2:1; however, this figure is an average. The ratio in the first 30° is closer to somewhere between 4:1 and 7:1; from 90° to 150° it is closer to 1:1.<sup>28, 29</sup> Thus, little movement occurs in the first 30°. Because the ratio changes with movement, it is often referred to as a rhythm. This rhythm changes with resistance.<sup>30</sup> With no resistance, the ratio starts at 7.9:1 and changes to 2:1 as the arm is raised. Light loads applied to the shoulder through the arm result in a rhythm ratio from 3:1 initially to 4.3:1 as the arm is raised. With heavy loading, the rhythm ratio starts at 1.9:1, going to 4.5:1 as the arm is raised. When excessive movement occurs at the scapula in the initial phase of abduction, weakness of the serratus anterior or other stabilizers is likely.

Scapular translation across the thoracic wall varies between 15 to 18 cm. A complex of abnormal positions or patterns has been referred to by various names, including scapulothoracic dyskinesis, floating scapula, and lateral scapular slide. A functional test for interscapular muscle weakness is to have the patient isometrically squeeze the scapulae together for 15 to 20 seconds, noting whether there is burning pain within 15 seconds. If so, this may indicate the need for strengthening. Another similar test is to have the patient hold a pencil between the shoulder blades for 30 to 60 seconds without dropping the pencil. In addition to static evaluation for scapular winging, a functional test called the lateral slide test is commonly performed.<sup>31</sup> The lateral slide test involves marking the inferomedial angle for each scapula with the reference point on the spine as the nearest spinous process (**Figure 7-5**). The distance is measured for each. In the second and third positions of the test, this measurement process is repeated. The three positions are: (1) arm at side, (2) hands on hips with fingers facing forward, thumbs posterior, with about 10° of shoulder extension, and (3) arm at or below 90° of

elevation with maximal internal rotation of the glenohumeral joint. Measurements are taken in each position. The interexaminer and intraexaminer reliability are generally good (about 0.84 to 0.88) for these measurements, with the least accurate position being the third (about 0.77 to 0.85).<sup>32</sup> Researchers have established a difference of 1.5 cm asymmetry as the threshold for abnormal.

Although the lateral scapular slide test has become a standard in detecting possible scapular dysfunction, researchers in one study compared the findings in asymptomatic competitive athletes.<sup>33</sup> They found that scapular position was commonly asymmetrical in asymptomatic individuals, calling into question the value of this finding as a distinct indicator of a cause of shoulder problems in symptomatic patients.

**Figure 7-5** Lateral scapular slide measurement. (A) The first position, with arms at side; (B) the second position, with hands on hips; (C) the third position, with arms at or below 90° abduction, with glenohumeral internal rotation.

If scapular muscle weakness or dyskinesia is suspected as a potential cause or aggravator of impingement, the examiner can perform a functional assist test by pushing laterally and upward on the inferior medial border of the scapula (simulating serratus anterior/lower trapezius function) while the patient raises the arm through various positions of elevation. If impingement symptoms are diminished, a relationship to scapular dysfunction is implied.

# Instability

Testing for instability or looseness of the shoulder is not performed in the acute dislocation scenario. This testing is reserved for those patients with a past history of dislocation or medical subluxation and those individuals who are suspected of having generalized joint laxity. There are a number of tests; however, most examiners focus on three: (1) the load and shift (L&S) test, (2) the apprehension test, and (3) the relocation test.

The L&S test (**Figure 7-6**) is usually performed with the patient seated with the arm abducted slightly ( $20^{\circ}$ ) and the hand resting on the lap.<sup>34</sup> The examiner then loads the joint by compressing the humeral head into the glenoid. While stabilizing the scapula with one hand held over the spine of the scapula and clavicle, the other hand pushes the humeral head first forward to test for anterior instability, then backward for posterior stability (**Figure 7-6A**) and finally inferiorly (**Figure 7-6B**). It is also possible to test the patient supine with the arm in  $20^{\circ}$  horizontal adduction,  $90^{\circ}$  abduction, and neutral rotation. In general, when inferior laxity is present, a sulcus sign or depression will appear below the AC joint. It indicates not only inferior laxity but also multidirectional instability. It will usually be found on the opposite shoulder, indicating an inherent looseness of the individual's shoulder capsules. It is important to understand the amount of laxity that occurs in normal shoulders. Using an objective measurement device (e.g., KT-1000, Medmetric Corporation, San Diego, California) with asymptomatic individuals, for women the nondominant shoulder range of translation was  $23.8 \text{ mm} \pm 4.2 \text{ mm}$ ; the dominant arm showed a translation of  $22.6 \text{ mm} \pm 4.6 \text{ mm}$ .<sup>35</sup> For men, significantly less translation occurred. The nondominant shoulder demonstrated translation of  $18.3 \text{ mm}$

$\pm 3.7$  mm; the dominant shoulder demonstrated  $17.1$  mm  $\pm 3.7$  mm.

**Figure 7-6** The L&S test involves stabilizing the scapula with one hand and grasping the humeral head with the other. Load the shoulder by pushing in toward the glenoid. (A) Then push forward to test anterior stability, and pull back to test posterior stability. (B) Pull downward on the arm to test inferior stability. A visible sulcus may appear under the acromion with a multidirectional loose shoulder.

Instead of measuring in millimeters, grading is generally based on the relationship of the humeral head to the glenoid. The grading system developed by Altcheck et al.<sup>36</sup> uses a grading system of 0 to 3. A grade 0 indicates no instability, while a grade 1 involves movement to the rim of the glenoid. A grade 2 occurs when the examiner can feel the humeral head translate over the glenoid rim but it does not lock. A grade 3 indicates the humeral head locks over the rim. Another commonly used system by Cofield and Mansat<sup>37</sup> uses the same descriptors; however, the numbers

1 through 4 are used to indicate the same respective findings as the Altcheck et al. grades 0 to 3.

The apprehension test (**Figure 7-7**) may be performed with the patient seated or supine.<sup>38</sup> The advantage of performing the test supine is the ability to move directly into the relocation test, which can be used as part of a sequential approach. The patient's arm is abducted and externally rotated. A first attempt is simply to continue the arm into more horizontal abduction (extension) at about 90°. If there is no pain or sense of apprehension, continue testing at a higher elevation and add a cautious pressure in an anterior direction on the posterior humeral head. If either pain or a sense of "going out" is felt by the patient, the test is positive for anterior instability. The test is re-performed; however, by applying an anterior-to-posterior force (**Figure 7-8**), the sense of either pain or apprehension will usually be reduced (relocation test).<sup>39</sup> When apprehension is reduced with this relocation maneuver, instability is confirmed. If pain is reduced with this test, posterior glenoid impingement probably is present due to an underlying anterior instability. The presence of pain with the apprehension test that is relieved by the relocation test has been demonstrated by arthroscopic examination to correlate with articular surface pathology. When the shoulder is abducted to 110°, patients demonstrate rotator cuff contact with the posterosuperior labrum.<sup>40</sup>

**Figure 7-7** The apprehension test may be performed lying or standing. With the patient supine, the examiner extends the patient's shoulder while at 90° abduction and externally rotated while pushing the humeral head from posterior to anterior.

**Figure 7-8** The relocation test is a repetition of the apprehension test; however, the examiner stabilizes the shoulder by applying an anterior to posterior force in an effort to relieve pain or a sense of apprehension.

## Labrum Tears

One of the most difficult pathologies to determine on the clinical examination is a labrum tear. When instability is

present or when an individual has complaints that sound like mechanical joint pain (e.g., shoulder gets “stuck” in certain positions or patient has a sharp pain in a specific position), labrum testing should be employed. There are two basic approaches with several variations. The original testing maneuver described in the literature is the clunk test. The patient is placed in the apprehension position with the examiner pressing the humeral head from posterior to anterior. The arm is then internally and externally rotated and circumducted in an attempt to elicit a deep “clunk” feeling or sound. Some examiners employ an axially compressive load (similar to Apley’s compression test for the knee). One such test is called the Crank test (**Figure 7-9**), and it involves placing the patient’s arm in maximum flexion, internally rotating and externally rotating the arm with an axial force applied. A positive response includes clicking with pain. The practitioners who developed the test found that when the Crank test, apprehension test, and L&S test findings were combined, the sensitivity of the clinical examination for labrum tears was better than with magnetic resonance imaging (MRI).<sup>42</sup>

More recent attempts at detecting labrum tears secondary to dislocation include the Kim test and the Jerk test. These may also indicate some underlying instability. The Kim test (**Figure 7-10**) is performed with the patient seated. Passively elevating the shoulder to 90°, the examiner applies an axial load while simultaneously lifting the distal humerus to impose a posterior inferior load to the shoulder. A positive would be a sudden onset of shoulder pain. The next test, the Jerk test (**Figure 7-11**) involves passive elevation of the shoulder to 90°; however, in this test, the scapula is stabilized. The examiner then imparts an axial compression while simultaneously horizontally adducting the shoulder across the chest. A positive result is an increase in shoulder pain that may or may not be associated with a click or clunk.

**Figure 7-9** Crank test—This test involves placing the patient's arm in maximum flexion while internally rotating and externally rotating the arm with an axial force applied. A positive response includes clicking with pain.

**Figure 7-10** Kim test—Passively elevating the shoulder to 90°, the examiner applies an axial load while simultaneously lifting the distal humerus to impose a posterior-inferior load to the shoulder. A positive would be a sudden onset of shoulder pain.

**Figure 7-11** Jerk test—Involves passive elevation of the shoulder to 90°, however, in this test, the scapula is stabilized. The examiner then imparts an axial compression while simultaneously horizontally adducting the shoulder across the chest. A positive result is an increase in shoulder pain that may or may not be associated with a click or clunk.

Although it is often assumed that with an anterior dislocation an inferior labrum tear has occurred, another type of tear related to excessive contraction of the long head of the biceps referred to as a superior labrum anterior to posterior (SLAP) lesion is difficult to detect. The long head of the biceps originates off the superior glenoid with a conjoined insertion with the superior labrum. The logic of testing is to begin with sensitive tests related to instability and labrum tears in general, and if positive, to focus on biceps-specific tests to confirm. Sensitive tests for instability would include the apprehension test, relocation test, and the load-and-shift test. Sensitive tests generally for labrum tears without distinguishing which type of tear include some compressive tests such as the Crank test (utilizing axial compression through the humerus and rotation), and clunk test.

Specific biceps contraction tests to further test for SLAP lesions include:

- Anterior slide test
- Active compression test (O'Brien's sign)

- Biceps load test II
- Speed's test
- Yergason's test

The anterior slide test (**Figure 7-12**)<sup>41</sup> begins with the patient seated or standing with the hand of the involved arm placed on the posterolateral iliac crest (the thumb pointing posteriorly). The examiner, standing behind the patient, places one hand on the top of the shoulder from behind, overlapping the index finger over the anterior acromion. The examiner's other hand takes the patient's elbow and directs an axial force anterosuperior into the shoulder. The patient is asked to press back against this attempt. A pop/click or pain localized to the front of the shoulder is considered positive for a superior labrum tear. Labrum tears also are suggested when popping and clicking are found on L&S testing or any distractive maneuvers coupled with internal rotation.

Another testing strategy known as the active compression test (also known as the O'Brien sign) is performed with the patient standing (**Figure 7-13**).<sup>42</sup> The patient brings the arm to 90° of forward flexion with the elbow fully extended. The patient then adducts the arm 10° to 15° across the chest. With the arm fully internally rotated (thumb down), the examiner (standing behind the patient) directs a downward force at the patient's forearm (patient's elbow remains extended). The test is then repeated by directing a downward force with the forearm supinated (palm-up). For this study, a positive test occurred when the first test position caused pain that was reduced or eliminated with the second test position. The distinction between AC versus glenoid labrum injury was based on where the pain was felt. Pain felt "at the top" of the shoulder indicated AC injury, whereas pain felt "deep" in the shoulder indicated labrum injury. The authors point out that if pain is not reduced or eliminated by the second test, the

test is not “positive.” They also indicate that the patient should be resisting the examiner’s downward force, not the opposite (examiner resisting patient’s upward force). Surprisingly, this test sequence produced a very reliable detection of labrum tears and AC injury. For detecting labrum abnormalities, the sensitivity was 100%, the specificity was 98.5%, the positive predictive value was 94.6%, and the negative predictive value was 100%. For AC abnormalities, the sensitivity was also 100%, the specificity was 96.6%, the positive predictive value was 88.7%, and the negative predictive value was again 100%. These statistics were derived by comparing active compression test results with findings at surgery.

**Figure 7-12** The anterior slide test involves the examiner stabilizing the shoulder joint while pressing through the long axis of the humerus in a superioranterior direction while the patient resists. A painful click, clunk, or pop is positive for a superior labrum tear.

**Figure 7-13** (A) First position of O'Brien sign. Patient's arm is in full internal rotation and 10° to 15° horizontally adducted. Examiner exerts a downward force while patient resists. (B) Test repeated with arm supinated. Pain felt in the first position and relieved or not produced during the second position is positive for a labrum tear if pain is felt deeply, or an acromioclavicular problem if felt superficially.

Kim et al.<sup>49</sup> developed a test referred to as the biceps load test for labrum tears. A redesign of this test was evaluated with better performance called the biceps load II test (**Figure 7-14**).<sup>43</sup> The test is performed by passively elevating the supine patients to 120° abduction and maximal, external rotated. The elbow is bent to 90° of flexion and the forearm is supinated. The examiner then asks the patient to flex the elbow while the examiner resists this attempt. The test is positive for a SLAP lesion if the patient has pain during the resisted attempt. Some examiners introduce resistance to supination to further stress the biceps. The biceps II test yielded the following results: sensitivity of 89.7%, specificity of 96.9%, a positive-predictive value of 92.1%, a negative-predictive value of 95.5%, and a kappa coefficient of 0.815.

**Figure 7-14** Biceps load II test—The test is performed by passively elevating the supine patients arm to 120° abduction and maximal, external rotation. The elbow is bent to 90° of flexion and the forearm is supinated. The examiner then asks the patient to flex the elbow while the examiner resists this attempt. The test is positive for a SLAP lesion if the patient has pain during the resisted attempt

Two other tests utilized are not specific to labrum tears per se but do challenge the biceps. One is the standard muscle test for forearm flexion and supination called Yergason's test (**Figure 7-15**). The second test more often used for impingement testing is Speed's test (**Figure 7-16**). The original test was described as starting with the patient standing and the entire arm passively extended (elbow extended). The examiner then resists the patient's attempt at forward flexion and allows a full isotonic contraction into full flexion. The positive with either of these tests is shoulder pain that localized to the superior shoulder.

To evaluate the sensitivity, specificity, and positive and negative predictive value of tests used for SLAP lesions, three tests were studied:<sup>45</sup>

1. Anterior Slide (AS)
2. Active Compression (AC)
3. Compression Rotation (CR)

The sensitivity, specificity, and positive and negative predictive values were determined using arthroscopic comparison. The most sensitive test was the AC test at 47%; the most specific was the AS test at 84%. The highest positive predictive value was the AC test at 10%; and the highest overall accuracy was the AS test at 77%. The lowest accuracy was the AC at 54%. The AC test was not good at localizing or producing a click. There was an overlap of positives for impingement decreasing specificity.

**Figure 7-15** Yergason's test—The standard muscle test for the biceps with resisted forearm flexion and supination

**Figure 7-16** Speed's test—The examiner resists the patient's attempt at forward flexion and allows a full isotonic contraction into full flexion. A positive result is shoulder pain; localized to the superior shoulder.

Another study by Stetson et al.<sup>46</sup> compared the diagnostic value of the Crank test, O'Brien test, and MRI in detecting labrum tears. The results were:

- The Crank test positive predictive value (PPV) was 41% and the negative predictive value (NPV) was 61%. The Crank test was found to be 56% specific and 46% sensitive.
- The O'Brien test had a PPV of 34% and an NPV of 50%. The O'Brien test was found to be 31% specific and 54% sensitive.
- MRI had a PPV of 63% and an NPV of 83%. MRI was found to be 92% specific and 42% sensitive.

Combination findings were:

- MRI ± O'Brien had a PPV of 71% with 82% specific and 50% sensitive.
- MRI ± Crank had a PPV of 60% with 67% specific and 43% sensitive.

Some similar findings were reported in studies by Parentis et al.<sup>47</sup> and Guanche and Jones.<sup>48</sup> The findings of these studies, similar to the Stetson et al. study, conflict with initial reports by the developers of these tests. The primary difference is that Parentis et al. and Stetson et al. used a random population and used arthroscopy to confirm findings. It seems that type I SLAP lesions are not as evident as type II SLAP lesions. Conclusions from the Parentis et al. study were that the two most sensitive tests for type II SLAP lesions were the active compression (65.2%) and the Hawkins' test (65.2%). The only other slightly valuable tests for sensitivity were Speed's test (40%), Neer's test (50%), and the relocation test (50%). The Yergason's, Crank test, pain provocation, and anterior slide were not sensitive. These same tests, though, had high specificity (Yergason's

93.5%, pain provocation test 90.2%, Crank test 82.6%, and anterior slide test 81.5%). Findings from the Guanche and Jones study are similar. The O'Brien test was 63% sensitive, 73% specific; and the Jobe relocation test was 44% sensitive, 87% specific. In their study, the Crank test, a test for tenderness of the bicipital groove, and the Speed test were not found to be useful in detecting labral tears.

Because many patients with anterior superior labral tears also have anterior supraspinatus tears, some authors coined the term SLAC lesion (superior labrum, anterior cuff). In one study, although impingement tests appeared to be generally negative with these patients, the Whipple test was positive in all 40 patients tested.<sup>51</sup> The Whipple test is a variation of the empty can test for the supraspinatus. The patient, holding the palm down and in front of the opposite shoulder, is asked to resist a downward force applied by the examiner.

Posterior labrum damage is common in weight lifters and in athletes who are hit with the arm held in front as a protection. Unfortunately, there are no tests for posterior labrum tears. About half of these patients experience clicking on load and shift testing.<sup>52</sup> Many patients possess full range of motion and demonstrate no indicators of instability.

---

## **Summary of Instability and Labrum Testing**

A systematic review by Luime et al.<sup>53</sup> attempted to determine the value of six tests commonly used to evaluate instability and/or labrum tears. Results for each test were:

- The relocation test (LR, 6.5; 95% CI, 3.0–14.0).
- Anterior release (LR, 8.3; 95% CI, 3.6–19).
- Biceps load I and II (LR, 29; 95% CI, 7.3–115.0 and LR, 26; 95% CI, 8.6–80.0), respectively.
- Pain provocation of Mimori (LR, 7.2; 95% CI, 1.6–32.0).

- Internal rotation resistance strength (LR, 25; 95% CI, 8.1–76.0).
- The apprehension, clunk, release, load and shift, and sulcus sign tests proved less useful.

A prospective, cohort-study by Parentis et al.<sup>54</sup> evaluated provocative maneuvers for the diagnosis of SLAP tears of the shoulder. The study included 132 consecutive patients scheduled for diagnostic shoulder arthroscopy. The results indicated:

- The sensitivity for type II SLAP lesions was highest for the active compression test and Hawkins', followed by Speed's, Neer's, and Jobe's. They were statistically different from the other four tests ( $P < 0.5$ ), but not from each other.
- The Hawkins' and active compression tests were the least specific. The most specific for type II lesions were the Yergason's and pain provocation tests ( $P < 0.5$ ).
- Positive predictive values were low for all tests.
- Negative predictive values were in the 80% range for each test.

The authors concluded that finding negative test results might be valuable in ruling out a SLAP lesion.

A more recent review evaluated the reliability and diagnostic accuracy of the history and physical examination for diagnosing glenoid labral tears.<sup>55</sup> Although the diagnostic accuracy of individual tests is quite variable, it was found that by combining the history and exam, the reliability increased. The combination of popping or catching with either a positive Crank test or anterior slide test was suggestive of a labral tear and the absence of this combination suggests the absence of a tear (sensitive and specific). Additionally, the combination of a positive anterior

slide with a positive active compression, or Crank test, suggests the presence of a labral tear.

**Exhibit 7-1** is a graphical representation of determining the likelihood of instability and/or labrum tears based on aggregate likelihood ratios for each test and combination of test.

## General Impingement

Impingement may occur under the subacromial arch, affecting mainly the supraspinatus, biceps, and subacromial bursa. Posterior impingement involves the posterior labrum, infraspinatus, and teres minor tendons. Subcoracoid impingement selectively impinges the subscapularis. Most tests designed for impingement focus on the subacromial arch. These are general tests and do not usually reveal a specific structure. One test is the painful arc discussed above in the ROM section. Other tests include the Neer test and the Hawkins-Kennedy test. The Neer test (**Figure 7-17**) is a passive test involving full forward flexion while holding down the shoulder (stabilizing with the other hand).<sup>56</sup> A positive result involves pain production at the end-range of full forward flexion, not in the midrange of motion. With the Hawkins-Kennedy test (**Figure 7-18**) the examiner places the patient's arm in an impingement position.<sup>57</sup> While standing behind the patient, it is important to prevent scapular elevation by hooking the hand over the top of the shoulder. The examiner's other hand lifts the arm into a position of 90° forward flexion, slight adduction, and internal rotation. The more internal rotation imposed in this position, the stronger the pain response. The positive pain response for impingement is anterior pain. Posterior stretch or pain implies involvement of posterior structures such as the infraspinatus and teres minor or posterior capsule. An interesting study by Pappas et al.<sup>58</sup> using three-dimensional

open MRI evaluated the actual internal effects of the Hawkins' and Neer's tests to determine if their theoretical basis was, in fact, true. They found that subacromial contact occurred for the supraspinatus and infraspinatus with the Hawkins position but not with the Neer position. Intra-articular contact of the supraspinatus with the posterosuperior glenoid occurred with both positions. Subscapularis contact also occurred with the anterior glenoid with both positions.

A radiographic evaluation of testing positions using open MRI by Gold et al.<sup>59</sup> evaluated the glenoid contact by the supraspinatus and infraspinatus with the shoulder in external rotation and abduction loaded (resisted), and unloaded. This is the standard apprehension test performed supine. A positive test result of pain has been suggested to indicate posterosuperior rotator cuff pinching due to instability. This study indicated that both the supraspinatus and infraspinatus do, in fact, contact the glenoid in this position; loaded or unloaded.

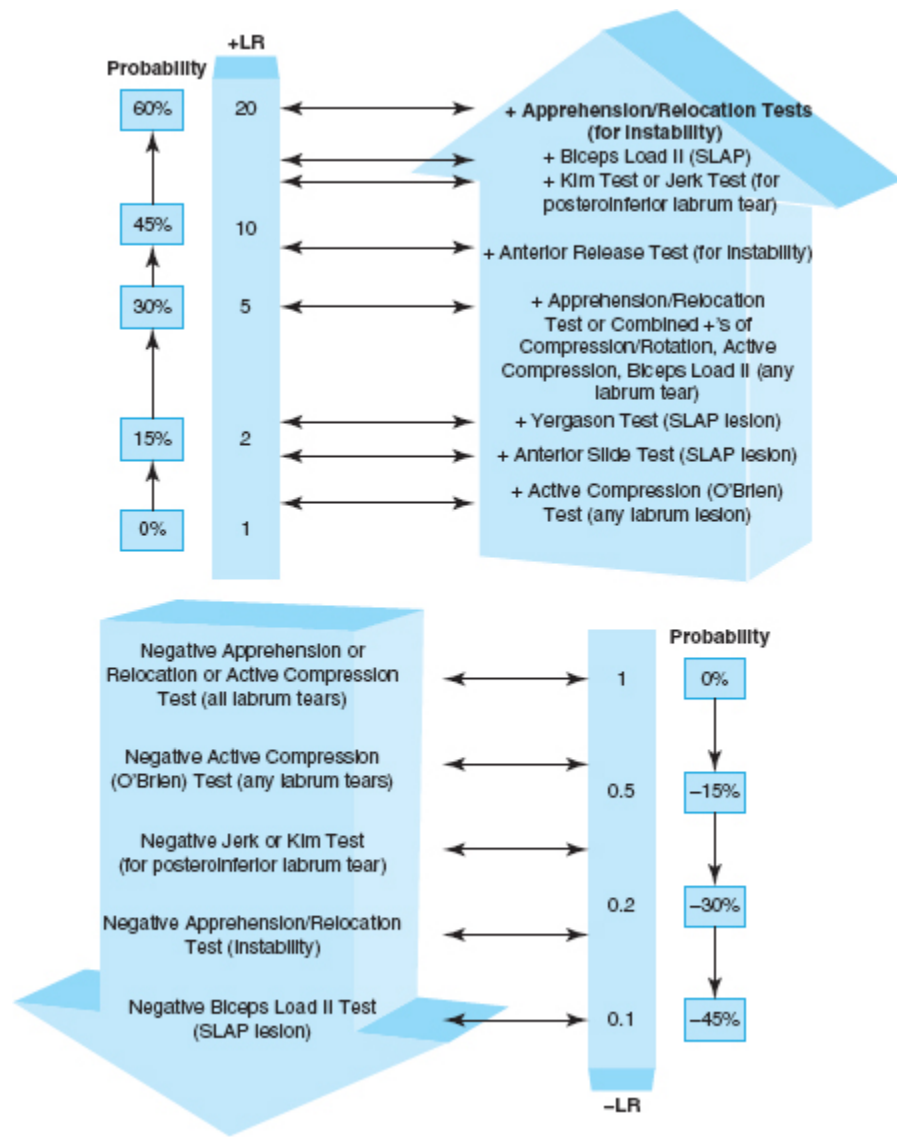

Posterior capsular tightness can be determined by having the patient lie on his/her side with the shoulder to be measured on top (**Figure 7-19**). The examiner stands in front of the patient and, while stabilizing the scapula, lowers the shoulder (elbow bent) as far as it will move passively down toward the examining table. A measurement may then be taken from the medial epicondyle of the elbow to the tabletop. When the general impingement tests are positive it is important to attempt to localize which structures are involved by more specific testing.

## **Summary of Impingement Syndrome Testing**

For impingement syndrome, diagnostic testing was evaluated in a cross-sectional study by Ardic et al.<sup>60</sup> and in a prospective study by Park et al.<sup>61</sup> In the Ardic study, comparison between clinical findings to diagnostic ultrasonography and MRI was performed. The most painful shoulders had a more frequent finding of glenoid labral tear and this correlated with more restricted extension on physical examination. Subacromial bursal effusion/hypertrophy was correlated with shoulder disability and impingement test maneuvers. Clinical tests as a whole had modest accuracy for rotator cuff tears and biceps pathology. In the Park study,<sup>61</sup> 913 patients underwent physical examination and diagnostic arthroscopy. The physical examination included eight clinical tests: Hawkins-Kennedy, Neer's, empty-can, Speed's, cross body adduction, infraspinatus strength test, drop-arm sign, and painful arc. Results indicated that the combination of the Hawkins-Kennedy, painful arc, and infraspinatus muscle tests yielded the best post-test probability (95%) for any degree of impingement.

### **Exhibit 7-1 Likelihood Patient Has Instability and/or a Labrum Tear Approximating Probability**

The likelihood ratios (LRs) in this graphical representation represent estimates of probability based on the aggregate of multiple reviews of each test finding. They are only approximations and only reliable indicators of a change in the context of a patient having an intermediate pre-test probability of between 20% and 80%. If the pre-test probability is very high or very low, the LR has little effect on changing the probability.

**Figure 7-17** The Neer test is performed by passively elevating the arm into forward flexion to end-range. End-range pain is a positive sign of impingement.

Given the likelihood ratio for these patients (knowing that they were surgical candidates), test performance may appear inflated as far as sensitivity is concerned. If impingement has a functional rather than a structural component, which is then not visible on arthroscopy, it is possible that arthroscopy may not be the gold standard for these functional cases.

**Figure 7-19** The maximum passive range of motion of the posterior capsule is determined by having the patient lie on his/her side and stabilize the scapula with the torso perpendicular to the table. The arm is brought toward the table in cross-body adduction (across the chest) until resistance is met. This may be visualized as an estimate or may be measured as the distance from the tip of the elbow to the examining table.

**Figure 7-18** The Hawkins-Kennedy test for impingement involves passive internal rotation with the shoulder flexed forward 90° while the scapula is stabilized.

**Exhibit 7-2** is a graphical representation of determining the likelihood of subacromial impingement based on aggregate likelihood ratios for each test and combination of tests.

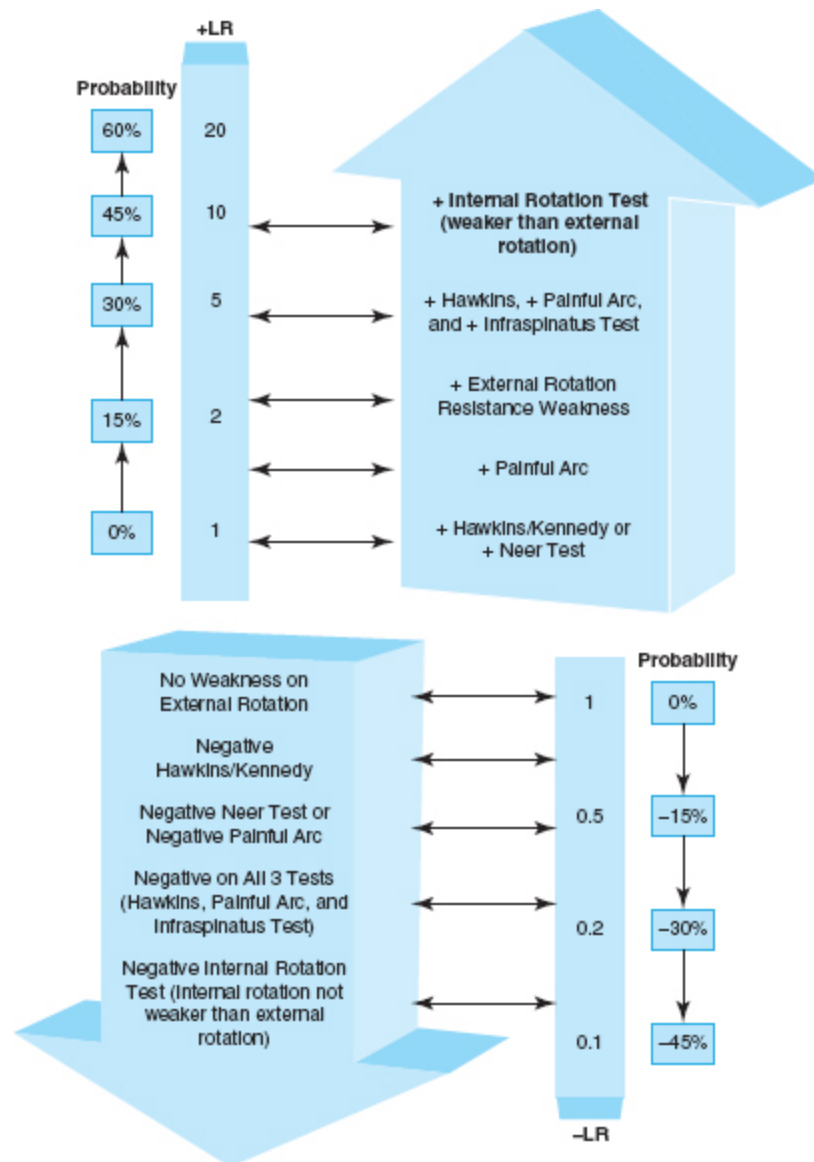

---

## **Rotator Cuff Tears (RCT)**

One general approach is to test for external rotation or by using the Rent test as a screen for a rotator cuff tear.<sup>62</sup> Resisted external rotation is often weak regardless of which tendon is involved. The Rent test (**Figure 7-20**) involves the examiner passively extending the shoulder with the elbow flexed. The examiner then palpates in front of the AC joint while internally and externally rotating the humerus through the elbow. Palpation of a prominence (the greater tuberosity) and an adjacent rent (depression) indicates a full thickness tear.

### **Exhibit 7-2 Likelihood Patient Has Subacromial Impingement Approximating Probability**

The likelihood ratios (LRs) in this graphical representation represent estimates of probability based on the aggregate of multiple reviews of each test finding. They are only approximations and only reliable indicators of a change in the context of a patient having an intermediate pre-test probability of between 20% and 80%. If the pre-test probability is very high or very low, the LR has little effect on changing the probability.

In a retrospective study by Ito et al.<sup>63</sup> common sites of pain were evaluated using clinical charts of 149 patients diagnosed with either rotator cuff tears or adhesive capsulitis confirmed by arthroscopic findings.

The results were that:

- The lateral and anterior shoulder were the most common sites of pain regardless of whether there was a tear or where the tear existed.

- Motion pain was more common than pain at rest for patients with rotator cuff tendinitis or tears.

The authors concluded that pain location was not useful in locating the site of a tear. However, the physical exam based on positive results to muscle tests with appropriate thresholds for muscle weakness was clinically useful. Specifically:

- Supraspinatus—the full can test and empty can test (**Figure 7-21**) showed higher accuracy when assessed with muscle weakness (78% and 79% respectively) than when assessed with pain (74% and 71% respectively).

**Figure 7-20** Rent test—The examiner passively extends the shoulder with the elbow flexed and internally rotated. The examiner then palpates in front of the AC joint while internally and externally rotating the humerus through the elbow. Palpation of a prominence (the greater tuberosity) and an adjacent rent (depression) indicate a full thickness tear.

- Infraspinatus—external rotation strength showed 50% accuracy using pain, and between 58% and 74% using weakness as a positive.
- Subscapularis—lift-off test (**Figure 7-22**) accuracy was 65% with pain and 62%–85% when using strength.

The researchers evaluated both pain reported by patients and pain provoked by muscle testing including the muscle grade at which a positive test occurred. Supraspinatus testing was the most accurate, with muscle strength at less than Grade V; infraspinatus testing was most accurate with the threshold of a positive at less than Grade IV; and for subscapularis, muscle strength at less than Grade III.

**Figure 7-21** The empty can test for the supraspinatus is performed with the patient's shoulder abducted 90° in the plane line of the scapula (30° to 45° forward). With the shoulder in maximum internal rotation, the patient is asked to abduct further against resistance.

**Figure 7-22** Lift-off test—The patient must have no pain on positioning the hand for the test to be specific for the subscapularis. If she or he is unable to lift the hand away from the back, the test is positive for a subscapularis tear.

Kim et al.<sup>64</sup> evaluated how often partial subscapularis tears were found at surgery. It was discovered that about 19% of shoulders had partial subscapularis tears. These were not apparent clinically. They were associated with supraspinatus tendon tears, rotator cuff disease, and posterosuperior labral tearing. Independent risk factors were increasing age, dominant arm involvement, and infraspinatus tears.

Specific testing of contractile structures includes the following:

- **Supraspinatus:** Muscle testing of the supraspinatus is best performed as the empty can test ([Figure 7-21](#)). The patient attempts to lift the arm in the plane line of the scapula (scaption), which is 30° to 45° forward of straight abduction. The arm is maximally internally rotated. If this is not painful, the examiner adds resistance to the attempt at approximately 90° of scaption. Pain and weakness indicate a supraspinatus tear. It is important to remember that the intention of this test is to contract the supraspinatus in an impingement position; however, other muscles do participate, as with all resisted testing.<sup>65</sup> It has also been found that testing with the arm in a thumb's-up position recruits as much electromyographic activity; however, it is less painful than full internal rotation.<sup>66</sup>
- **Biceps:** Although there are a number of tests for the biceps, the one considered most sensitive by investigators is the Speed test.<sup>67</sup> Most biceps tests cause contraction of the biceps without movement of the tendon in the intertubercular groove. The Speed test involves an isotonic contraction into forward shoulder flexion with the elbow extended. The examiner resists this attempt through a full ROM. In so doing, the intertubercular groove travels under the tendon and therefore is more likely to cause irritation if

there is an underlying inflammatory process or tendinitis.

- **Infraspinatus/teres minor:** Contraction into external rotation may cause pain if performed with the arm in the Hawkins-Kennedy position (90° forward flexion, forearm parallel to the floor).<sup>68</sup> This position places a stretch on the tendons prior to contraction. Kelly et al.<sup>66</sup> state that there is minimal pain produced, and therefore better test-retest reliability, when the infraspinatus is tested with the arm at the side (no elevation), 90° of elbow flexion, and the shoulder internally rotated 45° from the sagittal plane.
- **Subscapularis:** Although the subscapularis is an internal rotator, so are many other larger muscles; therefore, resisted internal rotation is a nonselective attempt at localization. If the subscapularis is involved, the lift-off test (**Figure 7-22**) may be positive. The patient places the hand behind the back and then attempts to lift the hand off the back. The patient must have no pain on positioning the hand for the test to be specific for the subscapularis. If she or he is unable to lift the hand away from the back or the attempt is significantly painful, the test is positive.<sup>69</sup> Jemp et al.<sup>68</sup> found the best position for isolating the subscapularis from the pectoralis major was arm elevation to 90° in the scapular plane (scaption) position of 30° to 45° anterior to the coronal plane with the arm in neutral. The examiner supports the arm to allow a better attempt at internal rotation without any associated abduction or adduction attempts by the patient. A 2014 publication<sup>70</sup> indicated that by utilizing three primary tests, the clinical accuracy was quite good for detecting a full subscapularis tear. These included the lift-off test, the bear hug test (**Figure 7-23**), and the belly press test (**Figure 7-24**).

**Figure 7-23** Bear hug test—The patient places his/her opposite hand on the top of the involved shoulder. He/she then presses down on the shoulder imparting internal rotation while the examiner augments the resistance by pushing up on the wrist and hand. Extreme weakness or the inability to maintain without incorporating movement at the elbow indicates a subscapularis full-thickness tear.

One would assume that muscle testing about the shoulder will indicate the presence of a partial tear or full rupture of the rotator cuff muscles. Logically, if there is a partial tear or full rupture, active resisted testing of the muscle should cause painful weakness with a partial tear and perhaps painless or minimally painful weakness with a full rupture. Given that rotator cuff musculature and tendon insertion is largely hidden by more superficial musculature, the observation of a displaced tendon or bulge of a retracted muscle tendon is not obvious.

A common testing procedure is the drop-arm sign where a patient's arm is elevated to above 90° and the patient is asked to hold the position. Inability to hold the position or lower through to the side without dropping indicates involvement of either the deltoid or supraspinatus, and given that the supraspinatus is more often torn, the assumption is that a tear of the supraspinatus has occurred. An extension of this concept is to add resistance to the position. This is often referred to as the Jobe sign. With the arm at 90° abduction, the examiner exerts a downward

force while the patient attempts resistance. The obvious confounding factor is that this test is likely to cause pain with mainly shoulder conditions and the pain is likely to cause a reflex inhibition of the muscles. The weakness, then, is more a neurologic response rather than a biomechanical inability to hold the position.

**Figure 7-24** Belly-press (Napoleon test)—the patient places his/her palm against his/her abdomen at about the height of the xiphoid process. The elbow is aligned to the trunk. The patient presses maximally against the abdomen using internal rotation. Inability to maintain the position of the elbow due to weakness indicates a subscapularis tear.

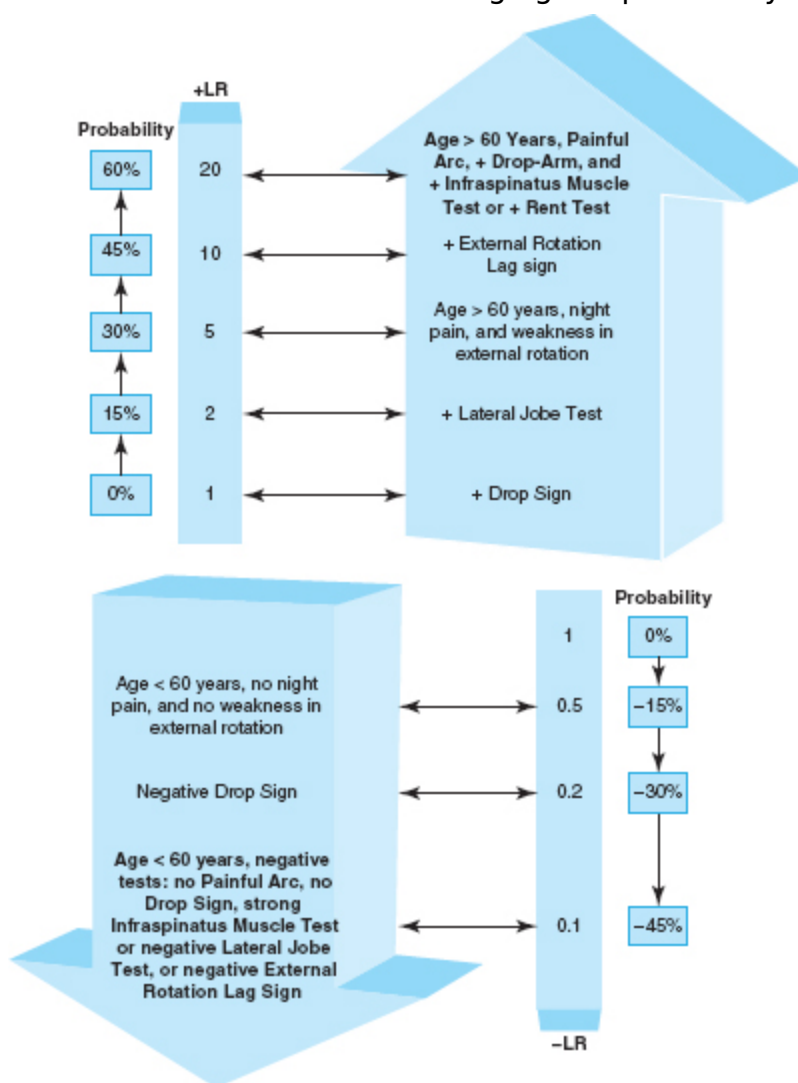

Park et al.<sup>61</sup> determined that there was a combination of three tests that taken together gave a high degree of diagnostic accuracy although taken individually, the tests were not very good. The combination of the painful arc, drop-arm sign, and infraspinatus muscle test produced the best post-test probability (95%) for a full-thickness rotator cuff tear when all are positive. **Exhibit 7-3** is a graphical representation of determining the likelihood of a full thickness RCT based on aggregate likelihood ratios for each test and combination of tests. Hertel et al.<sup>71</sup> performed an evaluation of 100 consecutive patients. The results of those patients who went on to arthroscopic or open repair of any rotator cuff muscle/tendon were examined to determine the

effectiveness of several tests in detecting a partial or full rupture. The tests incorporated into the study evaluation were:

### Exhibit 7-3 Likelihood Patient Has a Rotator Cuff Tear (General) Approximating Probability

The likelihood ratios (LRs) in this graphical representation represent estimates of probability based on the aggregate of multiple reviews of each test finding. They are only approximations and only reliable indicators of a change in the context of a patient having an intermediate pre-test probability of between 20% to 80%. If the pre-test probability is very high or very low, the LR has little effect on changing the probability.

**Figure 7-25** (A) First position of external rotation lag sign involves supporting the patient's elbow and externally rotating the shoulder, then backing off the end position by 5°. (B) Releasing the arm contact while continuing to support at the elbow may allow a "drift" of the arm into internal rotation if the test is positive.

- The Jobe sign—shoulder elevated to 90° abduction with internal rotation; patient maintains position with examiner exerting a downward force on the arm (similar to the empty can test).
- The lift-off test—the patient is seated with hand of involved arm placed palm outward on lower back; the patient is asked to lift the hand off of the back.
- The external rotation lag sign (**Figure 7-25**)—the patient is seated, the elbow is passively flexed to 90° and the shoulder is held at 20° elevation in the scapular plane in a position of near maximum external rotation (i.e., maximum external rotation minus 5° to avoid elastic recoil); the examiner supports the elbow and holds the arm in external rotation at the wrist; the patient is asked to hold the position while the examiner supports the elbow but releases the hold at the wrist; the degree of movement is estimated and is referred to as the "lag" (i.e., the difference between supported and unsupported passive ROM).
- The drop sign (**Figure 7-26**; different from the standard drop sign)—the patient is seated, the arm is

held at 90° elevation (in the scapular plane) and almost full external rotation with the examiner supporting the elbow and holding the arm in external rotation at the wrist; the patient is asked to hold the position while the examiner supports the elbow but releases the wrist hold; the degree to which the arm falls into internal rotation is the degree of lag.

- The internal rotation lag sign (**Figure 7-27**)—the patient is seated; the patient is asked to bring the arm behind the back with the palm facing outward; the arm is held in near maximum internal rotation and with the hand away from the back by approximately 20° of extension; the patient is asked to hold the position while the examiner supports the elbow but releases the wrist hold; if the patient is unable to hold the position, the lag sign is positive.

**Figure 7-26** (A) First position of the drop sign involves abduction and external rotation of the shoulder while supporting the patient's elbow. Back off of the end position by 5°. (B) Elbow is supported while forearm contact is released. A "drift" into internal rotation indicates a positive lag response.

The biomechanical principle used in the design of the lag sign was to place the muscle/tendon in the most disadvantaged position possible, thereby requiring full function of the muscle. Also, the position was designed to eliminate, as much as possible, contribution from other

synergists. False negatives may occur if there is a restricted passive movement pattern. False positives may occur if the arm is held in maximum rotation or if the patient has an excessive passive range of motion.

The results of the study indicate the following:

- For rupture of the supraspinatus and infraspinatus tendons, the external rotation lag sign was less sensitive but more specific than the Jobe sign; this is probably because the Jobe sign is often painful.
- The drop sign was the least sensitive but was as specific as the external rotation lag sign.
- Partial ruptures of the supraspinatus were not revealed with the external rotation lag sign.
- For the subscapularis, the internal rotation lag sign was as specific as but more sensitive than the lift-off sign.
- Partial ruptures of the subscapularis tendon could be missed with the lift-off sign but detected with the internal rotation lag sign.

## **Acromioclavicular Joint**

AC joint problems are usually evident from the history, observation, and direct palpation. A maneuver that may assist is compression, which is performed by cupping the shoulder from anterior and posterior with both palms and pressing together. Distraction using the spine of the scapula and clavicle may also cause some pain. The O'Brien sign, as described above, is also an important test for AC involvement. The sulcus sign, used to indicate instability of the shoulder, is also present with second- and third-degree AC separations.

# Radiography and Special Imaging

Radiographic examination of the shoulder is based on the suspected underlying pathology. General screening involves an anterior-to-posterior (AP) radiograph performed with the patient's arm internally and externally rotated. Some suggested views based on the structures or conditions suspected follow. Discussion of these views with illustrations of how to perform them may be found in the author's text *Sports Injuries of the Shoulder*.<sup>72</sup>

**Figure 7-27** (A) First position of internal rotation lag sign involves supporting the patient's elbow and internally rotating the shoulder with the arm behind the back, then backing off the end position by 5°. (B) Releasing the arm contact while continuing to support at the elbow may allow a "drift" of the arm toward the back if the test is positive.

- Impingement: Evaluation of the subacromial outlet may be seen with the anterior oblique or outlet view (Y view); other helpful views for acromial morphology include the AP view with 30° caudal tube tilt and the AP acromial view (15° cephalad tube tilt) (Zanca view).
- Anterior dislocation: An anterior dislocation is usually visible on an AP neutral; however, the AP internal rotation or anterior oblique (Y) view is best.

- Posterior dislocation: The best view is the Y view; supplementary views are the transthoracic and Velpeau or other axial projections.
- AC joint separation: Weighted and nonweighted anterior projections are often used to determine the degree of separation; these are bilateral shots; a coracoclavicular distance greater than 1.3 cm indicates third-degree separation.
- Instability: If traumatic instability is suspected, several modified axillary projections are of potential benefit in demonstrating residual Hill-Sachs and Bankart (glenoid lip avulsions associated with labrum tears) lesions; these include the West Point view and Didiée view for Bankart lesions, and the AP with internal rotation and the Stryker notch view for Hill-Sachs lesions.
- Osteolysis or fractures of the distal clavicle: The Zanca projection taken with 10° to 15° cephalad tube tilt (about half the technique of an AP shoulder projection) is used.
- Sternoclavicular (SC) joint: Two views are used to evaluate the SC joint—the Hobbs' view and the serendipity view.
- Humeral head fractures: Most fractures are visible on an AP radiograph with internal and external rotation.

Newly released radiographic guidelines for the chiropractic profession provide a very useful approach to determining both the need and type of imaging appropriate for a given patient scenario. In general, special imaging of the shoulder should be reserved for cases where conservative care has failed to resolve the problem. Available tools include MRI, computed tomography (CT), arthrography, and ultrasonography. The strengths of each are outlined below.

- MRI: MRI is a valuable tool when patients are unresponsive to conservative care. However, asymptomatic individuals may have partial or full-thickness tears. As many as 54% of asymptomatic individuals older than age 65 years were found to have partial thickness tears and 26% had full thickness tears.<sup>73</sup> Therefore, caution should be used when using MRI as the only indicator for need of operative repair. Full-thickness tears of the rotator cuff are readily apparent (sensitivity and specificity at 90% or above), whereas partial-thickness tears (sensitivity, 74%; specificity, 87%) may require fat saturation or other techniques to help differentiate them.<sup>74</sup> Glenoid labrum tears are less recognizable, and the sensitivity and specificity vary depending on the investigator. It is generally accepted, however, that the sensitivity is in the range of 75% or less.<sup>75</sup> This varies depending on the site. Superior tears are the most discernible, followed by a poor ability to visualize inferior tears (around 40% sensitivity), and even less ability to visualize posterior tears (about 7%).<sup>76</sup> New approaches being investigated and used in some facilities include the use of kinematic MRI and also performing standard MRI with the addition of gadolinium.<sup>77</sup>
- CT arthrogram: CT arthrograms are used mainly for glenoid labrum and rotator cuff tears; many consider them the imaging tool of choice. The difficulty is finding facilities that will perform them. The accuracy of CT arthrography with rotator cuff tears has been reported to be as high as 95% to 100%.<sup>78</sup> However, other studies have not demonstrated an advantage over MRI.<sup>79</sup>
- Ultrasonography: Ultrasonography (diagnostic ultrasound) can be an excellent tool for detecting full-thickness cuff tears. Partial tears are sometimes detectable.<sup>80</sup> Interpretation may be the weak point

because of the major variations in findings due to operator skill.

In an extensive systematic review by Dinnes et al,<sup>81</sup> studies involving clinical examination, ultrasonography, MRI, and MR arthrography (MRA) were evaluated. The review was specific to impingement syndrome and rotator cuff tear (full or partial). Cohort studies for clinical examination indicated that physical examination used by specialists can rule out the presence of a rotator cuff tear.

The interobserver agreement in the classification of rotator cuff tears using MRI was examined in a recent study.<sup>82</sup> Although there was good agreement in predicting full-thickness rotator cuff tears and the number of tendons involved, there was moderate agreement in predicting the involved side of partial-thickness tears, and poor agreement in predicting the grade of a partial tear compared at surgery.

One recent study<sup>83</sup> evaluated the classification systems used by surgeons in determining rotator cuff tears. Agreement was high for full-thickness tears and whether partial tears were articular or bursal. However, the study showed disagreement on the depth of the tear. For full-thickness tears, the highest agreement was found when they were classified by topography (degree of retraction) in the frontal plane.

## Management

In the event of an acute dislocation, relocation is accomplished with several maneuvers; the easiest to perform is the Milch maneuver.<sup>84</sup> This procedure involves slowly elevating the arm while maintaining external rotation and superior pressure on the humeral head. Another approach is to use two relocators. One provides traction or stabilization while the other uses long-arm traction of the

involved arm. This distraction will significantly relieve pain. An attempt at relocation through adduction and internal rotation may be attempted. If unsuccessful, maintaining traction will reduce pain until emergency help arrives. Relocation may be difficult, and when not possible requires emergency department referral. A postreduction radiograph should be obtained to determine if there are any associated fractures. The chiropractor can play a valuable role in rehabilitation, which has been shown to substantially reduce the risk of recurrence.<sup>85</sup>

If radiographs reveal signs of infection, fracture, or tumor, the patient should be referred for orthopaedic consultation. All other problems can be addressed conservatively unless the patient's pain threshold does not allow a nonmedicated course. Acute pain may be managed by various physical therapy approaches, including high-voltage galvanic or interferential. Over-the-counter medications may be necessary.

Support and stabilization are needed in several scenarios: AC separations, postrelocation, atraumatic instability, and acute bursitis. These may be provided by supportive strapping using various types of elastic tape or a sling. The advantage of taping is that it allows function, whereas a sling prevents use of the arm. The pain level and degree of injury dictate the better approach.

Rehabilitation of the shoulder generally proceeds through a sequential approach, beginning with a focus on the stabilizers (rotator cuff), followed by the scapular stabilizers (serratus anterior and trapezius). The large movers such as the pectoralis major and latissimus dorsi muscles can then be addressed. Without proper stabilization, the larger muscles may cause more damage due to abnormal glenohumeral motion; without proper scapular stabilization, impingement is more likely. Muscle inhibition and altered patterns of muscle activation may be the cause or the result of shoulder disorders. Two muscles that are commonly

inhibited are the serratus anterior and lower trapezius muscles.<sup>86</sup> The functional consequences are more likely to be evident in athletes than in an average sedentary individual.

Some recent important findings that may assist in choosing the appropriate exercise include the following:

- The work of Clisby et al.<sup>87</sup> and Britter et al.<sup>88</sup> suggests that to maximize infraspinatus activation it is important with isometric exercises to keep the load to 40% of a maximum contraction. When using concomitant adduction, keep the adduction component to a very mild contraction (10%) to avoid incorporation of the middle deltoid over the infraspinatus. With the arm at the side, the posterior deltoid may act as an adductor.
- It appears from Werner et al.<sup>86</sup> that the highest subacromial pressures occur with a combination of internal rotation, flexion, and abduction. Interestingly, paralysis of the supraspinatus or infraspinatus had no effect on subacromial pressure at rest, or with active shoulder movement. In a separate study by Gerber et al.<sup>89</sup> paralysis of the supraspinatus and infraspinatus resulted in a loss of external rotation strength by 80% and abductor strength by 75%.
- Regarding exercise performed with the shoulder in an immobilizer, Smith et al.<sup>90</sup> found the following. Scapular depression produced large serratus anterior activity with small rotator cuff, biceps, and anterior deltoid activity. Upper subscapularis activity was quite high with all exercises. The authors suggest that exercise is appropriate for patients postsurgically with the exception of those with initial subscapularis repair.
- Smith et al.<sup>91</sup> also evaluated the effect of protraction on shoulder strength. They found that internal rotation strength was reduced by 13% to 24%. External

rotation increased mildly in the internally rotated position while decreasing in the neutral, or externally rotated position. It is not clear whether this is clinically detectable.

A facilitation phase using mild isometrics in various movement patterns such as internal and external rotation is helpful. Another effective tool for facilitation and stabilization is use of rapid elastic tube exercises limited to about a 20° to 30° arc (back and forth) for 60 seconds or until fatigue or pain occurs. The general program begins with light weights (5 to 10 lb) and high repetition (15 to 20), using perhaps three sets performed every day. A core group of exercises has been recommended, including the following:<sup>92, 93</sup>

- scaption (abduction in the scapular plane of 30° to 45° forward) or flexion
- horizontal abduction with external rotation performed prone
- seated press-up
- bent-over row
- push-up with a plus (extending the arms at the top of the push-up)

Newer recommendations still include the exercises above with some recommended modifications and the addition of only a few new exercises based on recorded EMG activity. Following is a summary of more recent conclusions:

- The infraspinatus and teres major generated moderate to high activity with both the prone horizontal and prone external rotation exercises.<sup>94</sup>
- Using the proprioceptive neuromuscular facilitation (PNF) approach, a D1 and D2 diagonal pattern are good overall exercises with a focus on the serratus

anterior. These combination maneuvers use the entire upper extremity in a pattern of adduction, extension, and internal rotation for the D2 and abduction, flexion, and external rotation for the D1 exercise (lawnmower exercise).<sup>95</sup>

- Performing the push-up with a plus with the hands externally rotated and on an unstable surface provided the most stimulation for the serratus anterior.<sup>96, 97</sup>
- Only the press-up and push-up with a plus activate both the lower trapezius and the serratus anterior.<sup>98</sup>
- The side-lying wiper is a new exercise. The participant lies on his or her side, flexes the elbow 90°, abducts the shoulder 90° and supports the elbow with the opposite hand. The participant then proceeds to internally and externally rotate from this support position. Researchers found that this isolated infraspinatus activity without significantly incorporating the upper trapezius or posterior deltoid.<sup>99</sup>

The importance of the posterior cuff has been overshadowed by the interest in rehabilitating the supraspinatus. Yet due to the possibility of superior humeral head translation with the supraspinatus, it is considered more important to first focus on posterior rotator cuff strengthening.

The prime concern with impingement, though, is to avoid abduction or scaption above about 70° due to the force couple of the supraspinatus and deltoid that causes an increase superior translation of the humeral head on the glenoid, increasing subacromial impingement. This superior translation may be position-dependent. Blackburn et al.<sup>100</sup> evaluated exercises for the supraspinatus and posterior rotator cuff. Prone horizontal abduction with the shoulder abducted 100° and externally rotated (elbow extended) caused the most activity in the supraspinatus (**Figure 7-28**). With the patient prone and the glenohumeral joint at

90° and the elbow bent to 90°, external rotation caused maximum electromyographic activity of the infraspinatus and teres minor.

A recent study by Horrigan et al.<sup>101</sup> used MRI to evaluate activity of muscles while individuals performed three exercises: (1) scaption with internal rotation (SIR), (2) side-lying abduction (SLA; moving from neutral or adduction to 45° abduction with 8% of body weight for males and 5% of body weight used for females), and (3) the military press. The SLA exercise (**Figure 7-29**) demonstrated the most activity (determined by signal intensity increase on MRI) for the supraspinatus, deltoid, infraspinatus, subscapularis, and trapezius. The SIR exercise showed the second highest activity for these muscles. None of the exercises caused significant increased activity in the teres minor. In addition to the Horrigan study<sup>92</sup> that used MR relaxation time, researchers in a recent study evaluated the most effective exercise for the supraspinatus using the same measurement approach.<sup>102</sup> Using MRI T2 relaxation time to determine which exercise stimulated the supraspinatus most, the empty can, full can, and horizontal abduction (prone) were compared. The empty can and full can exercises had similar stimulation profiles, both demonstrating high levels of activity for the supraspinatus. Horizontal abduction was far less stimulating.

**Figure 7-28** Prone arm elevation toward the ceiling with the shoulder abducted 90 to 120° is an excellent all-around rotator cuff exercise.

**Figure 7-29** Side-lying abduction of the arm to 45° is an excellent exercise for the rotator cuff without risk of impingement. Muscles activated include the supraspinatus, deltoid, infraspinatus, subscapularis, and trapezius.

Electromyographic evaluation of a series of shoulder exercises using elastic tubing yielded the following results:<sup>103</sup>

- Shoulder shrug—this was considered the most effective exercise with regard to how many muscles were active; high activity was noted for the subscapularis (especially during the retraction phase), trapezius, and latissimus dorsi; other muscles that were stimulated included the supraspinatus, infraspinatus, and serratus anterior.

- Internal rotation—low levels of activity for a number of muscles including the subscapularis (which had higher activity with the shoulder shrug and narrow- and middle-grip seated rows) and pectoralis major as the two main muscles with lesser activity of the biceps, latissimus dorsi, and serratus anterior.
- External rotation—infraspinatus was the primary muscle activated; moderate activity of supraspinatus, subscapularis, pectoralis major, and serratus anterior.
- Forward punch—also considered a very effective exercise with the greatest activity from the supraspinatus, serratus anterior, and anterior deltoid; pectoralis major and infraspinatus were also stimulated.
- Seated row (middle-grip)—main activity in the supraspinatus and subscapularis.
- Seated row (wide-grip) (**Figure 7-30**)—same activity as middle-grip with addition of trapezius and infraspinatus.
- Seated row (narrow-grip)—primarily the subscapularis.

The authors suggest that for the subscapularis it might be appropriate to begin with internal rotation due to the low activity of the subscapularis and then progress to more demanding exercises such as the wide-grip seated row than progressing to the narrow- and medium-grip seated row. In contrast, for all other muscles, the wide-grip seated row is considered a more advanced exercise. In a recent study using needle EMG, nine men and six women were evaluated while performing a series of exercises, including the standard push-ups with a plus, internal rotation at the side, and diagonal exercises.<sup>104</sup> The findings indicated that upper subscapularis activity was greater than lower subscapularis activity for all exercises except internal rotation at the side. The push-up plus and diagonal exercises stressed both upper and lower portions of the muscle to the greatest

extent. The researchers concluded that the two sections of the subscapularis may have different functional responses with exercise.

**Figure 7-30** Seated rowing with a wide grip is an excellent exercise for the subscapularis, supraspinatus, and trapezius.

One recent study<sup>105</sup> determined surface electromyographic (EMG) activity of the serratus anterior in 20 healthy subjects performing the following exercises:

- Shoulder extension—elastic tubing is used; subject is standing with elbow flexed 90° and starting at waist height (tubing in front of body); subject extends shoulder while flexing the elbow and then returns to start position.
- Forward punch—elastic tubing is used; subject stands with tubing behind, then with starting position at side, elbow flexed 90°, subject then punches forward, flexing shoulder to shoulder height and extending elbow.
- Serratus anterior punch—elastic tubing, which is attached behind subject, is used; with the shoulder at shoulder height and elbow extended, the subject starts with the humerus internally rotated 45° and scapula

retracted, then the subject protracts the scapula moving the fist forward and then retracts to the starting position.

- Dynamic hug (**Figure 7-31**)—elastic tubing, which is attached behind subject, is used; subject is standing with elbows flexed  $45^{\circ}$ , arms abducted to  $60^{\circ}$ , and the shoulders internally rotated to  $45^{\circ}$ ; the subject then horizontally flexes following an imaginary arc until hands touch, then returns to the starting position.
- Scaption with external rotation—a small dumbbell is used; subject is standing and lifts the shoulder in the scapular plane to shoulder height with shoulder externally rotated (thumbs up).
- Press-up—subject is seated with hands on chair at level of buttocks, then extends elbows to lift the body off the chair; position is held for 3 seconds.
- Push-up plus—prone subject performs a standard push-up with hands shoulder-width apart, then protracts the scapula to rise higher vertically.
- Knee push-up plus—same as push-up; however, patient is supported by knees.

**Figure 7-31** The dynamic hug exercise has been shown to be an excellent exercise for the serratus anterior (along with push-up with a plus and forward punching).

The serratus anterior punch, scaption with external rotation dynamic hug, knee push-up plus, and push-up plus exercises demonstrated muscle activity greater than 20% of a maximal voluntary contraction. The greatest activity was demonstrated for the push-up plus and the dynamic hug. Both accentuated scapular protraction while maintaining an upwardly rotated scapula. The advantage of these exercises is they are all performed at or below 90° of abduction avoiding potentially painful or damaging higher elevations. These exercises were ranked primarily by average amplitude, and they represent low resistance, high reps emphasizing an endurance training approach. The serratus anterior is also maximally stimulated at all higher ranges of elevation including abduction, scaption, and flexion; however, these higher positions may be unattainable or dangerous with an injured or painful shoulder.

### **Low Energy Laser and Shockwave Therapy**

Given the current interest in low-energy laser (cold laser) treatment of soft tissue disorders, a brief description of the current evidence is warranted. Low energy laser is purported to activate the electron transport chain and thereby enhance the synthesis of ATP, which would then activate membrane ion carriers altering the flow of calcium between mitochondria and the cytoplasm. Taken as a whole, these changes theoretically speed healing through cellular mechanisms. This is accomplished without the thermal effects of higher energy lasers. There have been some small studies<sup>106, 107</sup> with patients suffering from myofascial chronic neck pain that suggest that low-level laser at 830 nm or 904 nm may be effective alone or in combination with other treatments compared to a sham laser treatment. Short-term effects of real shockwave therapy (SWT) include analgesic and anti-inflammatory results likely due to removal of inflammatory mediators coupled with nociceptive inhibition

through a gate-control mechanism. Longer term healing effects may be related to acute vessel rupture and subsequent angiogenesis in soft tissues. EFD between 0.04 and 0.22 mJ/mm<sup>2</sup> have very few side effects as reported in the literature, including pain, erythema, local soft tissue swelling, and local subcutaneous hematomas among others. High-energy SWT is quite uncomfortable without local anesthetic.

At the current time, based on literature evidence, treatment parameters appear empirical. The clinician weighs the advantage of high-energy treatment with the comfort level of low-energy treatment. It does appear that both high- and low-energy protocol procedures are equally effective if the total energy applied is approximately the same. The compensation, then, is to utilize a low-energy protocol but use more impulses over more treatment sessions to achieve a similar result to high-energy treatment protocols, especially when administered by chiropractors who are not able to use local anesthetic in-office.

A Cochrane review<sup>108</sup> which examined the value of low-level laser on rheumatoid arthritis suggests that there may be some benefit for short-term relief. They did conclude that success was influenced by several variables, such as wavelength, treatment duration, dosage, and site. More recent evidence seems to support the use of SWT for calcific tendinitis, adhesive capsulitis, and rotator cuff tendinosis.<sup>109, 110</sup>

## Manipulation

The literature on manipulation for the shoulder is both sparse and complex. Most studies that use the term manipulation are utilizing what chiropractors would consider mobilization (e.g., Maitland: Grade I-IV). Studies on

manipulation include the cervical spine as much, or more than, the shoulder joint itself.

The largest randomized controlled study (RCT) on manipulation and the shoulder was conducted by Winters et al.<sup>111</sup> Their group performed a follow-up study two years later.<sup>112</sup> In the original study, patients from general practices in the Netherlands were included. There were 198 patients with shoulder complaints divided into diagnostic groups: a shoulder girdle group ( $n = 58$ ) and a synovial group ( $n = 114$ ). These diagnostic groups were based on testing that indicated for the synovial group that pain or limited movement was due to the synovial structures about the shoulder including subacromial structures, the acromioclavicular joint, the glenohumeral joint, or any combination of these. Patients in the shoulder girdle group had pain and sometimes slightly limited range of active movement of the glenohumeral joint. The assumption was, for patients with shoulder problems without specific shoulder findings, that the source was unrelated to the synovial structures but could be due to functional disorders of the cervical spine, upper thoracic spine, or the upper ribs. Manipulation was performed by physical therapists and could include manipulation of the cervical spine, upper thoracic spine, the upper ribs, the acromioclavicular joint, or the glenohumeral joint. The method of manipulation was not clearly described. The shoulder girdle group was randomized to either manipulation or physiotherapy. Patients in the synovial group were randomized to corticosteroid injection, manipulation, or physiotherapy. In the shoulder girdle group, at five weeks, 70% of the manipulation group considered themselves cured compared to only 10% of the physiotherapy group. In the synovial group, at five weeks, 75% of patients in the injection group, 20% of the physiotherapy group, and 40% of the manipulation group reported a "cure." There was a shift of patients from the synovial group to the shoulder girdle

group as a result of treatment success with nonsteroid anti-inflammatory drugs (NSAIDs). Drop-out rates due to treatment failure in the synovial group were high in the manipulation group (59%) and in the physiotherapy group (51%). In the shoulder girdle group drop-out was 20% in the manipulation group, and 45% in the physiotherapy group. The large drop-out rates are of concern, particularly with regard to the “manipulation” approach in this study. The first concern is that there is no description of the method used. Secondly, the treatment was not standardized, in that any given patient might have had manipulation of the cervical spine only, the glenohumeral joint only, or multiple joints. There is no indication of who received which method. The advantage to this approach is that it may be more representative of clinical practice where the approach varies from patient to patient based on their specific needs. However, drawing conclusions about specific manipulation approaches is not possible with this method. The followup study two years later<sup>112</sup> indicated that the advantage of manipulation or corticosteroid injection was lost over time. Part of the reason may have been the high attrition rate and a failure of “success” cases to respond.

A more recent RCT by Bergman et al.<sup>113</sup> studied the effectiveness of manipulative therapy for the shoulder girdle in addition to usual medical care for relief of shoulder pain and dysfunction. The premise that cervicothoracic spine dysfunction is a cause or risk factor for shoulder pain was based upon one systematic review by Sobel et al.<sup>114</sup> and two studies by Norlander et al.<sup>115, 116</sup> All patients received usual medical care from general practitioners. Only the intervention group received additional manipulative therapy to the cervicothoracic area or adjacent ribs (but not to the shoulder). Treatment consisted of up to six sessions in a 12-week period. Follow-up was over a one-year period. At six weeks, no differences between groups were demonstrated. At 12 weeks, 43% of the intervention group (manipulation

plus usual medical care), and 21% of the control group reported full recovery. At 52 weeks, the same difference in recovery rate was reported. Of these groups, 16% had manipulation of a vertebral segment or joint outside the shoulder region.

In a small RCT by Conroy et al.,<sup>117</sup> patients were assigned to either a joint mobilization/comprehensive treatment group or a comprehensive treatment group that consisted of only the administration of hot packs, active ROM, physiologic stretching, muscle strengthening, soft tissue mobilization, and patient education. The joint mobilization utilized in the first group was of the Maitland type. Maitland mobilization involved applying oscillatory pressure of two to three oscillations per second. There was no indication of a Grade V Maitland (manipulation) being used. The experimental group (the one with joint mobilization) improved on all variables, while the control group improved only with mobility and function. The mobilization group had less 24-hour pain, and pain with a subacromial compression test when compared to the comprehensive treatment group. No differences in ROM and function were reported.

A very specific manipulation approach was evaluated in a study by Kebl et al.<sup>118</sup> The study involved 29 elderly patients with preexisting shoulder problems including tendinitis, bursitis, osteoarthritis, healed fracture, or neurologic impairment, and chronic pain in one or both shoulders. They were randomized to either an osteopathic manipulation therapy (OMT) group or a control group for 14 weeks. The OMT was a technique utilizing end-range isometric contractions against doctor resistance. The control group received a placebo treatment, which involved positioning only, with no contractions. Both groups had significantly increased ROM and decreased perceived pain. Those receiving the OMT demonstrated continued improvement in their ROM, while ROM in the placebo group decreased over several months. The manipulative technique was a specific

approach called the Spencer technique. It is not “true” manipulation but in fact a mobilization technique involving seven end-range positions held as an isometric contraction against resistance.

A case report by Vermeulen et al.<sup>119</sup> involving several patients diagnosed with adhesive capsulitis tested the effects of three months of end-range mobilization on increases in range of motion and increases in joint capsule volume. Out of the seven participants, four patients rated their improvement as excellent, two rated it as good, and one rated it as moderate as related to shoulder function. At the nine-month follow-up, all patients appeared to maintain some gain in joint mobility.

A small randomized, single-blinded, placebo-controlled trial of 30 participants was conducted to determine the effect of shoulder adjusting (high-velocity, low-amplitude) on patients with a diagnosis of shoulder impingement syndrome.<sup>120</sup> Patients were randomized to either a de-tuned ultrasound group or a shoulder adjustment group. At the one-month follow-up, there were significant positive treatment effects with regard to a visual analog scale and Short-Form McGill Pain Questionnaire. All other studies were case studies that tended to either be general,<sup>121-123</sup> specific to spinal adjusting for shoulder problems,<sup>124-126</sup> or specific to disorder.<sup>127-135</sup>

The Council on Chiropractic Guidelines and Practice Parameters (CCGPP) Upper Extremity team concluded that there is moderate evidence that manipulation (i.e., mobilization including Grade V Maitland [cavitation]) may be of short-term benefit and limited evidence for long-term benefit for patients with shoulder pain.<sup>136</sup>

The CCGPP expert panel made recommendations for use of high-velocity, short-amplitude (HVSA) manipulation that include avoidance of any anticipated risk. Further evaluation and management may be required for patients with a failure to respond to treatment within a reasonable period of time.

- For all patients who have fracture, suspected fracture, dislocation, severe generalized or local osteoporosis, infection, tumor, or infection, HVSA manipulation is contraindicated.
- For patients who have had surgery of the shoulder, consider date of surgery, extent of surgery, type of procedure, and other related factors in making decisions about use of HVSA manipulation.
- For all patients, an evaluation for joint stability must be performed. Based on the findings, it is recommended that no HVSA manipulation be used for patients with medical subluxation, hypermobility syndromes (e.g., Marfan's, Ehlers-Danlos syndrome), or gross looseness indicating multidirectional instability. Mobilization such as applying a load-and-shift or Maitland Grade I-IV type of translational movement may be appropriate in these case settings.
- For patients with adhesive capsulitis or any acute inflammatory condition such as rheumatoid arthritis, active hemarthrosis or extensive swelling, rheumatoid variant disease, crystalline disease (e.g., gout), or acute bursitis, it is recommended not to use HVSA. There is some literature evidence that aggressive mobilization may worsen or prolong the natural history of adhesive capsulitis.<sup>146</sup> Based on this evidence and the experience of our panel, it is felt that an HVSA approach is highly risky, certainly in the early stages of adhesive capsulitis. For the middle and later stages of adhesive capsulitis, chiropractors should consider a progressive application of increasing the grade of amplitude of manipulation. It is recommended that by using patient feedback and response as a guide, increasing grades of amplitude may be applied.
- For patients with impingement syndrome with a known structural cause (e.g., type 3 acromion, arthritis), it is

strongly recommended that any HVSA manipulation not be applied in a superior direction.

## **Disorder-Specific Recommendations**

Prior to prescribing a rehabilitation program for any patient it is important to understand the restrictions imposed by any underlying pathology. Some general recommendations for patients with specific shoulder problems follow:

- **Instability**—Although instability may either result from trauma or can be due to developmental or acquired “looseness” of the shoulder joint, the imposed restrictions in movement patterns are often similar. For anterior instability it is important to avoid the extremes of abduction, external rotation coupled with horizontal abduction (horizontal extension). This fits the general rule of thumb with any ligament/capsular injury: avoid the position of injury. Common weight-lifting maneuvers that may violate this rule are those that allow the elbow to drift behind the body, often as the starting or ending position of a given exercise. Common examples include the beginning stretch position of a “butterfly” maneuver for the pectorals. This may be imposed either by machinery (e.g., Cybex machine) or with free weights. Overhead presses with dumbbells or bars may also be dangerous if in the higher levels of elevation the elbows drift behind the body. The lat pulldown, which uses an overhead bar attached to a pulley, begins with the shoulders in a fully stretched position of elevation. Unfortunately, the shoulders are often relaxed prior to a sudden effort to adduct the arms. This does not allow proper stabilization of the shoulder.
- **Impingement**—Impingement may be secondary to instability or due to other functional or mechanical

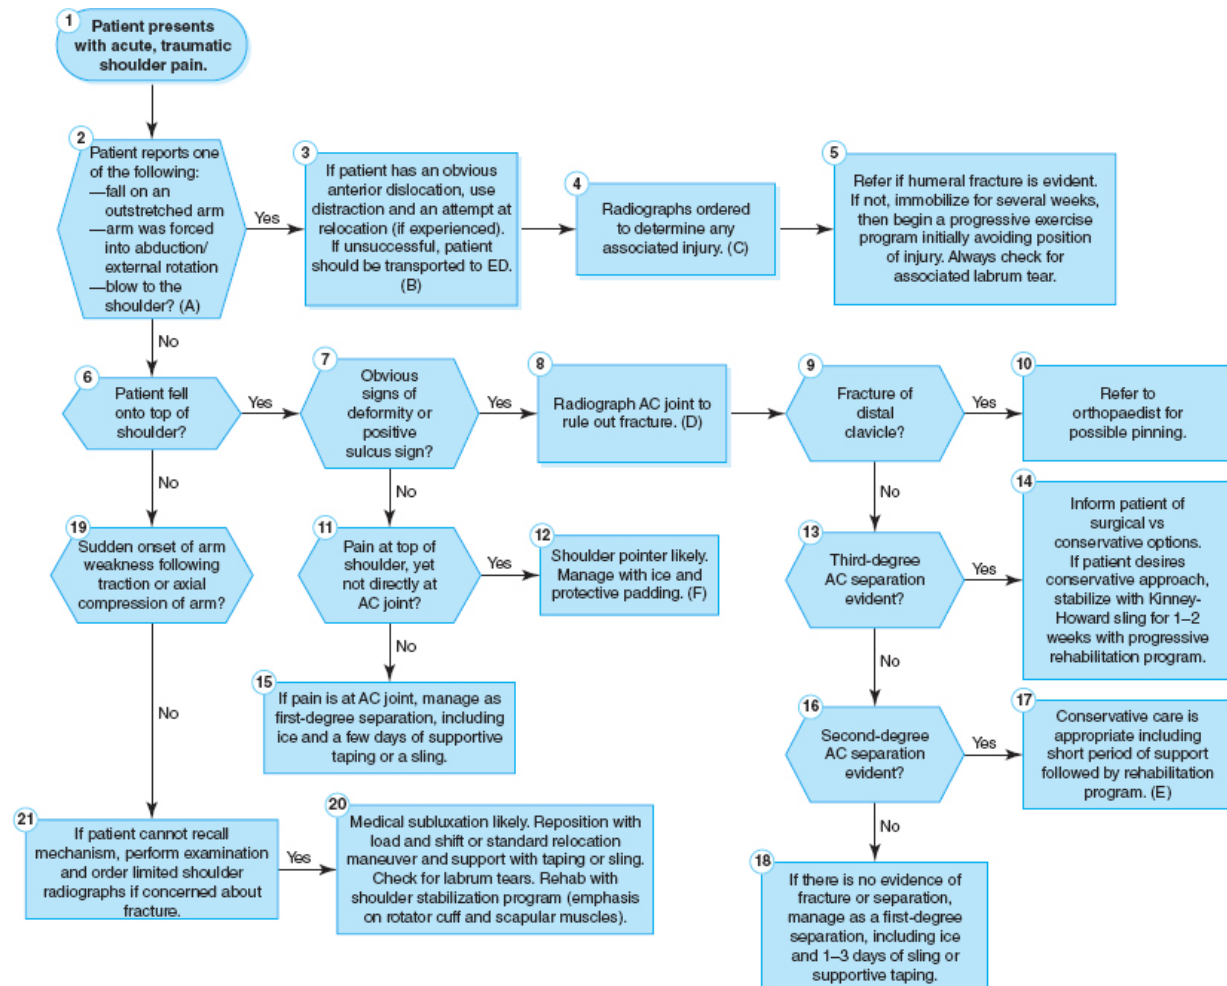

causes. When secondary to instability, it is important to use the above guidelines prior to focusing on impingement restrictions. Subacromial impingement is likely to be aggravated by the position of abduction (specifically  $90^{\circ}$ – $110^{\circ}$ ) and internal rotation. The most common offensive lifting maneuver is the lateral raise when the arm is in neutral or internal rotation. All overhead presses and Nautilus-type deltoid machines should be initially avoided.

- Biceps tendinitis—Given that with standard biceps exercises the tendon of the biceps is relatively stationary in relation to the intertubercular groove, these exercises are not usually the offenders. What does aggravate a biceps tendinitis is either excessive weight with traditional biceps curls, or more commonly, exercises that cause the tendon to travel up and down through the groove during the exercise. These exercises include forward flexion maneuvers such as forward raises and bench presses.
- Osteolysis of the distal clavicle—Repetitive grinding or compressive/shear forces may cause erosion of the distal end of the clavicle. Most often, the weight lifter is using a very heavy weight. It is important to avoid several exercises with this condition: bench presses using a wide grip, dips, and dead lifts. Some weight lifters also complain of pain with overhead presses. Substitution with narrow-grip bench presses, cable cross-overs, or incline or decline benching with lighter weights is suggested as an initial approach.

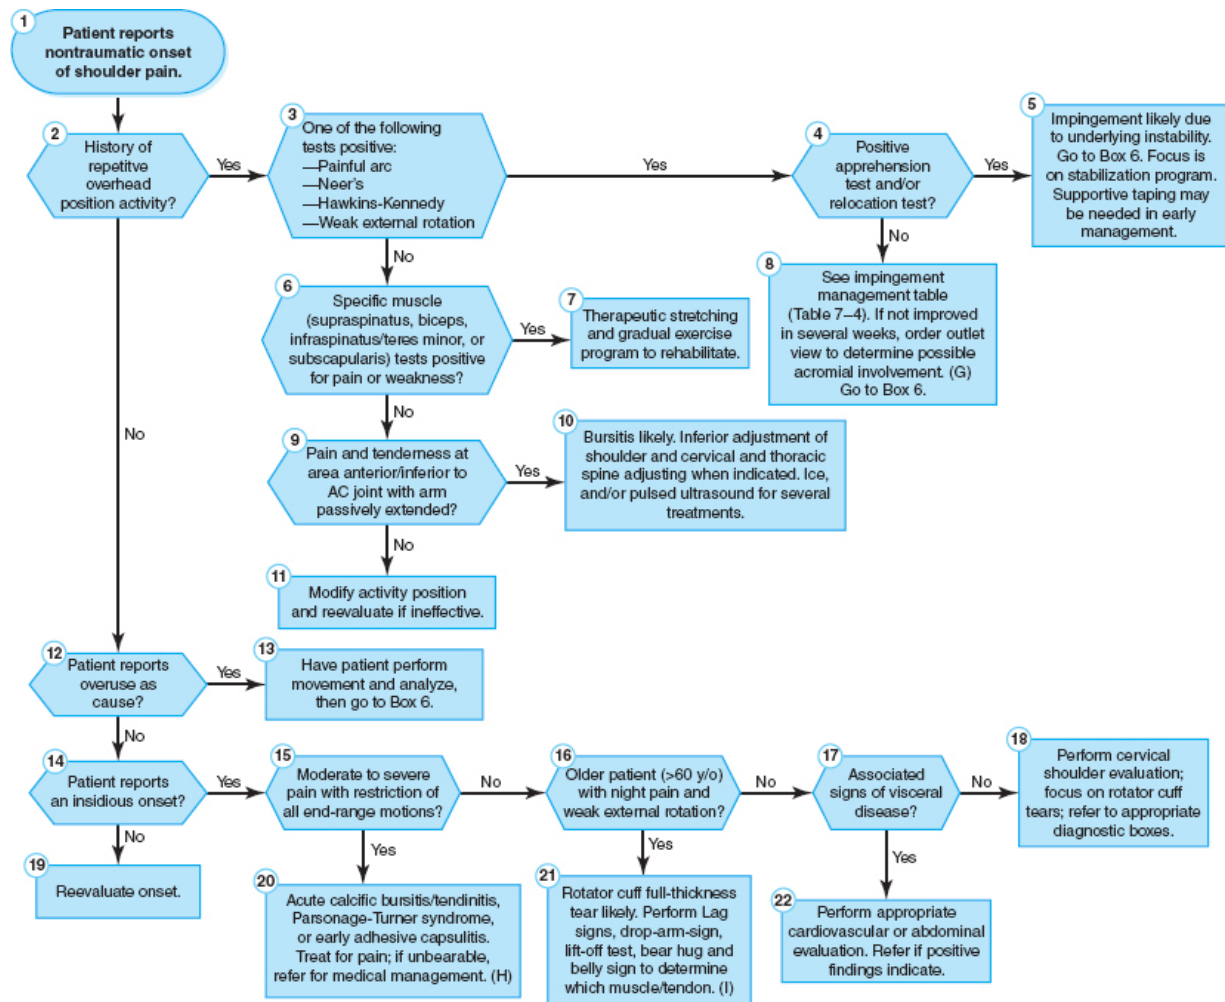

## Algorithms

Algorithms for evaluation and management of traumatic shoulder pain, nontraumatic shoulder pain, and shoulder

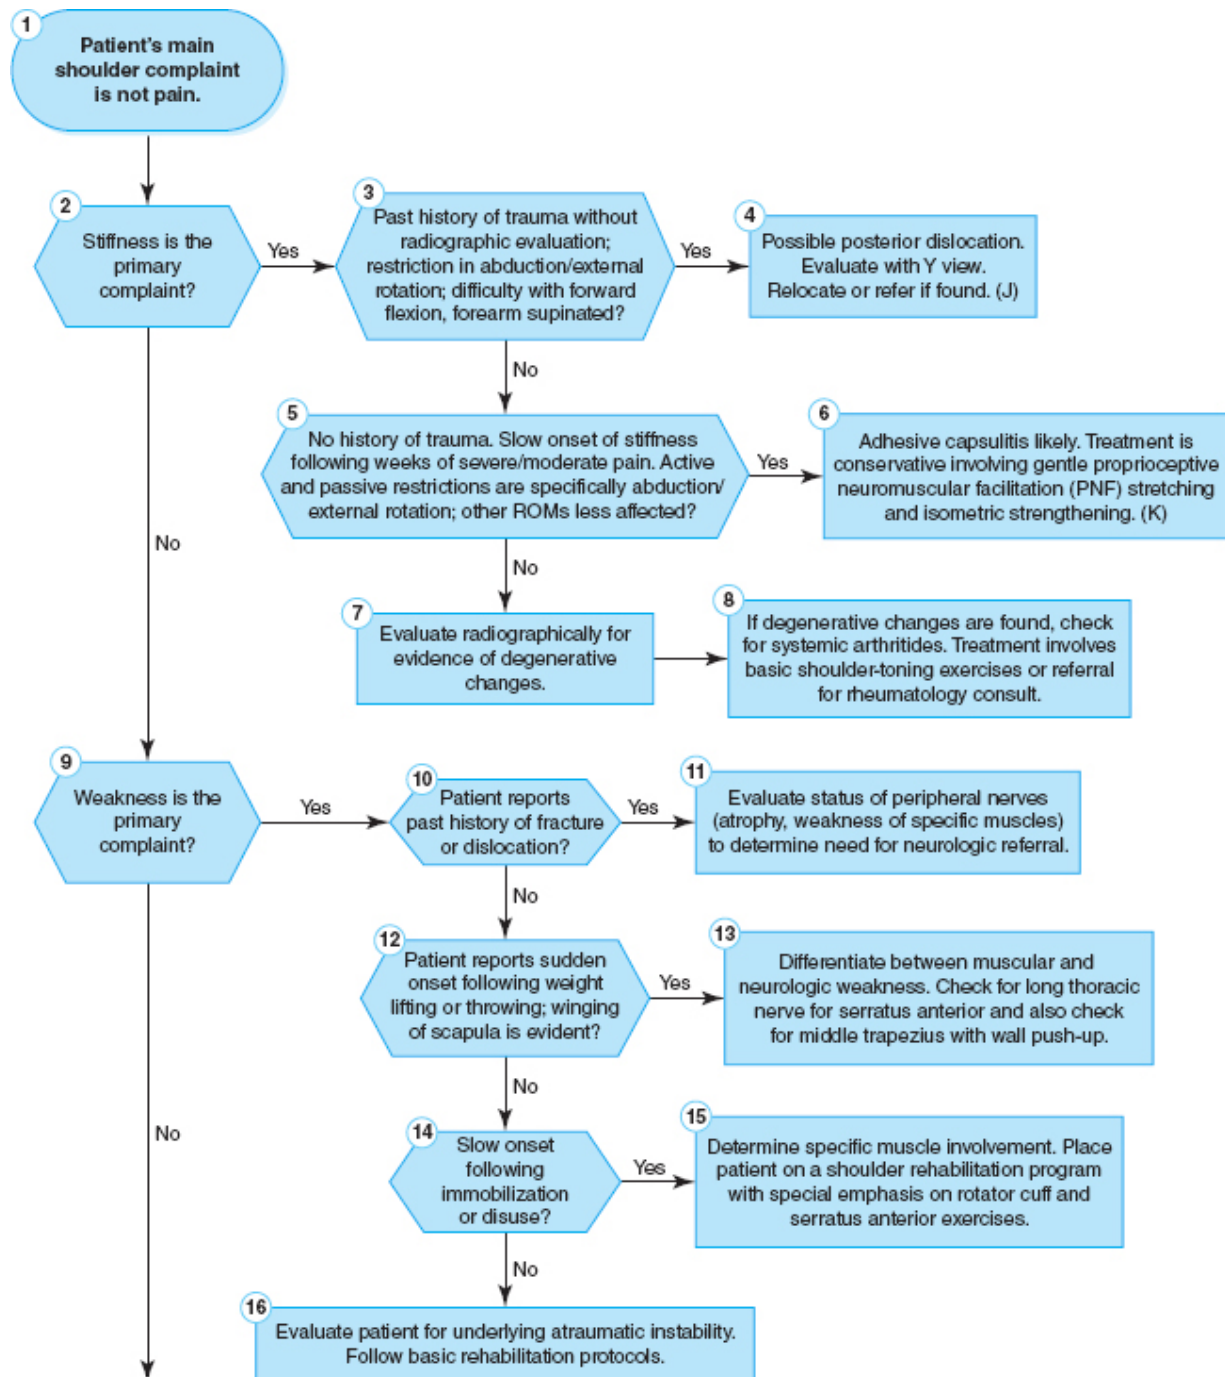

complaint other than pain are presented in **Figures 7-32 to 7-34**.

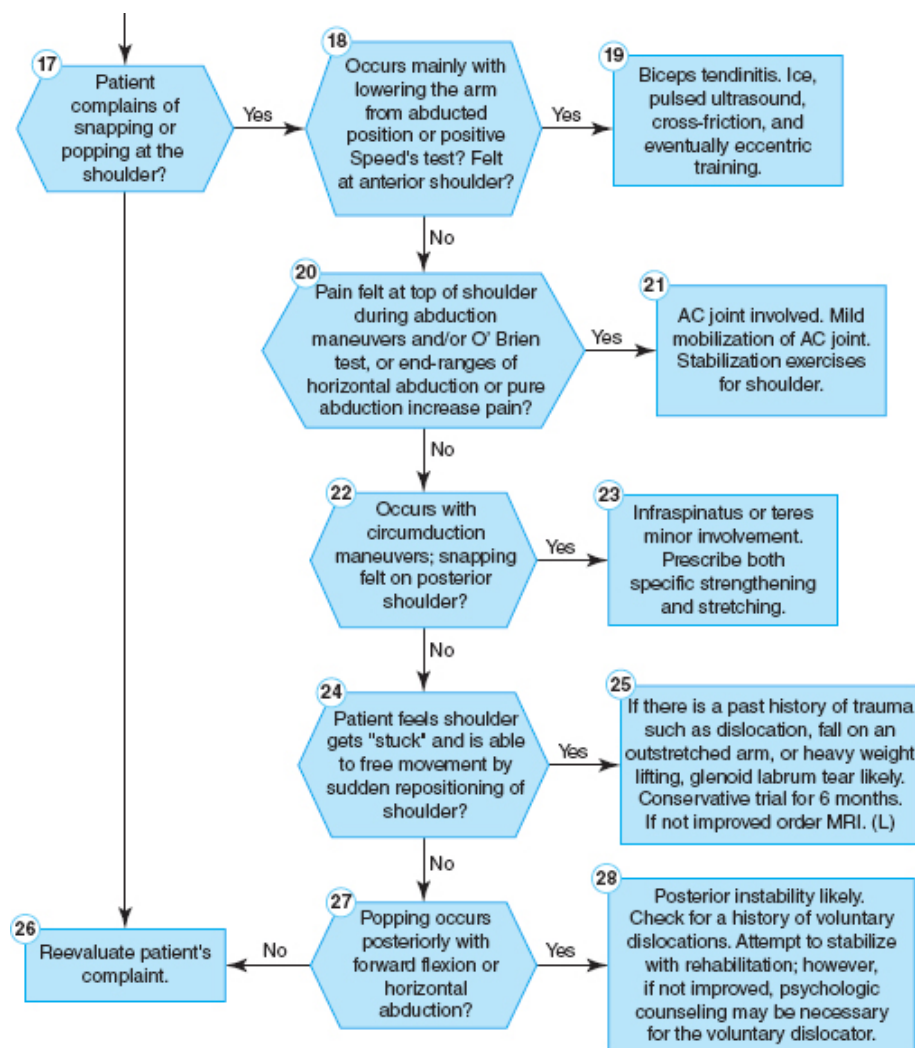

**Figure 7-32** Traumatic Shoulder Pain—Algorithm

**Figure 7-33** Nontraumatic Shoulder Pain—Algorithm

#### Annotations

- A. Anterior dislocations are usually due to a fall or a blow to the arm when it is in a position of abduction and external rotation.
- B. The Milch maneuver is an attempt to lift the arm through abduction with the arm externally rotated and at the same time maintaining superior pressure on the humeral head. Other approaches use distraction coupled with adduction and internal rotation.
- C. Dislocation is usually readily apparent without films; however, complications including Hill-Sachs lesion and Bankart lesions are visible on apical oblique films or Stryker notch films. Posterior dislocation and Hill-Sachs are visible on the Y view.
- D. If a deformity is present, take a Zanca (unilateral AC) radiograph (10°–15° degs. cephalad). Bilateral weighted views are rarely necessary because the distinction between second- and third-degree injuries does not alter management.
- E. Second- and third-degree separations are immobilized for 1–2 weeks with a Kinney-Howard sling. Progressive exercises focus on forward flexion and shrugs.
- F. A shoulder pointer is a contusion to the top of the shoulder usually involving the upper trapezius or deltoid muscle. Ice initially. Protect with doughnut padding if patient is involved in sports.
- G. The outlet view is a Y view with a 10° to 20° caudal tube tilt.
- H. Parsonage-Turner syndrome is a neurological inflammation probably due to a virus which often results in atrophy of involved muscles.
- I. The combination of an older patient with night pain and weakness in external rotation is sensitive for full-thickness rotator cuff tears. The lift-off test, bear hug, and belly press are sensitive for subscapularis tears. The drop-arm sign is more sensitive for supraspinatus or infraspinatus tears.
- J. The Y view is essentially a lateral scapular view positioning the scapula perpendicular to the bucky; central beam through the glenoid.
- K. A combination of mild PNF stretching called rhythmic stabilization and ultrasound is the primary treatment. Home stretches and pendulum exercises are also helpful.
- L. Labrum tests include the Crank, O'Brien, Anterior Slide, Jerk, Kim, and Biceps Load II tests (see text).

**Figure 7-34** Shoulder Complaint (Other Than Pain)—Algorithm

# Selected Disorders of the Shoulder

A summary of most of the shoulder disorders discussed below is presented in **Table 7-3**.

**Table 7-3** Summary of Shoulder Disorders

Condition	Signs/Symptoms	Exam Findings	Treatment
<b>Impingement syndrome</b>	Shoulder pain with overhead activities	Painful arc, Neer's, and Hawkins-Kennedy tests positive with secondary impingement, positive relocation test; radiographic assessment may include outlet view or Zanca view	Ice, rest from inciting activity, myofascial release to involved muscles; crossfriction to tendons; stretch posterior capsule; possible superior-to-inferior adjustment; exercise begins with arm slightly abducted, progressing from isometrics to isotonic with emphasis on rotator cuff
<b>Traumatic anterior instability</b>	History of shoulder dislocation (usually shoulder is overstretched into abduction/external rotation) or medical subluxation	Positive apprehension with improvement using relocation test; laxity evident on L&S testing; radiographic assessment may include standard views plus modified axillary views	Support in initial stage with bracing or taping; progressive strengthening program with initial avoidance of coupled abduction and external rotation
<b>Nontraumatic instability</b>	May have history of medical subluxation or simply overuse pain with overhead or repetitive activities	Positive for pain with the apprehension test; relieved by the relocation test; multidirectional, bilateral laxity found on L&S testing	Support in initial stage with bracing or taping; progressive strengthening program with emphasis on rotator cuff strengthening first; include scaption, flexion, and prone horizontal abduction/external rotation
<b>Adhesive capsulitis</b>	A period of pain lasting for weeks is followed by a period of gradual stiffening of the shoulder as the pain resolves	Restriction in both active and passive external rotation and abduction; an arthrogram is diagnostic in some cases but usually not necessary	Dependent on stage: pain stage requires efforts to reduce pain and inflammation; in the stiffening phase, rhythmic stabilization-based stretching and ultrasound are helpful
<b>Rotator cuff tear</b>	Sudden shoulder pain with overhead or lifting activity	Usually supraspinatus is involved—positive empty can test; tear visible with MRI, diagnostic ultrasound, or arthrography	Rest, ice, and support followed by a gradual strengthening program; with total rupture in an athletic patient, surgery is necessary.
<b>AC separation</b>	Patient fell on the shoulder or outstretched arm	Visible bump at AC joint; weighted and nonweighted views may indicate the degree of laxity and damage	Shoulder support for one to two weeks with gradual strengthening program for shoulder; focus on rotator cuff and trapezius
<b>Labrum tear</b>	Usually mechanical signs/symptoms with painful locking and “clunking” with a specific movement pattern	Various tests are available including the clunk test, Crank test, O'Brien sign, anterior slide test, and biceps load test (see text for description)	Some small tears may heal and respond to conservative management. Most require surgical debridement and repair.

## Impingement Syndrome

### Classic Presentation

The patient reports shoulder pain that is worse with overhead activities. The patient often will have a positive history for a sports or occupational requirement to work in an overhead position.

### Cause

Impingement of several structures may occur. The biceps tendon, superior labrum, supraspinatus tendon, and the subacromial bursa are all vulnerable to this anterolateral type of impingement. Structural causes include variant acromial types that are hooked or lengthened, degenerative changes on the undersurface of the acromion, and an inflammatory process in the subacromial space.<sup>137</sup> More recently, an MRI study revealed a significant number of patients with lateral, downward angulation of the acromion. In addition, medial osteophyte formation at the AC joint was found. Most of the lateral sloping acromia and medial AC joint osteophytes cannot be seen on standard radiography.<sup>138</sup> Functional considerations are primarily due to decreases in available subacromial space that occur with elevation and internal rotation, especially at 90°. Instability is often a coexisting problem, allowing excessive superior movement of the humeral head. There may also be a component of posterior capsular tightness that causes superior-anterior migration with arm abduction. Subcoracoid impingement may cause irritation of the subscapularis. Posterior impingement may be caused by a repetitive “cocking” position of the arm, irritating the infraspinatus or teres minor.

### Evaluation

The site of tenderness varies depending on the site of impingement. Subacromial impingement causes tenderness and pain at the anterior joint at the biceps tendon, supraspinatus insertion at the greater tuberosity, or under the AC joint. More posterior tenderness suggests impingement of the infraspinatus/teres minor tendons. Tenderness or pain at the coracoid process that is made worse by passive horizontal adduction may indicate subcoracoid impingement of the subscapularis. The traditional tests include demonstration of a painful arc, the Hawkins-Kennedy test, and Neer’s test.<sup>139</sup> The painful arc (Figure 7-4) is evident when a patient has an increase of pain in the mid-range of 70° to 110° of abduction with less or no pain above or below this range. The Hawkins-Kennedy test (Figure 7-12) passively places the patient’s arm in forward flexion 90° with the elbow flexed to 90° and passively rotated

internally. Neer's test ([Figure 7-11](#)) is a passive forward flexion test that is positive for pain at full end-range flexion. Another confirmatory test in patients with underlying instability is relief of pain with anterior-to-posterior support in the apprehension position, the relocation test ([Figure 7-8](#)).

## Management

The management approach is based on the severity of symptoms; however, the long-range goal is to stabilize the shoulder with a progressive rehabilitation program, stretching of the posterior capsule, and modification of sport or occupational activities ([Table 7-4](#)). If the patient is not responsive in several months, an MRI may be helpful in differential diagnosis or planning any surgical management. One study was based on the premise that there may be a delay in muscle activation with sudden movement of the shoulder that may lead to impingement.<sup>140</sup> The researchers used surface EMG and found muscle recruitment to sudden movement. The sequence was an initial activation of the middle deltoid followed by simultaneous contraction of all three heads of the trapezius. This pattern was not altered but was delayed in fatigued muscles. These findings may be used as part of a strategic prevention plan for impingement.

Researchers in another study focused on an approach to prevent impingement by affecting the position of the scapula through stretching and strengthening.<sup>141</sup> Researchers evaluated scapular position using a three-dimensional electromechanical digitizer that determined both thoracic inclination and scapular orientation and position. Twenty asymptomatic volunteers with a forward shoulder posture were given pectoral muscle stretching and also strengthening exercises for the scapular retractors and elevators and the glenohumeral abductors and external rotators. Exercises and stretching were performed three times per week for six weeks. Strength of horizontal abduction and internal and external rotation increased while anterior inclination of the thoracic spine decreased. The glenohumeral contribution to elevation increased. At 90° abduction, the scapula showed less upward rotation and less superior translation after the exercise test period.

A study evaluating the relationship between patients with impingement and posterior capsular tightness and any related effects on range of motion found that patients with impingement of the nondominant arm had posterior capsular tightness and restrictions in both internal and external rotation as compared to the control group (patients without impingement).<sup>142</sup> Patients with impingement of the dominant arm had posterior capsular tightness and limitation in internal rotation only as compared to the control group.

Borstad et al.<sup>143</sup> have demonstrated a possible relationship between a shortened pectoralis minor muscle and impingement. Shortening appears to alter scapular kinematics causing more anterior tipping and internal rotation. In a second study, Borstad et al.<sup>144</sup> evaluated three approaches to stretching

the pectoralis minor. One approach was the self-stretch in the doorway with the arm at 90° abduction and the patient rotating the trunk outward to stretch. The other doctor-assisted stretches included a supine stretch with the arm in the apprehension position and the other seated with scapular stabilization with the back hand while the front hand pushed posteriorly at the AC joint. The most effective approach was the self-stretch in the doorway.

**Table 7-4** Management of Impingement Syndrome and Tendinitis

Parameter	Acute Stage	Subacute Stage	Symptom-Free Stage
Criteria	Painful arc, +Hawkins-Kennedy and Neer's tests, pain with overhead activity; for isolated tendinitis, pain with specific muscle action	Tests are less positive for pain	Tests are no longer positive
Goals	Decrease inflammation and pain	Increase rotator cuff strength while avoiding impingement position	Train through impingement range; functionally train for occupational or sport activity
Concerns	May be caused by a mechanical irritation from os acromiale or type III acromion	Overzealous athlete or worker unable or unwilling to rehabilitate the rotator cuff	Overzealous with progressing through exercise routine or not maintaining improvement with a routine shoulder exercise program
Requirements for progression to next stage; approximate time needed	Able to perform isometrics throughout ROM without pain, pain-free passive ROM; 1 week	Able to perform three sets of 15 repetitions of primary exercises pain-free for several days in a row; 3–6 weeks	Able to perform functional exercises without pain
Manipulation/mobilization	Superior-to-inferior manipulation or mobilization may be helpful; check cervical spine and scapula for fixation	Superior-to-inferior manipulation or mobilization may be helpful; check cervical spine and scapula for fixation	Superior-to-inferior manipulation or mobilization may be helpful; check cervical spine and scapula for fixation
Modalities	Inferential at 80–150 pps/20 minutes daily with ice	Ultrasound at 1.4 wt/cm <sup>2</sup> for 5 minutes; ice after exercise	Ice after exercise
External brace, support, etc.	Usually not necessary; however, shoulder support taping may be of benefit	None	None
ROM/flexibility	Codman/pendulum exercises; begin stretching of posterior shoulder capsule	Continue posterior capsular stretching	Continue posterior capsular stretching
Open-chain exercise	Isometrics performed every 20° to 30°	Begin with midrange, short arc, fast reciprocating motions into internal and external rotation. Perform daily exercise with light weight (1–5 lb), working up to 3 sets of 15 repetitions; exercises include scaption or flexion, prone horizontal abduction, bent-over rowing, internal rotation	Perform plyometric exercises if patient is an athlete and uses upper body; plyoball tosses against a wall or mini trampoline
Closed-chain exercise	None	Wall push-ups, press-ups, push-ups with a plus	Balance ball and wobble board push-ups; stair-step machine using hands
Proprioceptive training	Passive PNF diagonal patterns into flexion and extension	Begin PNF diagonal patterns with accommodated resistance	Incorporate PNF functional patterns specific to sport or occupation
Associated biomechanical items	Scapular immobility, cervical or thoracic spine dysfunction	Scapular immobility, cervical or thoracic spine dysfunction	Incorporate lower body training to reduce stress on shoulder; include balance exercises on balance boards
Lifestyle/activity modifications	Avoid overhead activities; maintain aerobic capacity with bicycling or running	Gradually introduce minimal overhead activities; maintain aerobic capacity with bicycling or running	Perform every-other-day shoulder exercise routine

Key: PNF, proprioceptive neuromuscular facilitation.

In a prospective, randomized trial by Walther et al.,<sup>145</sup> it appears that patients with impingement syndrome managed with either conventional physiotherapy, a self-training program, or functional brace had the same significant improvement in function and pain at 12 weeks. A new approach

being used for chronic tendinosis throughout the body is a sclerosing of neovessels that develop in the involved area of the tendon. For the supraspinatus, one study's results indicate a potential use for recalcitrant patients.<sup>146</sup>

## **Traumatic Instability**

### **Classic Presentation**

The patient has a past history of shoulder dislocation. The patient currently complains of pain or weakness when the arm is placed in either an overhead position or the apprehension position of 90° flexion coupled with external rotation and horizontal abduction (horizontal extension).

### **Cause**

Dislocation of the glenohumeral joint causes significant damage to the capsule, some ligaments, often the glenoid labrum, and the humerus itself. The result is a diminished static support system that must rely on dynamic support from the surrounding musculature. A common acronym used for this type of instability is TUBS, which stands for Traumatic, Unilateral, Bankart (a Bankart lesion represents anterior-inferior labrum damage), and Surgery. This implies that this traumatically induced type of instability causes a labrum tear often requiring surgery. This is also referred to as Torn Loose instability. Anterior instability due to an anterior dislocation is the most common, accounting for 90% to 95% of cases.<sup>147</sup> Posterior instability is found in patients who chronically self-dislocate or patients who have seizures.

### **Evaluation**

Stability should be evaluated with an L&S test and the apprehension tests and its variants.<sup>34</sup> The L&S test (Figure 7-6) is a push-pull maneuver applied to the neutral shoulder in an attempt to determine in which direction instability is present. Inferior instability is suggestive of multidirectional instability. In other words, for there to be significant inferior displacement, much of the capsule must be damaged. The apprehension position (Figure 7-7) tests the patient for the reproduction of apprehension (a sense that the shoulder may go out of place) and pain. If either sensation is found, an anterior-to-posterior force is applied to the patient in the supine position as the apprehension position is acquired (the relocation test) (Figure 7-8). If the apprehension is ameliorated, instability is likely. If pain is reduced, a coexisting impingement syndrome may be causing discomfort. Glenoid labrum testing should also be

included. Several tests exist, including the Crank test, the O'Brien sign ([Figure 7-10](#)), and various shear tests in search of painful snapping or clunking felt deep in the shoulder.<sup>43</sup> Other tests include the jerk test and the Kim test, both described in the examination section of this chapter. Superior labrum anterior to posterior (SLAP) tears are further tested with specific tests challenging the origin of the long head of the biceps off of the superior labrum including Yergason's, biceps load test II, and Speed's test.

## Management

Results from a recent study suggest that patients who have a first-time dislocation are at risk for dislocation within the first six weeks.<sup>148</sup> Patients with substantial pain, a visible shoulder deformity, or restriction in movement at one-week post reduction should be reevaluated with radiographs to exclude redislocation.

A study by Itoi et al.<sup>149</sup> demonstrated a significant decrease in redislocation for first-time dislocators (anterior) if the arm is immobilized in an externally rotated (26% versus 42%) instead of the traditional internally rotated position. It was recommended for those 30 years of age or younger.

Unfortunately, shoulders with traumatic instability are less amenable to conservative management ([Table 7-5](#)). These shoulders often have underlying mechanical interference with normal movement. Until the mechanical factor is surgically removed or repaired, the patient may continue to experience symptoms. The need for surgery is based entirely on activity level and degree of incapacitation. Prior to surgical consultation, most patients should be taken through a six-month trial of conservative care with a focus on shoulder stabilization. In patients with instability, the middle and posterior deltoid, in addition to the scapular muscles, should be the focus.<sup>150</sup> The anterior head may provide significant shear force and should initially be de-emphasized.

Shoulder bracing for instability has been classified into three types.<sup>151</sup> The first uses a checkrein to keep the shoulder in a "safe-zone." The other two apply direct or indirect posterior forces to the shoulder, usually through neoprene or similar materials. However, it appears that the stabilizing effect is probably not related to restriction of shoulder external rotation and is likely proprioceptive in nature (similar to the effect of taping on stability).<sup>152</sup> The decision as to which is appropriate is dictated by cost, comfort, and if a sport is played, which one.

**Table 7-5** Management of Chronic Anterior or Multidirectional Shoulder Instability

Parameter	Initial Stage	Intermediate Stage	Advanced Stage
<b>Criteria</b>	Instability evident on L&S or other stability tests; pain or apprehension with apprehension test; relieved by relocation test	Instability testing remains unaffected; however, pain or apprehension is reduced when performing apprehension test	Full pain-free ROM present; all muscles test strong in all ROMs
<b>Goals</b>	Initiate shoulder stabilization program while avoiding positions of risk	Focus on rotator cuff and scapular stabilization exercises, protected return to sporting activity if support is worn	Functionally train the shoulder to meet the demands of a given sport or occupational activity
<b>Concerns</b>	May be an associated glenoid labrum tear that will interfere or prevent successful rehabilitation	Possible glenoid labrum tear or too early a return to activity, noncompliance of patient with exercise program requirements and restrictions	Patient compliance with continuing exercises in a preventive program
<b>Requirements for progression to next stage; approximate time needed</b>	Strength present within lower ranges of shoulder movement; scapula demonstrates stability with resisted abduction or protraction; no "mechanical" pain block in active movement patterns; 1-2 weeks	Pain-free shoulder ROM; muscles test strong without pain; able to perform three sets of 10 reps for 2-3 weeks without pain; 3-6 weeks	Pain-free performance of sport or occupational activity; 3-6 months
<b>Manipulation/mobilization</b>	Mild mobilization into restricted accessory motion; however, manipulation is contraindicated; cervical spine adjusting may be helpful	Mild mobilization into restricted accessory motion; however, manipulation is contraindicated; cervical spine adjusting may be helpful	Mild mobilization into restricted accessory motion; however, manipulation should be employed with caution; cervical spine adjusting may be helpful
<b>Modalities</b>	Ice after exercise	Ice after exercise	Ice after exercise
<b>External brace, support, etc.</b>	Shoulder support taping or bracing may be needed in the earlier stages while performing exercises	Shoulder support taping or bracing may be needed in the earlier stages while performing exercises	Exercises performed without bracing or taping; for high-level competition, it may be necessary to continue wearing a restriction brace for an extended period of time
<b>ROM/flexibility/massage</b>	Passive PNF diagonal patterns to facilitate functional movement patterns	Myofascial release technique for scapular and anterior chest muscles	As needed
<b>Open-chain exercise</b>	Isometrics in multiple arcs throughout a range of motion; then rhythmic stabilization in multiple arcs (reciprocal motion in a short arc performed as quickly as possible until pain or fatigue limits)	Core exercises include scaption or flexion, prone abduction, prone rowing, pressup, and prone flies (for midscapular muscles) performed with light weights or elastic tubing, performing 3-5 sets of 12-15 reps	Plyometric exercises using plyoballs against wall and mini trampoline (size of ball based on functional activity requirements)
<b>Closed-chain exercise</b>	None	Wall push-ups progressing to ground push-ups to push-ups with a plus	Balance on palms using balance ball stabilization approach; use balance devices to perform push-ups on; use stair-stepping machine using hands

Parameter	Initial Stage	Intermediate Stage	Advanced Stage
<b>Proprioceptive training</b>	Taping or support is primary proprioceptive stimulus plus PNF passive diagonals	Resisted PNF diagonal patterns (incorporates patterns that combine either flexion/extension with external rotation/ internal rotation, with abduction/adduction)	Accomplish to some degree by plyometrics; PNF sport-specific patterns can be emphasized; PNF exercises can be performed in various body positions that simulate the sport or occupational requirements
<b>Associated biomechanical items</b>	Address spinal posture as contributing factor, including hyperlordotic cervical and lumbar curves, and a hyperkyphotic thoracic curve creating a slumped position of the shoulder	Continue to address spinal posture with focus on reduction of thoracic kyphosis; begin strengthening lower extremity and trunk for need in reducing stress on shoulder muscles with throwing and other activities	Continue to address spinal posture with focus on reduction of thoracic kyphosis; begin strengthening lower extremity and trunk for need in reducing stress on shoulder muscles with throwing and other activities
<b>Lifestyle/activity modifications</b>	Avoid carrying objects that drag down on the arm; avoid overhead and abduction/external rotation positions	Avoid abduction and external rotation against resistance such as ball throwing or racquet hitting	Make shoulder exercises a part of every-other-day exercise routine

The standard for symptomatic TUBS patients is an open Bankart procedure (patients have torn the anterior-inferior labrum [Bankart lesion]). The procedure involves suturing of the capsulolabral complex to the anterior glenoid rim. Failure rates were originally reported at about 2% (redislocations). This study indicated that the failure rate was 11% with patient follow-up after four to nine years. (Subluxation [medical] was included in the criteria for failure.)<sup>153</sup>

In recent studies, researchers have attempted to determine the long-term effects of various surgical procedures for instability. One study<sup>154</sup> compared open to arthroscopically performed surgery and the outcome of redislocation rates, and researchers found that open surgery using suture anchors compared with arthroscopically placed bioabsorbable tacks (Suretac fixators) demonstrated a redislocation rate of 10% for the open and 15% for the arthroscopically performed procedures using a follow-up of two to five years. There appeared to be more limitation in external rotation with the open procedure than with the arthroscopic procedure.

One of the concerns with surgery is the loss of proprioception due to nerve damage. In one study<sup>155</sup> researchers evaluated the role of surgery in actually restoring proprioceptive reflex activity for patients with shoulder instability. Surgical interventions, whether arthroscopic, open, or thermal, seem to restore proprioceptive defects that existed after joint injury.

Thermal capsulorrhaphy, or thermal-assisted capsular shrinkage (TACS), is the delivery of thermal energy in the form of a laser or radiofrequency device used to shrink the capsule in individuals with capsular laxity without tearing (AMBRI patients). The primary change that occurs is conversion of collagen to a homogenous sheet of protein (hyalinization). A normal histologic appearance has been reported to take approximately 12 weeks to occur; however, in one study, patients who had failed procedures and were treated operatively had reported attenuation (thinning) of the capsule, making

surgery more difficult. Also, researchers found that histologic abnormalities can exist for up to 16 months post-capsulorrhaphy.<sup>156</sup>

Although many TACS procedures were performed without long-term information about outcome, in a recent study researchers reported the results of a 15- to 47-month follow-up.<sup>157</sup> Over time, 231 consecutive overhead athletes were followed. Of these, 87% returned to competition and 88% reported good to excellent long-term outcomes using the athletic shoulder outcome rating scale. With the recent advent of thermal-assisted approaches to tightening loose shoulder capsules, several concerns have developed. Due to reported failures, one study attempted to determine whether there were indicators of failure based on a follow-up study of 106 patients receiving TACS procedure.<sup>158</sup> Concomitant surgical procedures at the time of TACS were not associated with failure. The researchers found that TACS may have limited value for the following patients:

- Those who have had prior operations
- Those with multiple dislocations
- Those with multidirectional instability
- Those involved in contact sports

A more recent two-year, follow-up study by Hawkins et al.<sup>159</sup> evaluated the long-term effects of TACS. They concluded that the failure rates are still quite high for multidirectional and posterior instability. They recommend capsular placentation and/or rotator interval closure if used in the treatment of these cases. They also recommend lengthening the initial immobilization period. Articles by Wilk et al.<sup>160</sup> and Tyler et al.<sup>161</sup> review a theoretical approach to rehabilitation following TACS based on type of patient and procedure. For overhead athletes, they recommend not allowing excessive external rotation or elevation and no shoulder extension post-op. For those with congenital laxity, they recommend no passive ROM until after 14 days of immobilization. And for those with labrum procedures, they recommend avoidance of isolated biceps training for six to eight weeks post-op.

## **Nontraumatic Instability or Looseness**

### **Classic Presentation**

The patient is usually asymptomatic. When symptoms occur, they often are the result of a sudden traction on the arm that results in pain and weakness felt in the entire arm (subluxation); supporting the arm relieves symptoms. Another common presentation is difficulty working in overhead positions due to a sense of fatigue rather than pain.

### **Cause**

Most patients have an inherent looseness to their shoulder capsules (born loose).<sup>162</sup> This may be accentuated by sporting activities that constantly stretch the capsule, such as with throwing sports and swimming. The acronym for this type of instability is AMBRI: Atraumatic, Multidirectional, Bilateral, often responds to Rehabilitation, and does not require an Inferior capsular shift surgical stabilization procedure. Patients are asymptomatic unless the shoulder is subluxated with a distraction force or they develop impingement secondary to a loose capsule.

## Evaluation

The L&S tests ([Figure 7-6](#)) are the most practical ones. Pulling the humeral head forward or backward usually indicates a large degree of movement, sometimes enough to almost subluxate the joint. Most important, inferior traction often causes the development of a sulcus sign or depression under the AC joint. These findings are bilateral. Researchers in one study were interested in determining whether there were differences in translation between patients who had the traumatic type of instability (TUBS) versus the acquired (AMBRI).<sup>163</sup> Also, they wanted to determine any differences between symptomatic and asymptomatic shoulders. Open MRI was used with the shoulder in various positions with and without muscle activity. Results showed that those with TUBs had increased translation at 90/90 position; however, muscle activity helped to recenter the humeral head. Interestingly, those with AMBRI had increased translation of both shoulders that was not recentered with muscle activity.

Researchers evaluating swimmers versus other athletes who do not use shoulder elevation as a prominent feature of the sport (i.e., soccer) indicated that significantly more translation occurred in swimmers as compared to soccer players. However, there was no “instability” related to these findings in asymptomatic patients.<sup>164</sup> If the patient has developed secondary impingement, another finding (in addition to positive impingement tests) is pain that is produced by the apprehension test ([Figure 7-7](#)). The pain is reduced by the relocation test ([Figure 7-8](#)), in which an anterior-to-posterior force is applied to the proximal humerus as the arm is abducted and externally rotated (supine patient).

## Management

A standard strengthening program involving initial focus on the rotator cuff and serratus anterior is necessary to substitute for the laxity of the joint capsule ([Table 7-4](#)). This may be assisted by functionally taping the shoulder. Avoidance of positions that further stretch the capsule is important. Surgical stabilization is rarely necessary.

## **Adhesive Capsulitis**

### **Classic Presentation**

The presentation varies depending on the stage at which the patient presents. The patient is usually over age 40 years. In the acute phase, the patient complains of moderate to severe pain that limits all shoulder movement. In most instances, the patient cannot recall any specific event that triggered the pain. The pain interferes with sleep and in many instances causes the patient to seek prescribed pain medication. In the middle phase, the patient may present with a past history of the acute phase one to three months previously; now the pain is much less, but she or he notices that lifting the arm or turning it out is severely restricted. In the final phase, the patient may report a very slow increase in ROM, but he or she still has significant reduction.

#### **Cause**

The prevalence of adhesive capsulitis is 0.5% of the general patients while 4.3% of the diabetic patients meet the criteria for adhesive capsulitis.<sup>165</sup> The cause is unknown. The most accepted theory is that adhesion development occurs between or within the capsule of the shoulder; however, this is not always visible at surgery. Also, the patient often responds to stretching techniques that place little stretch on the capsule. Some individuals may be predisposed, such as those with diabetes, hyperthyroidism, or chronic obstructive or other lung disease, and those who have had a myocardial infarction.<sup>166</sup> It has been shown that, contrary to logic, this process is not due to immobilization. The process begins as an inflammatory process that resolves with fibrosis. The three stages are: (1) an acute inflammatory stage that causes a presentation that overlaps with other conditions, leading to (2) a stiffening stage, and months to years later (3) a thawing phase wherein some of the ROM is recovered.

### **Evaluation**

Most patients present in the stiffening phase. The classic restriction pattern is a significant and equal loss of active and passive ROM. The movements most affected are abduction and external rotation. Flexion is usually the least restricted. Muscle testing is usually strong within the available range. Loss of abduction is often substituted by shoulder shrugging or trunk leaning. Improvement of motion restriction following mild reciprocal isometric contractions (rhythmic stabilization) is confirmatory for adhesive capsulitis. Lack of improvement suggests a bony blockage possibly due to osteoarthritis or an undiagnosed posterior dislocation (if there is a history of trauma).

# Management

As noted in previous studies, Levine et al.<sup>167</sup> reiterate that conservative management of adhesive capsulitis has similar clinical outcomes to surgical management (manipulation under anesthesia). Patients treated conservatively generally showed significant improvement over a period of three to six months. Those who went on to surgery were generally younger patients and had usually attempted conservative management for about one year. Conservative management in this study included physical therapy with a large percentage of patients (37%) who received a corticosteroid injection at some time in their treatment. Supporting this observation was the study by Kivimäki et al.<sup>168</sup> Patients were randomized into a manipulation under anesthesia (MUA) group or a control group of home exercise only. After a one-year follow-up, there were no significant differences in pain or function.

Another approach to adhesive capsulitis is arthrographic distension therapy where fluid is introduced into the shoulder joint to distend the capsule and break up adhesions. Either steroids or a saline solution is typically used. In a 2008 Cochrane review,<sup>169</sup> there was fairly strong evidence that saline and steroid distension provided short-term benefits for pain, range of motion, and function; however, there was no indication that this was better than alternative treatments.

Yet another study<sup>170</sup> compared manipulation under anesthesia to distension therapy with steroid injection. The results, using standardized outcome measures such as a Constant Score, visual analog scale, and Short Form-36 (SF36), found no difference in the two groups after two years, with the researchers concluding that the higher risk of manipulation under anesthesia was a reason to preferentially use distension therapy. This was a small study and limited in strength for that reason. In a study<sup>171</sup> comparing not only pain relief but increases in external rotation, researchers found that in addition to a higher percentage of patients being painfree following distension (88%) compared to MUA (67%), a higher percentage of patients with distension therapy had an increase in external rotation compared to those with MUA. Again, the conclusions are limited by the small sample size of patients.

---

## Exhibit 7-4 Treatment of Adhesive Capsulitis

### Stage I (acute)

#### *In-office*

- Treatment in the acute stage focuses on pain relief through the use of aspirin or nonsteroid anti-inflammatory drugs and transcutaneous electrical nerve stimulation.

- Avoid aggressive mobilization or adjustive techniques.

### ***Home***

- Use passive Codman's exercises and mild isometrics (25% contraction for 5 to 8 seconds).
- Sleep on unaffected side with affected side supported by a pillow to avoid excessive internal rotation.

## **Stages II and III (subacute and chronic)**

### ***In-office***

- Continue treatment for pain.
- Use ultrasound for palliative pain relief and use prior to stretching.
- Use rhythmic stabilization and hold-relax techniques to increase ROM.
- Use passive stretching with moist heat pack and gravity assistance.

### ***Home***

- Do further stretching with self-mobilization with an emphasis on inferior glide.
- Do "giant ball" exercises, pulley exercises, and wand exercises for later stages of stretching.

Most patients in the acute phase do not respond to physical therapy attempts at pain control. During this phase, the pain is often disabling, requiring prescribed pain medication. The chiropractor is most effective in the later stages. In the stiffening phase, use of rhythmic stabilization, coupled with ultrasound, is usually effective in increasing ROM (Exhibit 7-1). This is supported by home exercises, including continuation of rhythmic stabilization, pendulum, and proper wall-walking exercises. Rhythmic stabilization involves taking the patient's arm to the available end-range of abduction/external rotation. The patient is then instructed to apply a minimal (15% to 25%) contraction into further abduction/external rotation for five or six seconds, followed by an immediate switch to the opposite pattern. This reciprocates back and forth several times. The patient relaxes, and the new range is passively acquired by the doctor. Mild mobilization at the joint may be helpful; however, forceful adjusting is likely to cause an inflammatory flare-up. Significant improvement should occur over a one- to three-month period. Failure to improve warrants referral for MUA.

## **Rotator Cuff Tear**

### **Classic Presentation**

There are two possibilities, dependent on age. For the younger patient, the patient is likely to give a history of an acute traumatic event such as lifting a heavy weight or a fall on an outstretched arm. Older patients may not recall the inciting event, complaining of insidious onset of pain felt at night. Patients usually complain of pain with overhead activities or weakness in lifting the arm.

### **Cause**

The most common tears are in the supraspinatus. There are generally two areas where tears occur—articular sided and bursal sided. Most partial tears are articular sided and may be related to poor vascularity.<sup>172</sup> Tears may be due to a sudden trauma (especially a pincer action) or more likely occur secondary to chronic degenerative changes in the tendon.

### **Evaluation**

The patient often has signs similar to those of the patient with impingement. The patient usually has difficulty raising or lowering the arm actively. The

combination of a painful arc, drop-arm sign, and weak external rotation is diagnostic of rotator cuff tear if all are positive. For the supraspinatus, weakness is found with the empty can test (Figure 7-14) or the drop-arm sign. External rotation is weak for both supraspinatus and infraspinatus tears. For the subscapularis, weakness is found with the lift-off test, the internal rotation lag sign, the belly press, and the bear hug tests. More recently, a number of “lag” signs have been evaluated (see description in the main text). Radiographically, there may be apparent superior head migration on an AP view. Further imaging can be accomplished with ultrasonography, MRI, or an arthrogram. Ultrasonography is accurate but operator-dependent, MRI is sensitive but may require fat suppression to distinguish rotator cuff tear from other changes, and an arthrogram cannot evaluate bursal-sided partial tears.<sup>173</sup>

## Management

Partial tears can be rehabilitated gradually, beginning with isometrics and gradually progressing through a strengthening program (Exhibit 7-2). A rest period from sports or occupational activities is required. Full-thickness tears are usually surgically repaired in younger individuals.

## Acute Calcific Bursitis and Tendinitis

### Classic Presentation

The patient presents with severe shoulder pain that increases with any shoulder movement, either with an insidious onset or subsequent to a fall or other major trauma.

### Cause

The prevalence of calcific tendinitis ranges from 7% to 36% of the population with a reported incidence of between 2.5% and 20%.<sup>174</sup>

The calcified tendon is visible on radiographs and was thought to represent a degenerative process. Rowe,<sup>175</sup> however, found that calcific tendinitis did not occur in patients under age 30 years or over age 60 years and that many patients with radiographic evidence of calcification were asymptomatic. For calcific tendinitis, there are intratendinous deposits of carbonated apatite. It appears that pain occurs on resorption of the calcium deposition. This is an inflammatory phase and causes pain that lasts about two weeks in the acute phase and up to three months in the chronic form of the disorder. Direct

trauma and trauma subsequent to cuff rupture are other more obvious causes.

## Evaluation

The patient exhibits a supportive posture, holding the arm against the side to avoid movement. All movement, active and passive, is painful. If possible, the bursa may be palpated by passively extending the shoulder and palpating in front of the AC joint for tenderness and swelling. There are two classifications utilized to rank calcifications based on size and clinical presentation. The Bosworth system<sup>176</sup> classifies calcium deposition as tiny (0.5 cm), medium (0.5–1.5 cm) and large (1.5 cm). The Gartner and Simons<sup>177</sup> classifications include: Type 1, pasting and not clear on radiographs; Type 2, pasting and clear on radiographs; and Type 3, without clear limits and a tendency toward spontaneous resolution. These classification systems are utilized in studies of effectiveness when utilizing ultrasound, shockwave therapy, or corticosteroid injection.

## Management

An attempt at sling support and palliative physical therapy application may be made. Evidence suggests that ultrasound helps in resorption of the calcific deposits.<sup>178</sup> In a recent study,<sup>179</sup> researchers randomized symptomatic patients with verified calcific tendinitis into one group treated with ultrasound (15-minute session with frequency of 0.89 MHz and intensity of 2.5 watts square centimeter on pulsed mode 1:4) while the other group received a sham insonation. Treatment was for six weeks, with daily treatments for the first three weeks and then three times/week for three weeks. After a nine-month follow-up period, 42% of patients had calcific deposition resolution and 23% had partial resolution if they had been treated with the pulsed ultrasound regimen. There was only 2% to 3% resolution in the sham group. There were greater decreases in pain at the end of treatment phase for the pulsed ultrasound-treated group versus the sham. However, at nine months the difference between the groups was no longer significant, suggesting that there may be a role in short-term management only.

Another approach to calcific tendinitis is the use of extracorporeal shockwave therapy. This approach is also used for lateral epicondylitis and plantar fasciitis, among other similar conditions. Researchers in one study evaluated the difference between two protocols, one using a low-energy density (1,500 impulses of 0.06 mJ/mm<sup>2</sup> compared to 1,500 impulses of 0.28 mJ/mm<sup>2</sup>), requiring the use of local anesthesia.<sup>179</sup> In the high-intensity group, 68% of patients rated the results of treatment good or excellent compared to only 52% in the low-energy group at a six-month follow-up. In a more recent publication,<sup>180</sup> in a small randomized trial, groups were also assigned to

different energy levels. One group received extracorporeal shock wave therapy (ESWT) at an energy level of  $0.20 \text{ mJ/mm}^2$ , and the other group received ESWT at an energy level of  $0.10 \text{ mJ/mm}^2$ . Both groups received 2,400 pulses once a week for four weeks. Although calcific deposits resolved in the same percentage of patients in both groups, an energy level of  $0.20 \text{ mJ/mm}^2$  appeared to be more effective than an energy level of  $0.10 \text{ mJ/mm}^2$  if matched to the outcomes of pain relief and functional improvement again supported by the previous study's findings.

---

## **Exhibit 7-5 Treatment of Acromioclavicular Joint Injury**

### **AC Separations**

#### ***Type I—Sprain (first-degree separation)***

- Use ice and analgesics for pain control.
- Rehabilitative exercises may begin quickly because the AC joint is stable.
- Protective doughnut pad should be worn during contact sport participation.

#### ***Type II—Partial subluxation (second-degree separation—torn AC ligament)***

- Use ice and analgesics.
- Immobilize with a Kinney-Howard sling with following recommendations:
  1. Two slings are used so that the athlete may shower with support.
  2. Changing slings should be done only with the elbow supported.
  3. Tightening of the sling also should be done with elbow support.
  4. The sling is worn for about two weeks, depending on extent of injury.
- Isometrics may be performed while in the sling, using the opposite hand (elevation of the arm or shoulder is avoided).
- After the sling, rehabilitate the shoulder muscles with emphasis on:
  1. deltoid with shrugs and raises (limited to below  $90^\circ$  initially)
  2. trapezius with shrugs and front rows
  3. biceps
  4. pectorals with light weights and avoiding extremes of horizontal adduction initially
- Return to sport requires protective pad sewn or taped into place.

### ***Type III—Total separation (third-degree separation—torn AC and coracoclavicular ligaments)***

- Use ice and analgesics for pain.
- Options suggested by various practitioners:
  1. Immobilization for two to four weeks in a Kinney-Howard sling with above rehabilitation (author's choice).
  2. No immobilization with use of progressive exercises and sports participation with protection in two to four weeks.
  3. Surgical repair including the following options:
    - stabilization of clavicle to coracoid with a screw
    - resection of lateral clavicle
    - transarticular AC fixation with pins
    - use of coracoacromial ligament as substitute AC ligament

## **Osteolysis of the distal clavicle**

- Athlete retires from competitive weight lifting.
- Modify weight-lifting activities, including the following:
  1. Substitute bench press with incline or decline press, or cross-cable exercises.
  2. Modify bench press using close grip instead of wide grip; reduce weight used.
  3. Eliminate dips and substitute with above pectoral exercises and triceps extensions.
- Athlete undergoes surgery, usually resection of lateral/distal clavicle.

## **Shoulder pointer and acromial apophysitis**

- Use ice and analgesics for pain.
- Avoid overhead activities for several weeks, in particular with weights.
- Protect the lesion with an acromial (doughnut) pad.

---

Reproduced with permission from T. Souza, *Sports Injuries of the Shoulder*, p. 427, © 1994, Churchill Livingstone.

Many patients with acute bursitis, however, are in severe pain requiring prescription medication in the early stages.

## **Acromioclavicular Separation**

### **Classic Presentation**

The patient presents with a traumatic onset of shoulder pain following either a fall on an outstretched arm or a fall onto the top of the shoulder.

### **Cause**

AC separations are classified into three grades (however, six types have been described by Rockwood et al.<sup>181</sup>). Grade I (first degree) indicates some tearing of the AC ligament, but no instability. Grade II (second degree) indicates rupture of the AC ligament. Grade III (third degree) involves tearing of the AC ligament and the coracoclavicular (conoid and trapezoid) ligaments. Both grades II and III are unstable.

### **Evaluation**

The mechanism of injury and the pain/tenderness and swelling or deformity at the AC joint are classic findings. Radiographs should be obtained to rule out a distal clavicular fracture or to determine degree of injury. Weighted and nonweighted bilateral views are used to demonstrate an increased coracoclavicular space. A space greater than 1.3 cm is usually consistent with a third-degree (grade III) separation. The displacement is due less to superior migration of the distal clavicle than to inferior displacement of the glenohumeral joint.<sup>182</sup> In other words, this represents a different form of shoulder instability and as a result requires stabilization and support more than replacement of the clavicle into its normal position.

### **Management**

All AC separations can be managed conservatively (see Exhibit 7-2).<sup>183</sup> As in previous studies, Calvo et al.<sup>184</sup> found that conservative management of third-degree separations result in the same successful, long-term clinical outcomes as surgical management. Those treated surgically had a higher

incidence of osteoarthritis and coracoclavicular ligament ossification. Grade III separations will leave a permanent bump at the shoulder, and for some patients may be a persistent site of minor discomfort. For those patients who require cosmetic perfection, or for those in whom conservative management has not sufficiently returned to normal function, surgery is an option. The standard treatment of AC separations includes a short period of support with a Kinney-Howard sling (shoulder support on same side as arm sling). Mild isometrics followed by isotonic exercises with emphasis on deltoid and upper trapezius exercises followed by biceps and pectoral exercises are usually sufficient to return to near full function. Padded protection should be worn in sports activities.

## **Osteolysis of the Distal Clavicle**

### **Classic Presentation**

Osteolysis may be secondary to AC trauma or excessive weight lifting. The weight lifter is usually a young man complaining of diffuse pain felt with the bench press, clean and jerk, or dip. The patient is a serious weight lifter who benches 300 pounds or more.

### **Cause**

The cause is unknown. However, direct trauma to the AC joint, as occurs with AC separations or repetitive compression from specific weight-lifting maneuvers, causes a resorption of the distal end of the clavicle.<sup>22</sup>

### **Evaluation**

Although the patient may complain of pain when abducting beyond 90°, the orthopaedic shoulder examination findings are usually unremarkable. This fact, combined with finding a discrete area of tenderness at the AC joint or distal clavicle, should raise the suspicion. Instead of a shoulder series, the radiographic view of choice is the AC spot (Zanca) view. This involves a 10° to 15° cephalad tube tilt shot, with about half of the technique used for a general shoulder radiograph. Resorption is usually evident with an increased widening of the joint space or subchondral defects.

### **Management**

Osteolysis requires a period of modification in weight-lifting activities. Modification includes switching to narrow-grip bench presses (instead of wide grip), cable cross-overs, and incline or decline presses. The dip should be avoided. If the pain persists, however, the only conservative solution is to stop lifting heavy weights for at least six months. If not effective or the patient is noncompliant, resection or acromioplasty may be somewhat effective.

## **Little Leaguer's Shoulder**

### **Classic Presentation**

A 14-year-old male baseball pitcher complains of shoulder pain that occurs mainly when throwing hard. The pain has come on gradually. He points to a tender area that is located at the proximal humerus.

### **Cause**

Rotational stresses on the growth plate of the proximal humerus result in a Salter-Harris Type 1 injury in pitchers who over-pitch or who pitch too frequently. More rarely, this may cause a Salter-Harris Type 2 fracture with a triangular metaphyseal avulsion.

### **Evaluation**

Researchers in a recent article attempted to determine whether those individuals with Little Leaguer's shoulder had similar characteristics given that there is no specific clinical test for this condition.<sup>185</sup> The problem is that, according to this study, the average child with Little Leaguer's shoulder had symptoms for over seven months before being diagnosed! The profile that developed follows:

- Male pitcher around 14 years of age (basemen were second most common, with outfielders and catchers least affected)
- Involved in youth or adolescent baseball
- Either playing continuously for 12 months on a single team or playing for six months on more than one team
- Pain of gradual onset (small percentage had sudden onset)
- Pain at the proximal humerus felt only when throwing hard
- Pain unrelated to a specific phase of throwing (in most cases)
- Pain for an average of seven months (wide range, from one week to two years in the current study)

Examination findings included:

- Swelling and loss of range of motion are uncommon findings.
- Tenderness over the proximal humerus is the most consistent finding. (Specific tenderness over the lateral aspect of the proximal humerus was found in 70% of patients in this study.)
- In this study, the only weakness detected was in external rotation.
- Various muscle testing positions increased the pain; however, the two most common were external rotation testing and the empty can test (thumbs-down abduction).

Radiographic findings included:

- The most consistent finding is widening of the proximal humeral physis.
- Additional findings include demineralization, sclerosis of the proximal humeral metaphysis, and fragmentation of the lateral aspect of the proximal humeral metaphysis.
- Bilateral views are recommended due to the variation in the “look” of epiphyses.
- AP internal and external views are recommended. (*Souza note: Always consult with a chiropractic or medical radiologist if there is any doubt.*)
- It may take several months for the widening of the proximal humeral physis to “heal” radiographically.

## Management

Although there is no agreed-upon management recommendation, it is clear that rest is essential, although how long is debatable. In the current study, an average of three months was used, with three caveats:

1. The radiographic “healing” may take longer than three months; however, this should not prevent the initial rehabilitation phase of return to easy throwing.
2. A gradual return to throwing is needed, with pain as the limiting factor.
3. Recovery time varies, and in some cases it may take as long as 12 months (until the next season) before the pitcher can return to throwing full force.

In the current study, resistance exercises often caused pain and therefore were not used as a primary approach to the return-to-play rehabilitation prescription. An interval training approach has been developed by Axe et al.<sup>186</sup> These recommendations are based on age and pitch speed. Although there are Little League rules regarding how often a pitcher can pitch, what often is not taken into consideration are practice sessions and that a player may play for more than one team. Also, adherence to the rules is variable. A good resource for coaches and parents is an article (written for parents) by Andrews and Feisig<sup>187</sup> about how many pitches should be allowed. Complications of Little Leaguer’s shoulder include the rare avascular necrosis, loose bodies, and early closure of the epiphysis.

---

# The Evidence Shoulder

## Translation Into Practice Summary (TIPS)

The literature on evaluation of the shoulder is extensive. It provides some strong direction as to what is and is not helpful in the diagnosis of specific conditions; however, overlap of terms and conditions makes a specific diagnosis sometimes difficult. Distinction between neck and shoulder pain versus shoulder pain alone is an important discriminator prior to testing the patient. Many of the diagnostic tests in the literature have been designed and tested in orthopaedic or sports centers and may not reflect the patient population of a practice environment that is not specialized. There is agreement in the literature that the diagnostic evaluation is very good at ruling-out serious conditions.

## The Literature-Based Clinical Core

- Age gives a helpful starting point in determining the risk of specific disorders.
- For labrum tears the history is neither sensitive nor specific except for a minimally helpful support when a patient reports popping, clicking, or catching.
- Range of motion is highly reliable but of unknown diagnostic value; however, it may provide some indications of functional capacity.
- Manual muscle testing is reliable with certain weakness thresholds indicative of specific pathologies:
  - a. Weak abduction and/or external rotation—subacromial impingement and/or full thickness rotator cuff tears
  - b. Weak internal rotation—subscapularis tears

- Evaluation of muscle or posterior capsular tightness is moderately reliable but is not helpful in distinguishing between symptomatic and asymptomatic patients, and is therefore of unknown value.
- For instability:
  - a.** The apprehension test is most valuable for identifying instability when “apprehension” is the positive finding.
  - b.** Labrum tear tests are highly variable; however, there is some evidence that the Kim and the jerk test may be helpful in ruling-in a labrum tear, with the biceps load test II useful in identifying SLAP lesions. None of the tests are good at ruling out a labrum tear.
  - c.** The combination of the Anterior Apprehension Test and Jobe Relocation Test may be of value in identifying but not ruling-out labrum tears.
  - d.** For ruling-in and ruling-out labrum tears, the combination of the crank, apprehension, relocation, load-and-shift, and inferior sulcus sign may be of value.
  - e.** For ruling-in or ruling-out SLAP lesions, combining two highly sensitive tests (compression rotation, anterior apprehension, and O’Brien tests) with one specific test (Yergason’s, biceps I & II, and Speed’s tests) may be helpful, whereas individually the tests are of little value.
- For subacromial impingement:
  - a.** The Hawkins-Kennedy and Neer tests together may be helpful in ruling-in or ruling-out impingement.
  - b.** The painful arc may add useful support for a diagnosis of impingement but is not specific.
  - c.** The combination of a painful arc, Hawkins-Kennedy, and weak external rotation has a good post-test probability of detecting impingement.
- For rotator cuff tendinitis:

- a.** The Hawkins' and Neer's tests alone may provide some value in ruling-in a rotator cuff tendinitis but they are specific to a particular tendon and may overlap with subacromial impingement test findings.
- b.** The combination of a positive response for both the Hawkins' and Neer's tests is more valuable than each test alone for identifying rotator cuff tendinitis.
- For rotator cuff tears:
  - a.** The combination of the history of a patient age 65 years or older suffering from night pain with weak external rotation is helpful in ruling-in rotator cuff tear if all are positive; if none are positive, good at ruling-out rotator cuff tear.
  - b.** The combination of a painful arc, weakness in external rotation, and a positive drop-arm sign together are good at ruling-in a rotator cuff tear though not any specific tendon. Ruling-out is strongest with the absence of positives on all the tests.
  - c.** Nonspecific tests for ruling-in but not ruling out rotator cuff tears are the belly press, bear hug, and Napoleon tests. The hornblower sign may be a good ruling-in and ruling-out test.
  - d.** Specific tests may identify some specific muscles if there is a full-thickness tear:
    - i.** Subscapularis—the lift-off test, internal rotation lag-sign are good for ruling-in a full-thickness tear.
    - ii.** Infraspinatus—resisted external rotation weakness is reasonably good at ruling in a full-thickness tear. The drop-arm test is a good rule-in and rule-out test for full-thickness tears.
    - iii.** Supraspinatus – the drop-arm test is a good rule-in and rule-out test for full thickness tears.
- For the AC joint:

- a. Findings of AC tenderness or positives for AC compression, the O'Brien sign, Paxinos sign, or palpation of the AC joint are not helpful in ruling-in or ruling-out AC disorders.
- b. There may be some value for the AC resisted extension test in ruling-in or ruling-out AC disorders.

### **The Expert-Opinion-Based Clinical Core**

- The observation of deformity with a history of trauma is useful in determining the need for radiographs.
- The limitation of forward flexion of the shoulder with the arm supinated is a good indicator of posterior dislocation.
- The limitation of abduction/external rotation and/or internal rotation that is the same with both active and passive ROM testing is a strong indicator for middle-phase adhesive capsulitis.

# APPENDIX 7-2

## Shoulder Diagnosis Table

Shoulder Diagnosis Table					
Diagnosis	Comments	History Findings	Positive Examination Findings	Radiography/Special Studies	Treatment Options
Subluxation or Fixation of: Glenohumeral Joint Acromioclavicular Joint Sternoclavicular Joint Scapulothoracic Joint (functional)	<ul style="list-style-type: none"> <li>Should be used when chiropractic manipulation is used as Tx for any shoulder problem/Dx</li> <li>Can be primary Dx if patient is asymptomatic or mildly symptomatic (e.g., mild stiffness or pain level &gt;2/10)</li> <li>Must indicate chiropractic exam findings to support Dx</li> </ul>	<i>Nonspecific</i>	<i>Palpation</i> —Local tenderness or other signs of subluxation <i>Ortho</i> —None <i>Neuro</i> —None <i>Active ROM</i> —Variable restriction <i>Passive ROM</i> —End-range restriction <i>Motion palpation</i> —Specific articular restriction or symptoms produced on end-range	<ul style="list-style-type: none"> <li>Radiography not required for the diagnosis of subluxation</li> <li>Radiographic biomechanical analysis may assist in treatment decisions</li> </ul>	<ul style="list-style-type: none"> <li>Chiropractic adjustive technique</li> <li>Decisions regarding specifically which technique(s) is/are applied and modifications to the given approach will be directed by the primary Dx and patient's ability to tolerate pre-adjustment stresses</li> </ul>
Infraspinatus or Teres Minor sprain/strain Subscapularis sprain/strain Supraspinatus sprain/strain Biceps Sprain/Strain Note: Sprain/strain is not synonymous with spasm or hypertonicity	<ul style="list-style-type: none"> <li>Requires an inciting event of trauma or overuse.</li> </ul>	<i>Mechanism</i> —Overstretch or overcontraction Hx as acute event <i>Worse with specific ROM</i> —Contraction of muscle or stretch of muscle or joint	<i>Ortho</i> —Specific tests for each muscle, including tenderness at muscle/tendon: <ul style="list-style-type: none"> <li>Supraspinatus—empty can or lag sign</li> <li>Subscapularis—lift-off test or lag sign</li> <li>Infraspinatus/teres minor—lag sign</li> </ul> <i>Biceps</i> —Speed's <i>Neuro</i> —None <i>Active ROM</i> —Pain on active ROM that contracts involved muscles <i>Passive ROM</i> —Pain on end-range stretch of involved muscle or ligament	<ul style="list-style-type: none"> <li>Radiography not required for diagnosis</li> <li>With significant trauma or for med/legal purposes, radiographs may be required</li> <li>If calcific tendinitis (726.11) is suspected, radiographs may be indicated</li> <li>If associated with impingement, an outlet view is suggested</li> </ul>	<ul style="list-style-type: none"> <li>Myofascial therapy</li> <li>Limited orthotic support (taping or brace)</li> <li>Ergonomic advice</li> <li>Strengthening and preventive exercises</li> </ul>

Adhesive Capsulitis	In early stages, adhesive capsulitis appears as an acute process indistinguishable from other processes such as an acute bursitis or tendinitis	<i>Onset</i> —Acute onset of pain that may or may not be traumatic. Stiffness is progressive; pain is not major feature in later stages <i>ROM comments</i> —Abduction and external rotation decreased first followed by internal rotation	<i>Ortho</i> —No specific tests <i>Neuro</i> —None <i>Active &amp; Passive ROM</i> —Equal restriction in both passive and active ROM, specifically in abduction and external rotation <i>Motion palpation</i> —Possible restriction globally	<ul style="list-style-type: none"> <li>• Radiography not used for Dx; however, may be used in ruling out other conditions such as calcific tendinitis in acute stages and OA in later stages</li> <li>• Arthrogram most sensitive test for adhesive capsulitis</li> </ul>	<ul style="list-style-type: none"> <li>• Myofascial therapy</li> <li>• Physiotherapy such as ultrasound</li> <li>• Daily exercises and stretches based on rhythmic stabilization; also wall-walking and pendulum exercises</li> <li>• Adjusting contraindicated in acute stage; mobilization possible</li> </ul>
Subdeltoid Bursitis	<ul style="list-style-type: none"> <li>• Subdeltoid (same as subacromial) bursitis is often found associated with impingement syndrome or may be found as an isolated condition</li> <li>• Calcific bursitis is particularly acute and painful, limiting all ROM and difficult to control pain</li> </ul>	<i>Mechanism</i> —Often no Hx of trauma, except with chronic bursitis where chronic repetitive micro-trauma may occur <i>Worse with specific ROM</i> —All ROM are often affected with acute bursitis, especially end-range forward flexion	<i>Palpation</i> —Tenderness found anterior to AC joint on passive extension of shoulder <i>Ortho</i> —None; most movement is painful, precluding most ortho testing; there may be some positives on impingement testing in subacute cases <i>Active ROM</i> —Most movements are painful, in particular forward flexion <i>Passive ROM</i> —End-range forward flexion and abduction are painful	<ul style="list-style-type: none"> <li>• Radiography not usually necessary initially except to rule out fracture/dislocation with acute trauma or when calcific bursitis is suspected</li> </ul>	<ul style="list-style-type: none"> <li>• Limited orthotic support</li> <li>• Physiotherapy for pain and swelling control</li> <li>• Herbal recommendations for pain and swelling</li> <li>• If pain is intolerable, referral for medical prescription for pain meds</li> <li>• Mobilization possible</li> </ul>
Impingement Syndrome	<ul style="list-style-type: none"> <li>• Impingement may be primarily mechanical (i.e., subacromial spurs) or primarily functional (e.g., related to instability)</li> </ul>	<i>Mechanism</i> —Variable; however, most commonly overhead activities over time produce impingement <i>Limited activities</i> —Overhead activities most restricted	<i>Ortho</i> —Neer's, Hawkins-Kennedy, and painful arc; more specific tests may then be used for specific structures <i>Neuro</i> —None	<ul style="list-style-type: none"> <li>• Radiography may be used, including an outlet view (for subacromial spurs or anomalies) and a Zanca view for the AC joint</li> </ul>	<ul style="list-style-type: none"> <li>• Myofascial therapy</li> <li>• Limited orthotic support</li> <li>• Ergonomic advice for sport or occupation</li> <li>• Preventive and strengthening exercises and stretches</li> </ul>
Diagnosis	Comments	History Findings	Positive Examination Findings	Radiography/Special Studies	Treatment Options
AC Separation (indicate degree)	<ul style="list-style-type: none"> <li>• AC separations are another form of instability (especially with 2nd and 3rd degrees)</li> <li>• Always consider associated distal clavicular fracture in acute cases and osteolysis in chronic cases (when pain is still present)</li> </ul>	<i>Mechanism</i> —Direct fall onto AC or fall on outstretched arm/hand are most common causes	<i>Observation/palpation</i> —With 2nd and 3rd degree there is an obvious step-deformity; palpation reveals localized tenderness and swelling <i>Ortho</i> —Compression or distraction at AC are painful (used for 1st-degree tears only)	<ul style="list-style-type: none"> <li>• Radiography must include weighted and nonweighted bilateral views of the AC joints; degree based on coracoclavicular distance</li> <li>• In chronic pain cases, consider a Zanca view for possible osteolysis</li> </ul>	<ul style="list-style-type: none"> <li>• Limited orthotic support using principle of Kenney-Howard sling; time frame based on degree of injury</li> <li>• Use isometrics while patient is in sling; progress to isotonic when pain permits</li> <li>• Consider referral for surgical stabilization when patient concerned about cosmetic appearance</li> </ul>
Anterior Dislocation Posterior Dislocation	<ul style="list-style-type: none"> <li>• Anterior, by far, is the most common</li> <li>• Posterior dislocations are often undiagnosed for at least one month following occurrence</li> </ul>	<i>Mechanism</i> —Arm pulled back into abduction/external rotation (anterior dislocation) or direct anterior blow to shoulder or fall on outstretched arm (posterior dislocation)	<i>Observation</i> —Arm locked in external rotation (anterior); prominent coracoid, flat anterior shoulder (posterior) <i>Neuro</i> —Check motor/sensory function distally <i>Active ROM</i> —Patient unable to fully supinate and raise the arm with posterior dislocation	<ul style="list-style-type: none"> <li>• Radiography required to determine any associated fractures; views vary based on presentation, although specialized views such as the Stryker view are valuable</li> <li>• Scapular or Y view for posterior dislocation</li> </ul>	<ul style="list-style-type: none"> <li>• Limited orthotic support in a sling for approximately 2–3 weeks followed by tape/support for several weeks</li> <li>• Avoid abduction/external rotation</li> <li>• Preventive and strengthening exercises</li> </ul>
Glenoid Labrum Tear	<ul style="list-style-type: none"> <li>• Labrum tears may be obviously traumatic (usually anterior/inferior) or less obvious (SLAP lesions; anterior/superior)</li> <li>• Types of tears are classified similarly to meniscus tears</li> </ul>	<i>Mechanism</i> —May be associated with anterior dislocation (anterior/inferior) or sudden contraction of biceps or fall on forward flexed arm (SLAP lesion)	<i>Ortho</i> —Instability testing may be positive in addition to specific testing including: Crank test, O'Brien sign, slide test, or pronation provocative test <i>Active ROM</i> —May have a painful "sticking" in movement relieved by repositioning and a "clunk"	<ul style="list-style-type: none"> <li>• Radiography may assist if there is bony involvement of the glenoid; these are best seen on modified axillary views</li> <li>• MRI is less sensitive than CT arthrograms</li> </ul>	<ul style="list-style-type: none"> <li>• Conservative trial of strengthening and modified work or sports activities</li> <li>• Patients unresponsive to conservative trial should be referred for surgical debridement and stabilization if necessary</li> </ul>

Myofascitis	<ul style="list-style-type: none"> <li>Also may be used if a strain is not evident from the history; however there are indicators of muscle tenderness, stiffness, or pain</li> </ul>	<p><i>Onset</i>—Nonspecific regarding onset</p> <p><i>Symptoms</i>—Patient usually complains of pain, aching, and/or tenderness in specific muscle or tendon areas that may radiate pain in nondermatomal pattern</p>	Trigger points are evident as localized tenderness in a muscle that corresponds to traditional (Travell/Simons) trigger point charts; these points may be local or refer pain when compressed	<ul style="list-style-type: none"> <li>Not required or recommended</li> </ul>	<ul style="list-style-type: none"> <li>Myofascial approaches, such as myofascial stripping, trigger point massage, or spray and stretch approaches, are the standard</li> <li>Home stretching and modification of activity suggestions</li> </ul>
Laxity Hypermobility	<ul style="list-style-type: none"> <li>Requires physical examination confirmation.</li> </ul>	History of a single event, traumatic injury to the joint is not found; however, either overuse (micro-trauma) or generalized inherent looseness is/are evident	Capsular or ligament testing reveals "looseness" that falls within the physiologic range of normal	<ul style="list-style-type: none"> <li>Not usually recommended unless when differentiating pathological laxity from congenital or overuse acquisition</li> </ul>	<ul style="list-style-type: none"> <li>Strengthening program</li> <li>Bracing or functional taping during rehabilitation or during strenuous activities</li> </ul>

## **CHAPTER 8**

# **Elbow Complaints**

## **Context**

Although anatomically analogous to the knee, the elbow is injured far less often. In large part, this is due to the non-weight-bearing function of the elbow. As the link between the shoulder and the wrist/hand, the elbow is functionally challenged with repetitive activities. These overuse mechanisms account for the majority of complaints. Overstrain is common at the origin of the wrist extensors (lateral elbow) and the wrist flexors (medial elbow). With athletes, valgus stress predominates, in particular in throwing sports and in activities requiring the use of an arm extension such as a bat, racquet, or club. These devices increase the medial stress across the elbow by increasing the length of the lever arm. As with the rest of the upper extremity, the elbow becomes weight-bearing when an axial force is applied acutely during a fall, or chronically with gymnastic maneuvers and with some chiropractors due to adjusting maneuvers.

## **General Strategy**

## **History**

- Clarify the type of complaint.
  - 1.** Is the complaint one of pain, stiffness, looseness, crepitus, locking, or a combination of complaints?
  - 2.** Localize the complaint to anterior, posterior, medial, or lateral.
- Clarify the mechanism if traumatic.
  - 1.** Did the patient fall on an outstretched hand?  
Consider fracture or dislocation (in children, consider a supracondylar fracture).
  - 2.** Did the patient fall on the tip of the elbow (olecranon)? Consider olecranon fracture.
  - 3.** Did the patient have hyperextension of elbow?  
Consider dislocation and supracondylar fracture.
  - 4.** Did the patient have sudden stretch to the inside of the elbow? Consider medial collateral ligament sprain or lateral compressive injury to the radial head or capitellum.
  - 5.** Did the patient have sudden traction to the elbow?  
Radial head subluxation is likely.
- Determine whether the mechanism is one of overuse.
  - 1.** In what position does the patient work?
  - 2.** Does the patient perform a repetitive movement at work or with sports involving pronation and supination? Consider muscle strain, trigger points, or peripheral nerve entrapment.
  - 3.** Does the patient perform a repetitive movement at work or with sports involving cocking or medial stretch to the elbow? Consider medial collateral ligament sprain, flexor muscle strain, or ulnar nerve stretch irritation.
- Determine whether the patient has a current or past history/diagnosis of his or her elbow complaint or other related disorders.
  - 1.** Are there associated neck or shoulder complaints or diagnoses?

2. Does the patient have gout, rheumatoid arthritis, chronic renal pathology, or psoriasis?

## Evaluation

- With trauma, palpate for points of tenderness and obtain a radiograph for the possibility of fracture/dislocation.
- Challenge the ligaments of the elbow with varus and valgus stress.
- When nontraumatic, challenge the musculotendinous attachments with stretch, contraction, and a combination of contraction in a stretched position.
- When trauma or overuse is not present, evaluate the patient's elbow for swelling and deformity (olecranon bursitis, gouty tophi, osteoarthritis).

## Management

- Refer fracture/dislocation for orthopaedic management.
- Refer cases of infection, unresolving bursitis, and gout.
- Manage soft tissue disorders and articular disorders with conservative care.

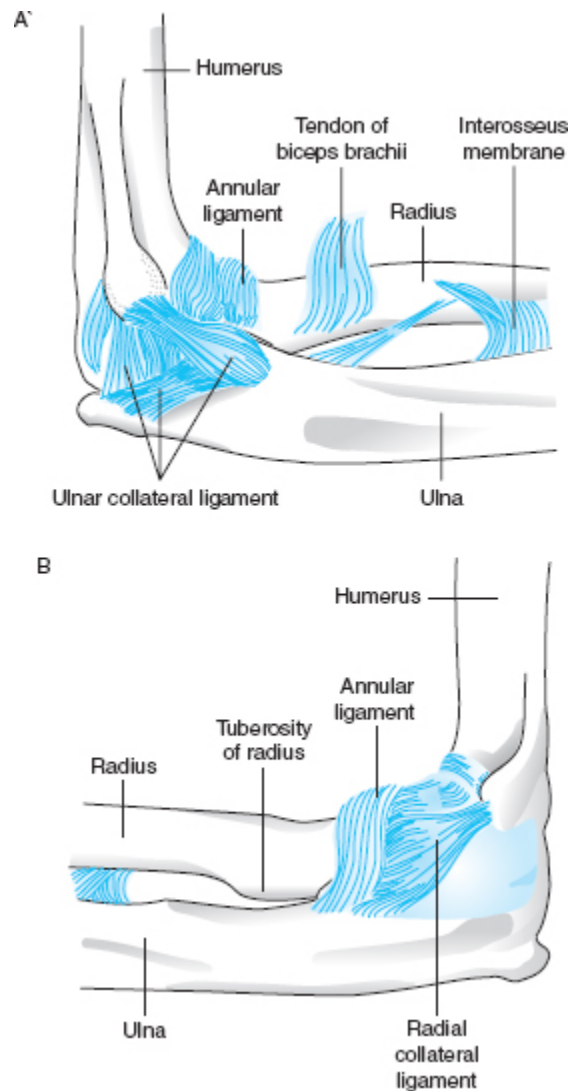

## Relevant Anatomy and Biomechanics

The elbow joint performs two movement patterns: (1) extension/flexion, and (2) pronation/supination of the forearm. The “hinge” function of extension/flexion occurs primarily at the ulnotrochlear joint, the articulation between the distal humerus and proximal ulna and the olecranon

process of the ulna and the distal fossa of the humerus. Most daily activities require elbow participation in a range of motion (ROM) between 30° and 130°. <sup>1</sup> Functionally, flexion is accomplished by the biceps, brachialis, and brachioradialis. Extension is primarily due to triceps contraction. As one might guess, the larger muscular contribution to flexion makes it the stronger movement. Extension is approximately 70% as strong as flexion. <sup>1</sup> Supination and pronation occur at the proximal radioulnar joint and the radiocapitellar joint, the articulation between the radial head and the capitellum of the distal humerus. Functionally, supination is accomplished through contraction of the biceps brachii and the supinator muscles. Supination is more effective with the elbow flexed because of the prestretch of the supinator muscle and mechanical advantage of the biceps. Pronation is accomplished by the pronator teres and less effectively by the pronator quadratus. Pronation is more effective with the elbow extended, placing a prestretch on the pronator teres. Supination is slightly stronger (15%) than pronation due to the contribution of the biceps. The biceps and triceps cross both the shoulder and elbow joints. Flexion of the shoulder decreases effectiveness of the biceps with elbow flexion and supination; extension decreases effectiveness of the triceps with extension.

As with all joints, stability is provided by a contribution of position-dependent ligamentous and capsular tension, bony congruity, and static/dynamic muscle/tendon support. Similar to the knee, a bony lock occurs in full extension, providing some protection from varus and valgus forces. In the elbow, the fit of the olecranon process of the ulna into the olecranon fossa of the distal humerus provides some stability with extension. This tongue-and-groove lock is aided by tension in the anterior capsule and collateral ligaments. The main restraint to valgus strain in extension is from the anterior oblique portion of the medial collateral

ligament (**Figure 8-1**). With the elbow flexed to between 10° and 60°, the medial collateral ligament becomes lax. It is in this midrange position that most medial-sided injuries occur. When the elbow is flexed to 90° and beyond, the posterior aspect of the medial (ulnar) collateral ligament becomes tight. Medial stability is statically and dynamically provided by the flexor/pronator muscle group, which takes its origin off of the medial epicondyle of the humerus. Lin et al.<sup>2</sup> evaluated the role that muscles and tendons play in stabilizing the elbow. They found that the flexor carpi ulnaris (FCU), flexor carpi radialis (FCR), and flexor digitorum superficialis (FDS) act as dynamic stabilizers for valgus stress with the static protection provided by the FCU. The extensor carpi ulnaris and extensor digitorum communis increased medial ulnar collateral ligament strain and valgus at both 45° and 90°. Lateral stability is provided by a very weak lateral collateral ligament, and more significantly from the anconeus muscle.<sup>3</sup> Lateral stability is assisted statically and dynamically by the extensor wad of muscles that take their origin off the lateral epicondyle.

**Figure 8-1** The elbow joint: (A) medial view; (B) lateral view.

Restriction to overextension is provided by stretch of the anterior capsule and biceps tendon in addition to the bony block of the olecranon in the olecranon fossa. Flexion is restricted by muscle contact, tension in the posterior capsule and the triceps tendon, and radial head and humerus contact. Pronation is restricted by the crossing of the radius and the ulna. Supination is limited by tension in the pronator muscle group.

## Evaluation

# History

First, determine the type of complaint or complaints the patient has: pain, stiffness, locking, etc. Determine if there is a history of trauma (recent or distant), whether there is an overuse component, or whether the complaint had an insidious onset. Attempt to localize the complaint to the anterior, posterior, lateral, or medial aspect of the elbow. The answers to these questions should sufficiently narrow the possibilities to allow for a more focused examination (**Table 8-1**).

**Table 8-1** History Questions for Elbow and Forearm Complaints

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Was there an injury?	Fracture, dislocation, sprain (capsular/ligamentous)	Hyperextended (overextended)?  Fell on hand with elbow extended? Fell on tip of elbow? Overstretched inside of elbow?  Sudden traction on arm?	Anterior capsule sprain Elbow dislocation Supracondylar fracture in children Radial head fracture  Olecranon fracture or bursitis Medial collateral ligament sprain or rupture Damage to ulnar nerve Medial epicondyle avulsion Capitellum fracture Radial head subluxation
Was there any repetitive activity?	Overuse leading to tendinitis, trigger points (TrPs), osseous reactive changes	Throwing?  Racquet sport?   Pain on outside of elbow with typing, hammering, using a screwdriver?	Compression injuries on lateral side; stretch on medial Lateral pain—lateral epicondylitis or supinator TrP Medial pain—medial epicondylitis or pronator TrP Lateral epicondylitis or supinator TrP
Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Do you have weakness at the elbow?	Biceps rupture or strain, cervical disc, neural compression/entrapment	Associated with pain? Any associated neck pain and/or radiation?	Possibly due to pain inhibition Cervical disc or subluxation
Do you have stiffness or restricted movement?	Osteoarthritis (OA) or other arthritide, flexor contracture, osteophytes, effusion	History of excessive throwing? Early-morning stiffness? Swelling with blocked extension?	Flexor contracture, osteophytes, loose bodies OA Effusion or bursitis
Do you have superficial swelling?	Bursitis or tophi (gout)	Back of elbow? Also big toe swelling?	Olecranon bursitis Gout

## Pain Localization

The following are possible causes of pain based on location (**Figure 8-2**, A and B, and **Table 8-2**):

- anterior
  1. traumatic—anterior capsular sprain, distal biceps tendon strain, fracture, or dislocation

- 2.** nontraumatic—capsular sprain, biceps tendinitis, and pronator teres strain
- posterior
  - 1.** traumatic—olecranon fracture, bursitis, triceps strain
  - 2.** nontraumatic—olecranon bursitis, triceps tendinitis, degenerative joint disease
- medial
  - 1.** traumatic—ulnar collateral ligament sprain, ulnar nerve traction, epicondyle avulsion, flexor/pronator strain
  - 2.** nontraumatic—minor ulnar collateral ligament sprain, chronic ulnar nerve irritation, flexor/pronator strain (medial epicondylitis)
- lateral
  - 1.** traumatic—radial head fracture, radial head subluxation, osteochondritis dissecans of the capitellum
  - 2.** nontraumatic—lateral epicondylitis, osteocartilaginous fragments from the radial head or capitellum

## **Traumatic and Overuse Elbow Pain**

As with all traumatic onsets, a search for dislocation or fracture and the possible complications associated with each is the first order of business. Dislocation and fracture are often the consequence of hyperextension of the elbow. In particular in children, the possibility of a supracondylar fracture should always be considered with a history of a hyperextension injury due to a fall on an outstretched hand or a direct blow just above the antecubital fossa.<sup>4</sup> These fractures account for two thirds of children's elbow fractures; one third of adult elbow fractures are distal

humeral.<sup>5</sup> Unfortunately, these types of fractures resemble dislocations, but they are often more serious. Dislocations at the elbow are usually posterior. They also occur with hyperextension and are the result of a leverage effect. As the olecranon is blocked by the olecranon fossa, the trochlea is levered over the coronoid process. The medial collateral ligament is ruptured, and there may be associated radial head or capitellar fractures. These types of injuries are usually seen in an acute, on-the-field or playground scenario. Attempts at relocation should be tempered by the possibility that a dislocation is in fact a fracture. Attempts at relocation may cause neurovascular injury.

**Figure 8-2** (A) Lateral elbow; (B) medial elbow.

**Table 8-2** Elbow Pain Localization

#	Structures	Overt Trauma	Insidious or Overuse
1	Olecranon, triceps insertion	Olecranon fracture, olecranon bursitis	Triceps tendinitis, valgus-extension overload
2	Lateral epicondyle of humerus, origin of extensor wad	Supracondylar fracture (or slightly above)	Lateral epicondylitis
3	Radial head, capitellum	Radial head fracture, radial head subluxation	Radial head subluxation, osteochondritis dissecans of the capitellum
4	Supinator, proximal radius	Proximal radius fracture	Supinator syndrome, posterior interosseous nerve syndrome (palpation point)
5	Ulnar nerve	Damage from associated fracture	Ulnar neuritis, subluxating ulnar nerve
6	Medial epicondyle of humerus, origin of flexor quad	Supracondylar fracture, ulnar collateral ligament sprain	Medial epicondylitis, Little League/pitcher's elbow (apophyseal injury)
7	Ulnar collateral ligament	Collateral ligament sprain	Collateral ligament sprain
8	Wrist flexors	Contusion	Flexor tendinitis
9	Biceps tendon insertion/tuberosity of radius	Biceps avulsion	Distal biceps strain
10	Pronator teres	Contusion	Pronator teres syndrome (palpation point)

*Note:* See [Figure 8-2](#) for localization of numbered areas.

Valgus stress to the elbow is less often an acute injury; more often it is a chronic overuse phenomenon. If a sudden valgus force is applied to the elbow, avulsion of the medial epicondyle, medial collateral ligament sprain, and capitellum fracture should be considered. A direct fall onto the tip of the elbow with the elbow flexed may result in either an olecranon fracture or olecranon bursitis. Sudden traction on the forearm of a young child may result in a radial head entrapment phenomenon often called nursemaid's elbow.

Overuse injuries account for many of the problems presenting as medial or lateral elbow pain. Disorders associated with repetitive flexion maneuvers and medial elbow pain are suggestive of medial epicondylitis. Repetitive extension maneuvers associated with lateral elbow pain are suggestive of lateral epicondylitis. Repetitive pronation maneuvers associated with medial anterior elbow and forearm pain suggest pronator involvement, especially if associated with distal neurologic signs and symptoms. These are discussed in more detail in [Chapter 9](#).

Repetitive sports activities are probably the most common cause of persistent elbow pain. Throwing sports or sports that require leverage at the elbow through an arm extension such as a bat, racquet, or club are the main instigators. The cocking portion of the throwing act places enormous medial stretch and lateral compression stress into the elbow joint. The forearm contributions to various pitches in baseball may selectively strain the pronator or wrist flexor group of muscles. At the end of acceleration, there may be a posterior compressive force component that should be considered in athletes complaining of pain on passive and active end-range extension.

## **Weakness**

Weakness at the elbow without associated pain should suggest the possibility of a biceps tendon rupture. There should be a history of a sudden flexion contraction with an associated proximal migration of the biceps muscle belly. Most other causes of localized elbow weakness are due to pain. Some patients with elbow flexion contracture may perceive elbow movement as weak.

## **Instability**

Instability will be the consequence of a past fracture, dislocation, or sudden valgus force. Following elbow dislocations, only about 1% to 2% of patients have significant instability.<sup>6</sup> More frequently, instability is the result of constant valgus loading of the immature athletic elbow. It is important to ask about other joints. A generalized looseness of all joints first may be noticed in the elbow. Most of these are “normal” variants based on age and female gender; however, some connective tissue

disorders such as Ehlers-Danlos syndrome and Marfan syndrome must be considered.

## **Restricted Motion**

Restriction to passive flexion or extension coupled with a traumatic history suggests joint effusion or fracture. A nontraumatic restriction to passive extension suggests a tight biceps or anterior capsule. A history of overuse is usually found. A nontraumatic restriction to passive flexion suggests a tight triceps or posterior capsular adhesions.

## **Locking or Crepitus**

Locking or crepitus in a young patient is suggestive of osteochondritis dissecans, whereas in an older patient it is suggestive of degenerative changes. If the patient complains of crepitus or locking with pronation and supination, a search for radiocapitellar involvement is warranted. If the patient complains of crepitus on extension of the elbow, osteophytic involvement of the medial epicondyle or olecranon is possible. If there appears to be a pop with extension, the radial head is likely the source at the lateral elbow and a subluxating ulnar nerve at the medial elbow.

## **Superficial Complaints**

The most common superficial complaints at the elbow are the skin lesions associated with psoriasis. Swellings are usually due to either gouty tophi (also seen with chronic renal failure) or an olecranon bursitis. A history of resting on

the elbow or an occupation requiring constant support onto the elbow is often found.

Numbness and tingling complaints are almost always associated with a pattern including the forearm and wrist or neck and shoulder. A search for specific peripheral nerve localization findings or nerve root findings is presented in [Chapter 9](#) and [Chapter 2](#), respectively.

## Examination

In an acute scenario, a quick check of distal neural and vascular integrity should be made with simple wrist and finger movements coupled with palpation of distal pulses while the history is being elicited.

Observation of the carrying angle of the elbow may indicate past or current bony derangement. The carrying angle for males is between  $5^{\circ}$  and  $10^{\circ}$ ; for females,  $10^{\circ}$  and  $15^{\circ}$ . Cubitus valgus (greater than  $20^{\circ}$ ) suggests laxity of the medial joint or possible compression injury to the lateral joint at the radial head or capitellum. Cubitus varus (less than  $5^{\circ}$ ) is sometimes referred to as a gunstock deformity and may indicate fracture or epiphyseal damage. When the patient assumes a pain-relief position of about  $70^{\circ}$  of flexion and  $10^{\circ}$  of supination, joint effusion is often the cause. Note proper alignment of the posterior elbow with the elbow flexed. The three bony landmarks, the medial epicondyle, lateral epicondyle, and olecranon, should form a triangle of points; with extension they are horizontally aligned.

Swelling about the elbow is unusual unless there is an underlying fracture, bursitis, or gouty tophi deposit. Olecranon bursitis is the most common and is unmistakable due to its posterior location and size. Superficial skin lesions that are isolated to the elbow (and perhaps knees and scalp) are most often psoriatic. These lesions are silver, scaly

patches found mainly on the extensor aspect of the forearm or elbow.

Palpation is useful in locating common bony or soft tissue damage sites. The olecranon process posteriorly may be tender due to a traumatic fracture (history of a fall on the elbow) or a stress fracture (excessive elbow extension). The medial epicondyle may be tender to palpation with ligament tears or flexor muscle strain. The lateral epicondyle may be tender to palpation with lateral epicondylitis or, more rarely, lateral collateral ligament sprain. Tenderness at the radial head is found with both fracture and subluxation.

Orthopaedic testing focuses on stability, internal derangement, nerve entrapment, and muscle/tendon problems. Additional testing may incorporate cervical spine testing for nerve root or referral pain sources, and biomechanical factors due to shoulder or wrist dysfunction. Following are the standard orthopaedic tests for the elbow:

- Valgus testing:<sup>7</sup> By flexing the elbow to 15° or 20°, the stability provided by the olecranon is eliminated and the anterior joint capsule is relaxed (**Figure 8-3**). The shoulder is then externally rotated to prevent any shoulder rotation during the stability testing. A valgus force is applied to the medial elbow while palpating for instability or restrictions. Opening at the joint indicates damage to the primary stabilizer, the anterior bundle of the medial collateral ligament. Pain with no instability may occur as a result of minor and/or chronic medial collateral ligament sprains or flexor/pronator muscle strains.
- Valgus/extension overload: With the elbow slightly flexed, a valgus force is applied. The elbow is then extended while maintaining the valgus force. Pain indicates an impingement phenomenon that occurs between the olecranon and posteromedial aspect of the humerus or olecranon fossa.<sup>8</sup>

- Varus testing: By flexing the elbow to 20° or 30° , a varus force will be focused more on the lateral collateral complex (**Figure 8-4**). The shoulder should be internally rotated to eliminate any shoulder contribution that could be misinterpreted as coming from the elbow.
- Mill's test: Lateral epicondylitis will usually be more painful with passive stretching of the extensors. This is accomplished through passive wrist flexion with the elbow extended (**Figure 8-5**).

**Figure 8-3** Valgus testing for stability is performed with the elbow held at 15° to 20° flexion and the forearm supinated. A force is applied from lateral to medial.

**Figure 8-4** Varus testing for stability is performed with the elbow bent to 20° to 30° flexion and the arm internally rotated. A medial to lateral force is applied.

**Figure 8-5** Mills' maneuver for lateral epicondylitis involves passive stretching of the extensors through passive flexion of the wrist with the elbow extended.

- Reverse Mill's test: Medial epicondylitis will usually be more painful with passive stretching of the flexors. This

is accomplished through passive wrist extension with the elbow extended.

- Cozen's test: Resisted wrist extension (with the elbow both flexed and extended) will usually increase the pain of lateral epicondylitis (**Figure 8-6**). Weakness on wrist extension is more indicative of radial nerve or C7 nerve root involvement.
- Tinel's test: With ulnar nerve irritation due to compression or hypermobility (subluxating or dislocating ulnar nerve), tapping over the nerve at the posterior elbow may cause pain or paresthesias down the medial forearm. This should be compared with the opposite elbow to determine the patient's sensitivity to this maneuver.
- Ulnar compression test: Full elbow flexion held for 3 to 5 minutes may cause pain, paresthesias, or a numbness down the medial arm when the ulnar nerve is irritated. A complementary test is to palpate for ulnar nerve subluxation/dislocation when the elbow is taken from extension to full flexion.

Functional patterns that are suggestive of specific disorders include the following:

- **Triceps tendinitis**—Posterior pain on resisted extension with full shoulder flexion and/or pain with passive flexion of the elbow with the shoulder fully flexed.

**Figure 8-6** Cozen's maneuver for lateral epicondylitis is performed with the elbow flexed or extended. The patient is asked to extend the wrist against resistance.

- **Distal biceps tendinitis or avulsion**—Anterior pain on resisted flexion/supination with the shoulder fully extended and/or pain with passive wrist and elbow extension with the shoulder fully extended.
- **Pronator teres strain**—Anterior pain on resisted pronation with the elbow in neutral and extended and/or pain with passive supination with the elbow extended.
- **Supinator strain**—Anterolateral pain on resisted supination and/or passive pronation (sometimes with a Yergason test).
- **Lateral epicondylitis**—Lateral pain on resisted wrist extension and/or passive flexion of the wrist with the elbow extended/forearm pronated and/or resisted finger extension.
- **Medial epicondylitis**—Medial pain on resisted wrist flexion with the elbow extended and/or passive wrist extension with the elbow extended/forearm supinated and/or resisted finger flexion.

Radiographic evaluation of the elbow begins with two standard views: the anterior-to-posterior (AP) and lateral. In addition to obvious signs of fracture, indirect indicators of intra-articular fracture are positive fat pad signs. On a normal lateral view a small anterior fat pad may be visible as a small radiolucent triangle at the distal humerus. The posterior fat pad is not usually visible because of the overlap of the humeral condyles. When a patient presents with acute elbow trauma, a diligent search for an enlarged anterior fat pad (ship's sail shape) and a posterior fat pad should be made. A positive fat pad sign is indicative of intracapsular bleeding, usually due to intracapsular fracture.<sup>9</sup> When a positive fat pad sign is evident yet a fracture is not obvious on the two standard views, additional views should be utilized until the fracture is located. If still not visible, the patient should be supported for five to seven days and reexamined radiographically to be sure.<sup>10</sup> A false-positive fat pad sign may occur if the lateral view is not positioned properly caused by even slight rotation.<sup>11</sup>

When the radial head and neck are the areas of concern, a lateral oblique view is helpful.<sup>12</sup> Another excellent view is the radial head-capitellum view (patient position same as for lateral view projection with a 45° tube angle toward the patient).<sup>13</sup> This view is also valuable in finding osteochondritis dissecans of the capitellum (Panner's), and radial head, capitellum, and coronoid process fractures. Coronoid process fracture or pathologic lesion is best visualized with the medial (internal) oblique projection. When restriction to extension is found on examination, an axial view is helpful in demonstrating osteophytes of the olecranon-trochlear joint.<sup>14</sup> Patients who demonstrate ulnar nerve signs should be evaluated with a cubital tunnel view in an effort to visualize medial trochlear osteophytes. This is similar to the axial view; however, the elbow is positioned in 15° of external rotation (maximally flexed).<sup>15</sup>

Approximately 25% of patients who appear clinically to have either lateral or medial epicondylitis may demonstrate soft tissue calcification at the attachment sites of the respective muscle groups on standard elbow views.<sup>16</sup> However, this is not necessary for establishing a diagnosis. It is essentially an incidental finding.

## Management

- Fractures and dislocations require referral to prevent neurovascular or long-term biomechanical complications.
- Tendinitis disorders are treated with protected rest, icing, and physical therapy (PT) modalities for pain. Nonsteroid anti-inflammatory drugs (NSAIDs) or alternatives might be helpful in the acute stage. Cross-friction massage with the tendon under stretch, and myofascial release techniques to the involved muscles every other day for two to three weeks should resolve most problems. Modification or elimination of an inciting activity is required for prevention of future recurrence.
- Little League elbow without radiographic evidence of damage may be managed conservatively with rest and ice. Slow return to pitching with strict adherence to Little League rules and avoidance of curve balls and side-arm pitching will usually control the problem.
- Little League elbow with radiographic evidence of medial stress or lateral compression injury should be referred or comanaged.
- Valgus-extension overload may be managed initially with taping or bracing to prevent extension. Avoidance of any forceful extension activities is required. If the patient wants to pursue the activity (usually sports),

referral for decompression of the posterior elbow is suggested.

## **Lateral Epicondylitis (LE)**

Lateral epicondylitis (LE) is a relatively common disorder. Although prevalence studies are limited, the most commonly reported study is from 1974.<sup>17</sup> The range reported is between 1% to 10% with a range of 1% to 3% quoted most often. The incidence of LE in general practice is estimated between 4–7 per 1,000 patients.<sup>18</sup> For chiropractic practice, the incidence is less clear.

Lateral epicondylitis is a condition characterized by the development of lateral elbow pain worsened by resisted wrist extension and gripping. It is a degenerative process, not an inflammatory condition as once thought. Even though LE is also referred to as tennis elbow and accounts for between 75% to 80% of the 50% of recreational tennis players who complain of lateral elbow pain, tennis players account for only 5% of all LE patients.<sup>19–22</sup> By far, the most commonly reported causes are work-related.<sup>23–26</sup> Between 35% and 61% are related to work, and 27% with leisure activities. Unknown precipitating cause accounts for 30%.<sup>27</sup> Among workers, LE results in an average time off from work of 12 weeks in as many as 30% of those affected.<sup>28</sup>

A U.S. National Institute for Occupational Safety and Health (NIOSH)<sup>29</sup> review found no evidence for an association between repetitive work and LE, or postural factors with LE. The study did find strong evidence for a relationship between a combination of risk factors (i.e., force, repetition, and posture) and LE. Lateral epicondylitis is seen more often in individuals between the ages of 40 to 60 years, with an equal distribution between men and women.<sup>28, 30</sup> Lateral epicondylitis appears to be self-limiting with a reported duration per episode of between six months and two years.<sup>31</sup>

In a prospective study of patients with LE, Waugh et al.<sup>32</sup> indicated that women were more likely than men to have work-related onset, repetitive keyboarding jobs, and cervical joint signs. Among women, these factors were associated with higher final disabilities of the arm, shoulder, and hand (DASH) and visual analog scale (VAS) scores. Women and patients who report nerve symptoms are more likely to experience a poorer short-term outcome after physiotherapy management of LE.<sup>33</sup> There were two recent systematic reviews for LE: one by Bisset et al.<sup>34</sup> and one by Smidt et al.<sup>35</sup> It is clear from these reviews that although there are a large number of studies, many have insufficient power and some have conflicting results. Also, there are a low number of quality studies per intervention. There were no clinical studies found on the diagnostic accuracy or reliability for the clinical examination of LE.

In an RCT evaluating cost effectiveness for interventions for LE, Korthals-de Bos et al.<sup>36</sup> determined that the success rate for a physiotherapy group was 91%, 69% for a corticosteroid injection group, and 83% for a wait-and-see group; 83% at one year. They concluded that from a cost perspective a wait-and-see approach should be the first approach. Similar to the Korthals-de Bos study, Smidt et al.<sup>37</sup> randomized patients to corticosteroid injection, physiotherapy, or a wait-and-see group. Follow-up was at 3, 6, 12, 26, and 52 weeks. There was a clear advantage at six weeks for corticosteroid injection. However, there was a high recurrence rate in the injection group. At 52 weeks, there was no advantage, with 69% of the injection group reporting success, compared to 91% of patients reporting success with physiotherapy, and 83% of patients in the wait-and-see group reporting success. As a long-term approach, it was suggested that either physiotherapy or wait-and-see are more effective; however, dependent on pain levels, injection may be needed.

Although the Bisset<sup>34</sup> review indicated lack of evidence for long-term benefit using physical interventions for lateral epicondylitis, there was limited evidence that exercise may have an effect on pain reduction but not on maximum grip strength. Also, some limited evidence was found for an effect using a combination treatment that included ultrasonography, exercise, and transverse friction massage when compared to a corticosteroid injection. The one study included in the Bisset review was a follow-up, prospective study by Pienimäke et al.<sup>33</sup> of an RCT conducted in 1996.<sup>38</sup> The program utilized in this study consisted of a four-step exercise for eight weeks with a 36-month follow-up ( $n = 30$  patients). The exercise group improved more when compared to a pulsed-ultrasound group with lower pain scores on a visual analog scale. At the three-year follow-up, the exercise group had pain scores and pain drawings that had improved significantly more than the ultrasonography group. Five patients in the ultrasonography group had resorted to surgery, whereas only one patient in the exercise group had surgery. In the Smidt<sup>35</sup> review, only ultrasonography demonstrated a clinically and statistically relevant positive effect, although the evidence was rated as weak. They did conclude, though, that one study determined that exercise was significantly better than ultrasonography combined with friction massage.

Braces or splints are commonly used for LE. These range from small “counter-force” braces to larger braces, and even wrist braces. There is some disagreement as to whether the imposed rest by bracing/splinting is beneficial or detrimental to either the initial or overall outcome. This concern arises from conflicting results in the literature. In a retrospective study by Derebery et al.<sup>39</sup> of 4,614 workers, those who were splinted had higher rates of limited duty, more medical visits and charges, higher total charges, and longer treatment durations compared to patients who were not splinted. One criticism of the study is that, as a

retrospective study, the pretreatment differences between patients would not have been randomly allocated, although the study attempted to neutralize some of the effect using propensity score methodology. Another criticism is that the types of braces were not standardized. In an RCT by Struijs et al.,<sup>40</sup> a brace-only group was compared to a combination group that received both a brace and physiotherapy. At six weeks, physiotherapy was superior to brace only for pain, disability, and satisfaction. The brace-only group was superior on ability of daily activities. At six months and one-year follow-ups, there were no significant differences between treatment approaches. A more recent RCT by Faes et al.<sup>41</sup> used a specialized dynamic extensor brace custom-made for each patient. They compared a brace group to a no-brace group. Brace treatment resulted in significant pain reduction, improved functionality of the arm, and improvement in pain-free grip strength. After the treatment period, the brace group maintained beneficial effects at a one-year follow-up. Unfortunately, this specific brace is not necessarily available, and the cost of the brace was not stated or considered.

Takasaki et al.<sup>42</sup> evaluated numerous positions to determine the best stretch for the extensor carpi radialis longus and brevis. They found the combination of elbow extension, forearm pronation, and wrist flexion/ulnar deviation to be most effective.

As with other chronic tendinopathies, lateral epicondylitis may be approached using an eccentric training program. There are few studies specific to this area. However, one study<sup>43</sup> incorporating an isokinetic eccentric approach has been published. The control group in this study was treated with cross-friction, stretching, ice, TENS, or ultrasonography, but was not given any exercise program. The exercise group performed their program on a Cybex isokinetic machine. Focus was placed on the wrist extensors and forearm supinators. The elbow flexion angle was maintained at 60°.

Progression through the program involved an initial submaximal contraction of about 38% and a speed of 30° per second. Subjects were treated three times per week for an average duration of about nine weeks. There were marked improvements in pain and function in the exercise group as compared to the control group.

The literature includes studies on both local manipulation/mobilization of the elbow and nonlocal manipulation for lateral epicondylitis. The nonlocal manipulative approaches included cervical and/or cervicothoracic spine manipulation and manipulation of the wrist. The systematic reviews by Smidt<sup>35</sup> in 2003, which included all physiotherapy approaches, concluded that there was insufficient evidence for mobilization techniques, specifically for the wrist for LE. The systematic review by Bisset<sup>34</sup> in 2004 indicated that there was some evidence that local manipulation may have an immediate effect; however, the study was a single-treatment approach without follow-up. The study referred to by Bisset was by Vicenzino.<sup>44</sup> He demonstrated a substantial increase in pain-free grip during treatment using a lateral-glide mobilization (Mulligan-type). Patients were randomized to a lateral-glide treatment group or a position-only (no gliding) group. As mentioned above, the study indicates only the immediate effect but had no follow-up to determine how long effects lasted.

The Bisset review also concluded that wrist manipulation did not demonstrate a significant difference when compared to a treatment group that included crossfriction massage, exercise, and pulsed-ultrasound. The study referred to was an RCT by Struijs et al.<sup>45</sup> that utilized a Lewit-type mobilization of the wrist. This study demonstrated a similar positive outcome for both groups in visual analog scale, grip strength, and pain threshold at the end of six weeks. This study was rated low by our group.

Specific studies related to chiropractic management of lateral epicondylitis include only one randomized, prospective study<sup>46</sup> and an occasional case report.<sup>47</sup> In the randomized, prospective report by Langen-Peters et al.,<sup>46</sup> patients were treated with either adjusting (manipulation) of the elbow with associated stretching or ultrasonography. Both groups demonstrated improvement; however, there was no control group for comparison. This small study indicated that either manipulation of the elbow with stretching/strengthening or ultrasonography is effective in the short term.

An RCT by Vicenzino et al.<sup>48</sup> utilized a lateral-glide mobilization at the C5-C6 vertebral segments. This small study of 15 patients demonstrated significant improvements in pain threshold, pain-free grip strength, and pain scores, relative to placebo or control. There was no measure of duration of effect in any short- or long-term follow-up. The second study was a retrospective evaluation by Cleland et al.<sup>49</sup> This study compared ultrasonography, soft tissue mobilization, and elbow joint mobilization versus a group treated with cervical spine manual therapy, which included passive accessory mobilization and movement techniques. Data were derived from a telephone interview over an undesignated time period that appears to be at least one to three years. Seventy-five percent of the local treatment group, and 80% of the local-plus-manual therapy group had a successful outcome. The local-plus-manual therapy to the cervical spine group achieved a successful long-term outcome in fewer visits (mean of 9.6 visits for local versus a mean of 5.6 visits for the local plus C-spine manipulation group).

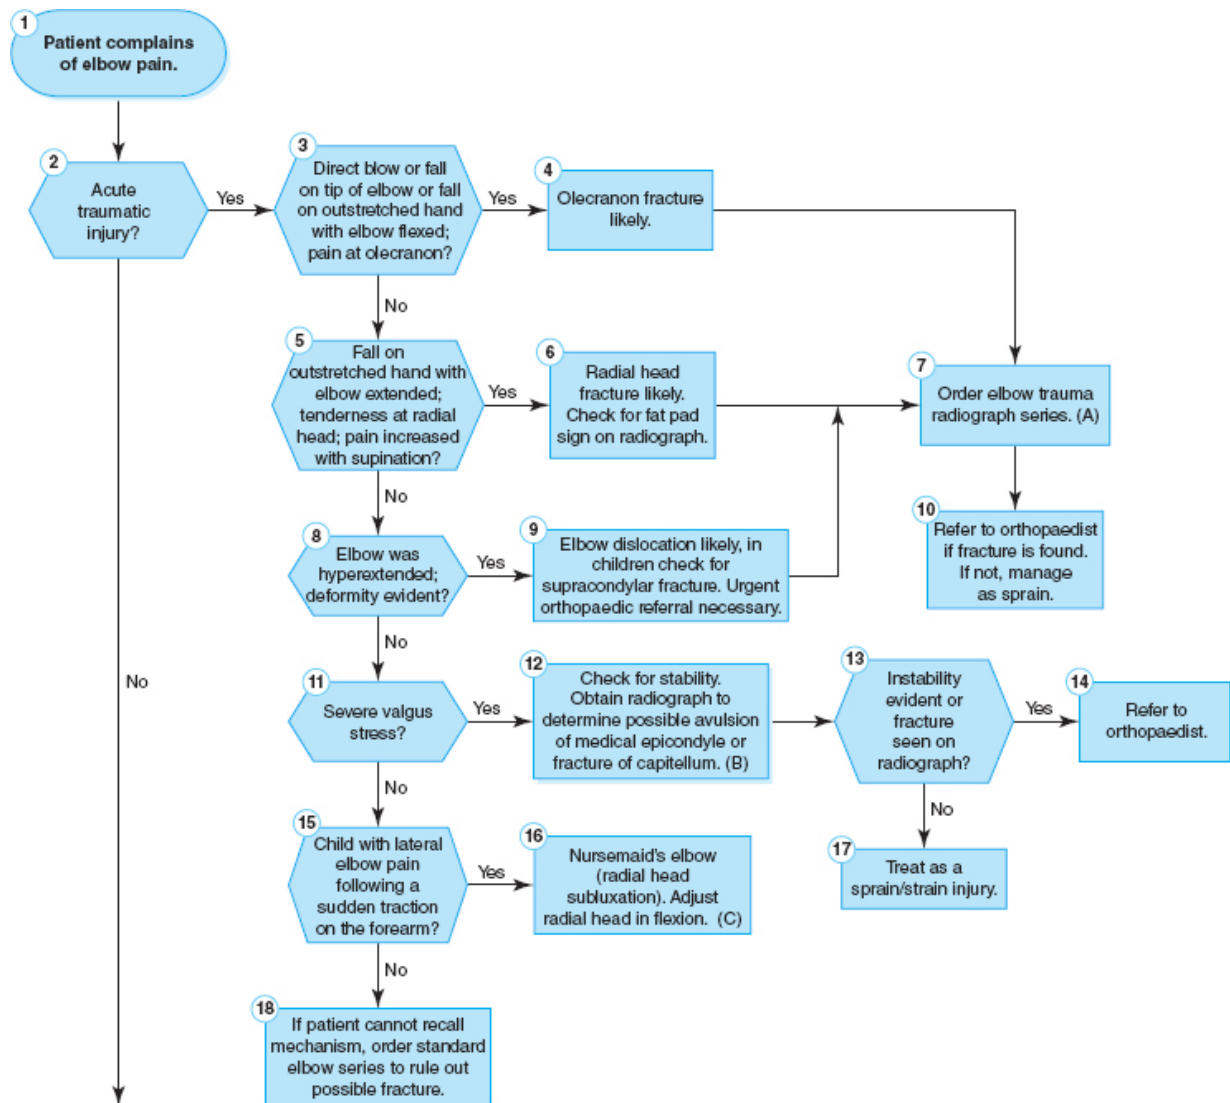

There is moderate evidence to suggest that mobilization of either the elbow, cervical spine, or wrist may produce some immediate benefit but no evidence for or against long-term benefit. There is no evidence for or against high-velocity, short-amplitude (HVSA) adjusting of the elbow in

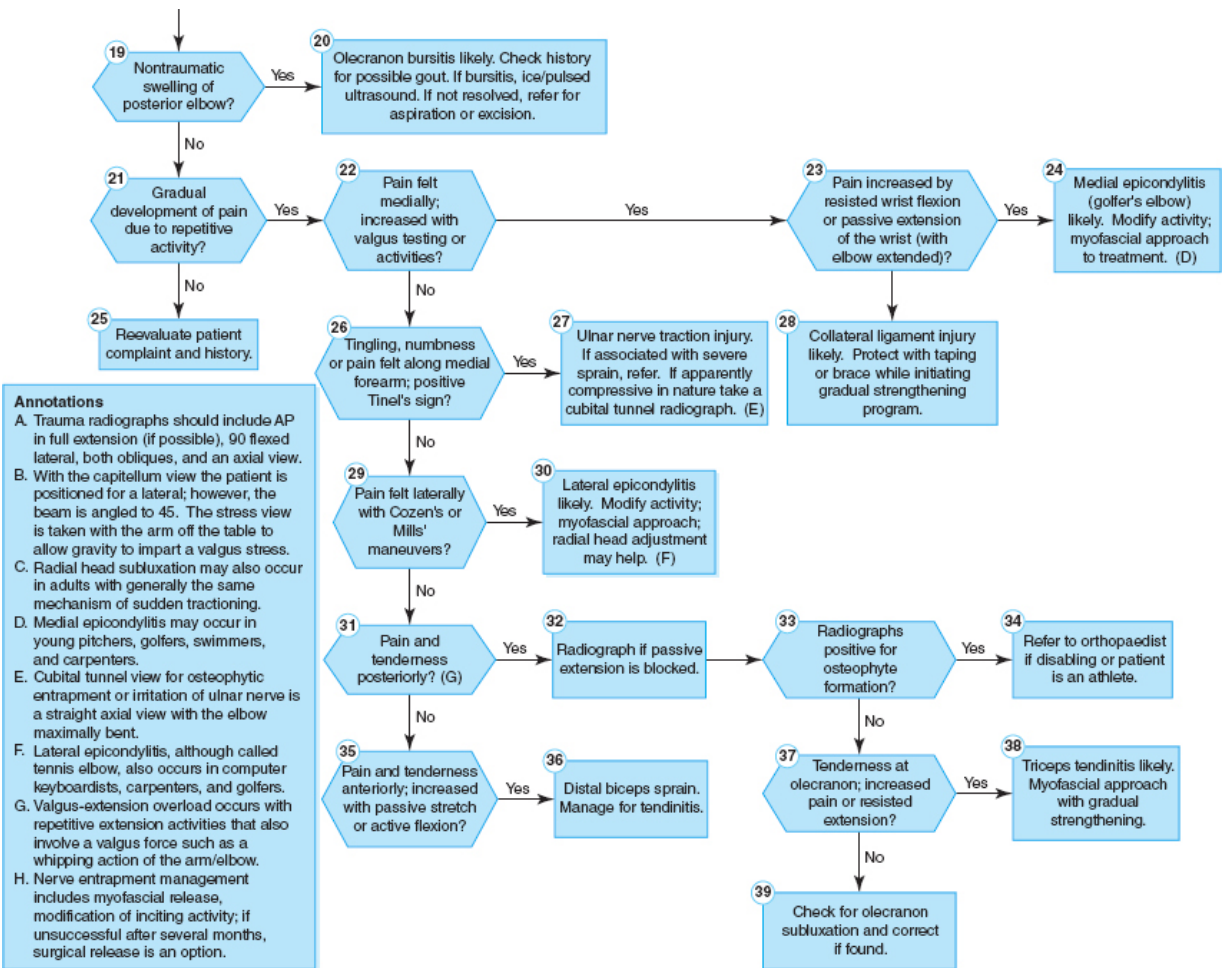

the management of LE. The CCGPP Upper Extremity Team expert opinion supports the use of HVSA manipulation (adjustment) of the elbow with some recommendations for use that include avoidance of risk. Further evaluation and/or management are required for patients who fail to respond to treatment within a reasonable period of time.

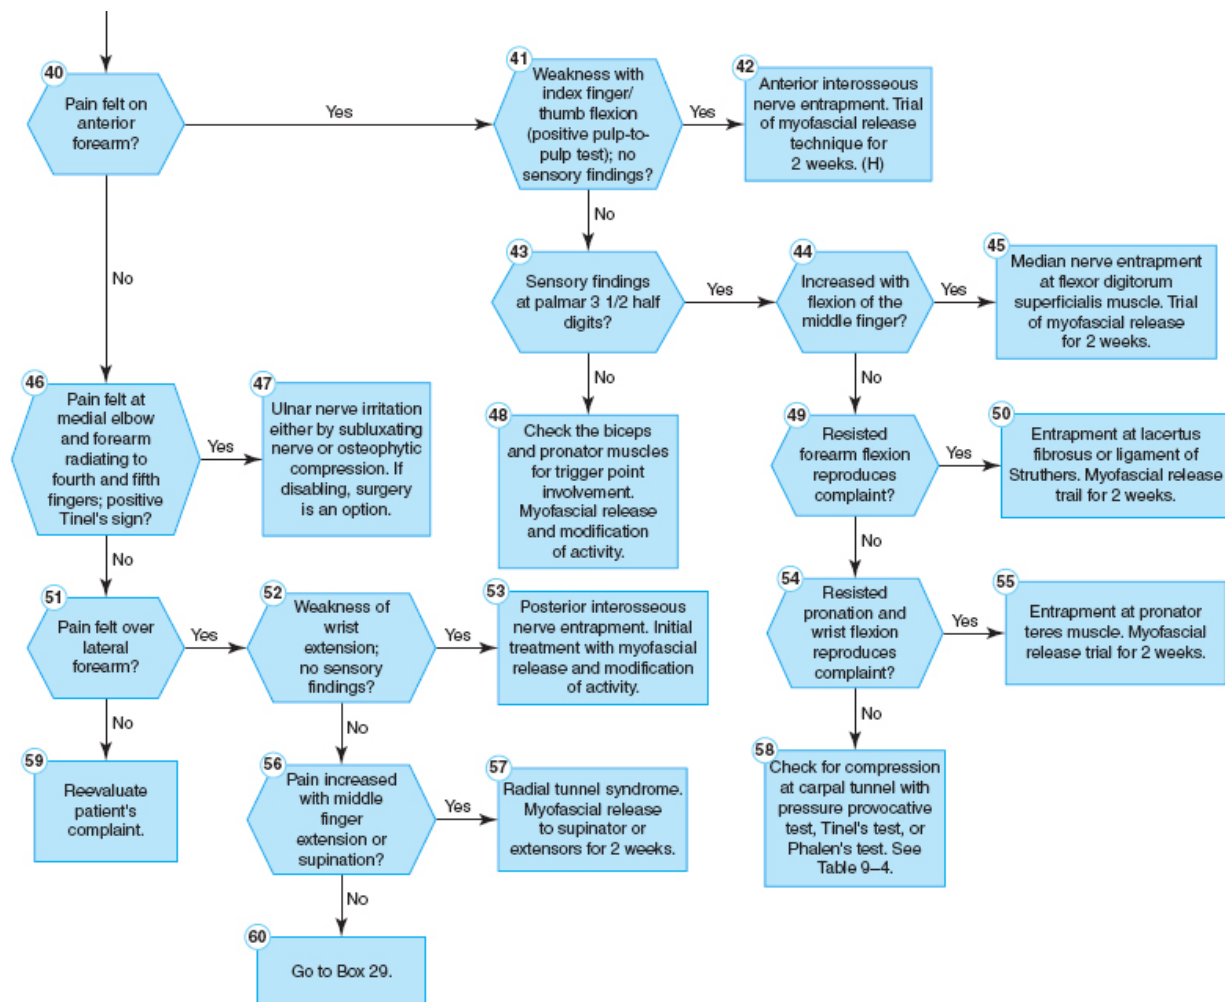

- For all patients who have fracture, suspected fracture, dislocation, active hemarthrosis or extensive swelling, severe generalized or local osteoporosis, infection, or tumor, HVSA manipulation is contraindicated.
- For patients who have had surgery of the elbow, consider date of surgery, extent of surgery, type of procedure, and other related factors in making decisions about the use of HVSA manipulation.
- Cautious or modified application of manipulation should be considered for the following: known joint mice, traction spurs, or olecranon arthrosis.
- For all patients, an evaluation for joint stability must be performed. Based on the findings, it is recommended that no HVSA manipulation be used for patients with hypermobility syndromes (e.g., Marfan, Ehler-Danlos), or gross looseness indicating multidirectional instability. Mobilization such as applying a Maitland Grade I-IV type of translational movement may be appropriate in these case settings.
- For patients with any acute inflammatory condition such as rheumatoid arthritis, crystalline disease (e.g., gout), or acute bursitis it is recommended not to use HVSA. For some patients with olecranon bursitis, HVSA manipulation may be safely applied if the bursitis is chronic, or the application is not specific to the olecranon.

## **Algorithm**

An algorithm for evaluation and management of elbow/forearm pain is presented in **Figure 8-7**.

**Figure 8-7** Elbow/Forearm Pain—Algorithm

## Selected Disorders of the Elbow

### Lateral Epicondylitis (Tennis Elbow)

## Classic Presentation

The patient presents with lateral elbow pain associated with a repetitive sport or occupational activity.

# Cause

Many theories have been proposed and many structures have been implicated; however, the currently accepted theory is that initially there is tearing of the extensor carpi radialis brevis (ECRB) origin.<sup>50</sup> This process may extend to the extensor digitorum communis (EDC) or the extensor carpi radialis longus (ECRL). The histologic description of the change in tissue is called angiofibroblastic hyperplasia.<sup>51</sup> Repetitive movements requiring forceful wrist extension, radial deviation, and supination are the most common causes. Although it is associated with tennis, other sports and occupational activities are also possible causes. Meat cutters, plumbers, and weavers are examples of those who may be affected. With tennis, novice players with poor backhand technique account for most cases. With professional players, the forehand or the serve may be the cause. The more frequently an individual plays, the higher the risk of developing tennis elbow.

# Evaluation

Tenderness is elicited at the lateral epicondyle, specifically at the origin of the ECRB. Tenderness 5 mm anterior and distal to the lateral epicondyle is most common. Provocative maneuvers include contraction of the wrist extensors with the elbow flexed or extended (Cozen's maneuver [[Figure 8-6](#)]) and stretching of the wrist extensors with passive wrist flexion with the elbow extended (Mill's maneuver [[Figure 8-5](#)]). Painful resisted middle or ring finger extension implicates the EDC. Wrist extension with radial deviation implicates the ECRB or ECRL. Another suggested test is the chair lift test. The patient is asked to pick up a light chair by the chair back. The patient's elbow is extended with the

forearm pronated. This is usually impossible for the patient with lateral epicondylitis because of the pain. Radiographs may demonstrate calcification in as many as 25% of patients with lateral epicondylitis, although they are rarely indicated.<sup>16</sup> Synovial plicae of the elbow may mimic lateral epicondylitis. Some distinctions are that the point of maximum tenderness is posterior to the lateral epicondyle and centered more at the posterior radiocapitellar joint. There may be a small loss of extension range of motion. Diagnostically, MRI may be helpful. To date, the literature is only on arthroscopic treatment revealing good short-term results.<sup>52</sup>

## Management

In the acute phase, ice and rest from the inciting activity are essential. Imposed rest through the use of a splint with the wrist in 30° to 45° of extension may relieve tension on the ECRB.<sup>53</sup> Through a graded program of slow stretching and isometric exercise progressing to isotonic exercise of the wrist extensors with an eccentric focus, resolution and prevention may be initiated. Myofascial release techniques are effective. Cross-friction massage, manipulation, and mobilization are helpful in the subacute phase.<sup>54</sup> During the subacute phase, the use of a tennis elbow brace may help redistribute forces distal to the ECRB. Recommendations are to use a pneumatic or Velcro type that is 3.0- to 3.5-in. wide.<sup>55</sup> If tennis is the culprit, recommend a midsize ceramic or graphite racquet with natural gut strings. The string tension should be 3 to 5 lb below what the athlete is used to (usually 52 to 55 lb).<sup>56</sup> Use the Nirschl approach to proper grip size.<sup>57</sup>

A common approach to tendon problems is eccentric rehabilitation exercises. A standard protocol involves usually three sets of ten with the last set being uncomfortable. A

systematic review in 2014 indicates that eccentric exercise is an effective approach for LE.<sup>58</sup>

In a review of treatment approaches to lateral epicondylitis, researchers compared corticosteroid injections, physiotherapy, and a wait-and-see approach.<sup>59</sup> Although short-term benefits for corticosteroid injection were far superior (92% success rate) compared to physiotherapy (47%) and the wait-and-see policy (32%), the differences between injections and physiotherapy were lost in long-term follow-up, indicating physiotherapy at one year was far superior (91%). In fact, the wait-and-see policy patients were significantly better at one year (83%) compared to injection (69%). Contrasting this study is a systematic review by the same researcher<sup>59</sup> that indicated there was insufficient evidence for the use of most physiotherapy interventions for lateral epicondylitis due to contradicting results, insufficient power, and a small number of studies.<sup>60</sup> Only ultrasound had weak evidence for efficacy.

Injectables have become more recently popular; in particular, platelet-rich plasma (PRP) injections. The theory is that by creating a concentrate of platelets from the patient's own blood, growth factors will help stimulate healing. A comparison study for various injectables including corticosteroid, PRP, sclerosing agents, and sodium hyaluronate concluded that sodium hyaluronate compared with placebo showed consistently better results.<sup>61</sup> The study also found that corticosteroids were effective for short-term relief but may be worse than other treatments over the long run. Another similar study found value for prolotherapy and sodium hyaluronate.<sup>62</sup> Yet another study in 2013 using a double-blinded randomized approach found no difference between patients' pain relief at three months when treated with saline as compared with glucocorticoids or PRP.<sup>63</sup> Another study not only confirmed this but said that none provided an acceptable level of pain relief for those with LE.<sup>64</sup> There has been an increased use of shockwave therapy

for lateral epicondylitis over the last few years. In one recent review study, researchers found a mixed report based on two studies using similar protocols.<sup>65</sup> The researchers recommended further study prior to drawing conclusions or making recommendations. The older studies include the following and their conclusions:

- A double-blinded, randomized controlled trial using shockwave therapy compared to a sham therapy: Results indicated a significant placebo effect with no evidence of benefit using shock therapy.<sup>66</sup>
- A small one- and two-year follow-up study with a control group (sham treatment): Results indicated that 61% of patients treated with shockwave therapy were free of complaints while the control group patients were unchanged.<sup>67</sup>
- A randomized, double-blind study with 74 patients: Results indicated that all patients improved significantly over time and that there was no evidence that shockwave therapy was better than placebo.<sup>68</sup>

Yet the preponderance of newer studies find value in the use of shockwave therapy for both acute and chronic LE.

- A 2013 study found value for patients with recalcitrant LE.<sup>69</sup>
- A 2012 study found that using an initial treatment with shockwave for acute LE was also effective.<sup>70</sup>
- A publication in 2012 indicated that shockwave therapy was effective for short-term relief.

Although used for years, only recently has there been support for the use of low-level laser treatment (LLLT) for tendinopathies.<sup>71</sup>

A small, recently published study compared manipulation of the wrist with a second protocol of ultrasound, friction massage, and muscle stretching and strengthening for the management of lateral epicondylitis.<sup>72</sup> Short-term success was better for manipulation of the wrist compared to the traditional ultrasound, friction massage, and muscle

stretching/strengthening approach. Long-term studies are needed to determine whether these benefits are maintained.

An investigative approach is topical nitric oxide application. Researchers in a randomized, double-blinded, placebo-controlled clinical trial compared a combination of a routine rehabilitation program with either a transdermal patch of glyceryl trinitrate or a placebo patch in the management of chronic extensor tendinosis.<sup>73</sup> This topical application of nitric oxide is believed to stimulate collagen synthesis in fibroblasts. It appears that the treated group had a good response with regard to reduction in elbow pain with activity at two weeks and decreased tenderness at six and 12 weeks. Follow-up at six months demonstrated that 81% of the treated patients were asymptomatic during activities of daily living compared to 60% who had performed the rehabilitation program but received the placebo patch. It appears that both are effective, with some advantage to using the patch.

## **Medial Epicondylitis**

### **Classic Presentation**

The patient complains of medial elbow pain following a repetitive activity such as hammering or use of a screwdriver. In athletes, the inciting activity usually involves wrist flexion and pronation such as in serving and overhead and forehand strokes. Golfing (“golfer’s elbow”), climbing (“climber’s elbow”), or throwing may also cause symptoms. Patients may also complain of pain or weakness on gripping.

### **Cause**

Medial epicondylitis is believed to be a tendinopathy of the origin of the wrist flexors and pronator teres.

## Evaluation

Tenderness is found at the medial epicondyle. Pain is reproduced with resisted wrist flexion and pronation. Passive stretching of the wrist flexors with wrist extension, keeping the elbow straight, may also elicit pain (reverse Mill's test).<sup>7</sup> In chronic cases, an elbow flexion contracture may occur, leading to restriction of extension and/or supination. An ulnar neuropathy may coexist with medial epicondylitis.<sup>74</sup> Tinel's sign may be positive over the ulnar nerve. Routine radiographs may reveal calcifications in close proximity to the medial epicondyle in 20% to 30% of patients with epicondylitis.

## Management

In the acute phase, ice and rest from the inciting activity are essential. Imposed rest through the use of a splint with the wrist in 10° of flexion may relieve tension on the flexor muscle group. If the flexor carpi radialis is involved, 10° of radial deviation should be added. For pronator involvement, a splint that blocks forearm rotation may be needed. In most cases, however, myofascial release of the flexor muscle mass and pronator teres is sufficient to alleviate the patient's problem. Through a graded program of slow stretching and isometric exercise progressing to isotonic exercise of the wrist extensors with an eccentric focus, resolution and prevention may be initiated. Cross-friction massage, manipulation, and mobilization may be helpful in the subacute phase. During the subacute phase, the use of a tennis elbow brace may help redistribute forces. Other

treatment approaches are similar to lateral epicondylitis. There is evidence for the use of shockwave therapy for both.

## **Triceps Tendinitis (Posterior Tennis Elbow)**

### **Classic Presentation**

The patient complains of pain at the tip of the elbow after a repetitive extension activity or a single event involving forceful elbow extension.

### **Cause**

Strain of the triceps insertion on the olecranon is usually due to common athletic endeavors performed by boxers, weight lifters, pitchers, shot-putters, and occasionally tennis players.<sup>75</sup>

### **Evaluation**

Tenderness is found at the olecranon process. Pain is increased with resisted elbow extension, especially with a starting position of elbow flexion.

### **Management**

Myofascial release techniques are used for the triceps. Cross-friction may be applied to the insertion point at the olecranon. Ice and rest from the inciting activity are essential. Decrease the amount of weight used in elbow extensions if the patient is working out.

## **Posterior Impingement Syndrome**

### **Classic Presentation**

The patient is usually an athlete complaining of a sharp posterior elbow pain, especially on quick extension of the elbow. There may be associated complaints of popping or clicking with extension or an occasional complaint of locking.

### **Cause**

Repetitive extension leads to posterior compression between the olecranon trochlea and olecranon fossa, which may simply cause a reactive synovitis or progress to degeneration and the production of osteophytes or loose bodies.

### **Evaluation**

There is often a blockage to active and passive extension at end-range accompanied by pain. The valgus-extension overload test involves applying a valgus stress while extending the elbow.<sup>8</sup> Pain and often crepitus are produced with this maneuver. Radiographically, an axial view is required. A cubital tunnel view may also be revealing. If the radiographs are negative, computed tomography or arthrography may be necessary to reveal cartilaginous loose bodies.

### **Management**

If loose bodies are evident, referral for surgical consultation should be made. If there appears to be primarily synovial hypertrophy or pinching, an acute pain program should be initiated with rest, ice, and use of an extension-block brace or taping.

## **Nursemaid's Elbow**

### **Classic Presentation**

A parent presents a child (usually between ages two and four years) with lateral elbow pain after either swinging the child by his or her arms or sudden jerking of the child's arm.

### **Cause**

The radial head is not fully formed, allowing damage or entrapment of the annular ligament by a distraction/rotation force.

### **Evaluation**

Exquisite lateral elbow pain and tenderness in a child without obvious trauma such as a fall or a blow to the elbow are indicative of nursemaid's elbow. Palpation may reveal the malpositioned radial head.

### **Management**

Reduction is accomplished by elbow flexion and rotation. Radiographic confirmation of reduction should be performed.

## Little League Elbow

### Classic Presentation

The patient is usually an adolescent baseball pitcher who complains of either medial or lateral elbow pain.

### Cause

Little League elbow is really a syndrome.<sup>76</sup> The repetitive valgus stress incurred with pitching causes stretch injury to the medial elbow and possible compression injury to the lateral elbow. Medial elbow pain is due to microtrauma to the medial anterior oblique ligament as well as accelerated growth and fragmentation of the medial epicondylar epiphysis. Laterally an osteochondritis dissecans of the capitellum and various degrees of radial head injury, including premature closure, may occur.<sup>77</sup>

### Evaluation

Tenderness may be found at both the medial and the lateral elbow. Valgus testing (**Figure 8-3**) may reveal laxity and/or pain that must be distinguished radiographically to determine whether ligament damage or epiphyseal damage is the cause. Alternating supination and pronation performed actively or passively may cause palpable or audible crepitus at the head of the radius when osteochondritis dissecans or radial head damage is present.<sup>78</sup> A flexion contracture may be evident on passive ROM evaluation. Popping and clicking or locking may occur on full-range active movement. Radiographically it is

important to include specialized views, including the radial head-capitellum view and the valgus stress view.<sup>13</sup>

## **Management**

If radiographically confirmed, referral for an orthopaedic consultation is warranted. If clinically apparent, yet radiographically normal, modification or elimination of the inciting activity is needed. Modification of pitching should include decreased time pitching (following Little League rules), avoidance of throwing curve balls, and teaching proper mechanics. Proper mechanics would include use of trunk and legs with less dependence on the elbow and wrist, avoidance of whipping or snapping of the elbow, and slow practice to accentuate proper form. The typical acute pain modalities should be used initially, and proper warm-up and stretching should be used prior to any activity.

### **Osteochondrosis (Panner's Disease)**

## **Classic Presentation**

The patient is usually a young male complaining of unilateral (dominant arm) lateral elbow pain and stiffness. Associated complaints may include clicking and locking. The patient is often involved in a sport activity several times a week.

## **Cause**

Osteochondrosis of the capitellum is caused by avascular necrosis. This may be due to trauma or other causes

disturbing the circulation to the chondroepiphysis of the capitellum.<sup>79</sup> The vessels that supply this area pass through unossified epiphyseal cartilage and may be compressed. Also, there may be an anomalous distribution with no anastomosis decreasing the available blood supply. Other names for osteochondrosis of the capitellum include Panner's disease,<sup>80</sup> osteochondrosis deformans, osteochondritis, and aseptic/avascular necrosis.

## Evaluation

A history of excessive throwing, as occurs in Little League pitching, or repeated weight bearing, as occurs in gymnastics, should always dictate the need for radiographs in any child with elbow pain. The diagnosis of Panner's disease is largely radiographic. The examination should include passive and active supination and pronation with the elbow extended in an effort to palpate or hear crepitus at the radial capitellar joint. Radiographs must include obliques and a radial head-capitellum view. Fragmentation or loose body formation is a clear indicator of this condition.

## Management

The best prognosis is for children with an open epiphysis. Reducing or eliminating any identifiable causative activity is required. A period of rest and splinting for two to three weeks should be followed by gradual stretching and strengthening. Gradual return to the activity is allowed if symptoms do not persist. If there are loose fragments or a locked elbow, referral for orthopaedic consultation is necessary. Failure of a conservative trial of several months should also warrant an orthopaedic consultation.

A management approach used for osteochondral problems of the knee and ankle is also being used for the elbow. Autologous osteochondral mosaicplasty is an approach that uses osteochondral grafts from the patient's body (femoral condyles) to implant in the capitellum in an effort to repair the articular defect. Recent evidence<sup>81</sup> suggests that this is a viable approach for advanced lesions in Little League pitchers. Long-term effects are not known at this time.

## **Olecranon Bursitis**

### **Classic Presentation**

The patient presents with an obvious swelling just distal to the point of the elbow.

### **Cause**

The olecranon bursa acts as a cushion when the elbow is in contact with any surface. Therefore, a single fall on the elbow, or more commonly, repeated weight bearing or dragging of the elbow on the ground as occurs in wrestling causes irritation and swelling.

### **Evaluation**

The goose-egg sized swelling at the elbow is difficult to miss. It must be differentiated from other swellings such as tophi in patients with gout and kidney failure. It is also crucial to distinguish between an infected or simply an inflamed bursa. Infection is more likely when there is an

obvious wound near the bursitis. Additionally, the infected bursa will be warm and more tender than a simple bursitis.

## Management

Protection with a doughnut support taped to the elbow, avoidance of the inciting activity when chronic, and ice or pulsed ultrasound are usually sufficient. When unsuccessful, referral for aspiration and possible excision should be made. Bursas usually grow back in six to 24 months. Patients with an infected bursa should be referred immediately for aspiration and antibiotic treatment.

## The Evidence

### Translation Into Practice Summary (TIPS)

There is little literature evidence on evaluation of the elbow. Although there is some evidence for tests that tend to rule-in or rule-out fracture, medical collateral ligament damage, and cubital tunnel disorders, there is no evidence for or against the use of diagnostic tests for lateral epicondylitis (LE), proximal median nerve entrapment or radial nerve entrapment syndromes.

### The Literature-Based Clinical Core

- Supine elbow-extension may be helpful in making decisions about possible fracture at the elbow.
- The moving valgus-stress test is good at ruling-out MCL involvement and moderately good at ruling-in.
- Tinel's and elbow flexion are valuable for ruling-in or out cubital tunnel entrapment of the ulnar nerve.
- Range of motion testing is reliable for flexion, extension, and forearm pronation/supination but its

clinical utility is not known.

- There are no studies evaluating the value of tests for lateral epicondylitis.

### **The Expert-Opinion-Based Clinical Core**

- Deformity, crepitus at the radiocapitellar joint, and inability to extend post-trauma suggest the need for radiographs.
- Severe pain with pronation and supination following trauma suggests fracture (if compression injury) and nursemaid's elbow if in a child and distraction is the mechanism.
- Valgus extension testing may provoke pain and crepitus with olecranon joint pathology (especially in athletes).
- Mill's, Cozen's, resisted finger extension, and/or the chair lift test may be valuable for identifying lateral epicondylitis.
- For pronator syndrome, the following may be of value:
  - Resisted forearm pronation with elbow extended, wrist flexed (repeated)
- For supinator syndrome, the following may be of value:
  - Resisted middle finger extension with elbow extended
  - Extreme forearm pronation with wrist flexion
  - Elbow flexion Resisted supination with elbow flexed (repeated)
  - Resisted elbow flexion and forearm supination with elbow fully flexed
  - Resisted finger flexion

## **CHAPTER 9**

# **Wrist and Forearm Complaints**

### **Context**

The wrist is a complex of multiple joints that are required to function as the flexible link between the hand and the forearm. In essence, there are no tendon attachments that function at the wrist. Tendons cross the wrist to insert into the hand, fingers, and thumb. Stability, therefore, is inherently ligamentous. Problems affecting muscles that originate off the elbow and forearm may be manifested clinically as pain at the wrist. Biomechanical friction or inflammatory processes may affect the tendons as they cross the wrist.

Wrist complaints are often the result of direct trauma, falls, overuse, and arthritides. With trauma, the most likely possibilities other than sprains are fractures and instability due to ruptured ligamentous support. Unfortunately, it is far too common for wrist pain to be dismissed as a simple sprain if no fracture is evident radiographically. Varying degrees of instability, however, may occur without associated fracture, and unless the examiner is testing for possible instability or is radiographically focused on the signs of instability, chronic pain and dysfunction may result from mismanagement.

In the athletic and computer operator population, overuse is common. Positions that strain muscles repetitively are likely to result in an insidious onset of wrist pain. Weight lifting, rowing, and racquetball are among the common activities that may overstrain the wrist. Cumulative trauma in the workplace has become an important Occupational Safety and Health Administration concern. Most injury is due to assembly-line movement patterns and computer use.<sup>1</sup> The ergonomics of these overuse problems have been studied extensively, and technologic advances in design have provided a proactive approach to these patients.

When the wrist becomes a weight-bearing joint, injury occurs. Two common scenarios of transformation from a non-weight-bearing joint to a weight-bearing joint are bracing the body for a fall and the chronic demands placed on the gymnast or chiropractor. The injury mechanism for gymnasts is obvious when handstands and other support or balance maneuvers add an element of forced, dorsiflexed weight-bearing, often with torque added.<sup>2</sup> The mechanism for the chiropractor is repeated extension/compression injury with side-posture or double-transverse adjusting. Some chiropractors also experience wrist pain with cervical chair adjusting if the wrist is not kept straight (in neutral).

Forearm pain and wrist pain are often concomitant complaints. With a history of trauma, fracture should be ruled out. Insidious onset of forearm and wrist complaints is often due to overuse. When a complaint of pain is associated with either weakness or numbness/tingling, peripheral nerve entrapment is likely.<sup>3</sup> A history of overuse or misuse is usually evident, often involving repeated pronation/supination or flexion/extension. Patients who are pregnant or have metabolic disorders or rheumatoid conditions are also prone to develop reactions at the wrist, including median nerve entrapment and tendinopathies.

Chiropractors are often confronted with the patient who has been diagnosed with or is suspicious he or she has carpal tunnel syndrome. Carpal tunnel syndrome is a common diagnosis in the United States with an increase in reported cases from the 1980s to the 1990s. More than 200,000 carpal tunnel release procedures are performed each year in the United States. The direct medical costs are estimated at \$1 billion per year.<sup>4</sup> It is hoped that through proper evaluation, differentiation from other causes of hand pain and numbness, and initial conservative management, this financial impact may be lessened.

## General Strategy

### History

- Clarify the type of complaint.
  1. Is the complaint one of pain, stiffness, looseness, crepitus, or a combination of complaints?
- Clarify the mechanism if traumatic (see **Table 9-1**).
  1. For a fall on an outstretched hand, consider scaphoid fracture, carpal instability, and/or distal forearm fractures; for patients younger than age 12 years, consider epiphyseal damage or torus fracture.
- Determine whether the mechanism is one of overuse.
  1. In what position does the patient work?
  2. Does the patient perform a repetitive movement at work or during sports activity?

### Evaluation

- With trauma, palpate for points of tenderness and obtain radiographs to evaluate possibility of

fracture/dislocation or dissociation.

- If radiographs are negative for fracture, challenge the ligaments of the wrist, in particular the scapholunate (Watson's test) and the lunotriquetral (ballottement test) articulations; if unstable include stress views to the radiographic series.

**Table 9-1** Fractures of the Upper Extremity

Fracture Site	Common Mechanisms	Radiographs	Management
Scaphoid	Fall on outstretched hand or blow to an object with the palm (60% to 70% of all carpal bone fractures)	Scaphoid series—PA, lateral, 45° pronation PA, ulnar deviation PA; optional Stecher view (PA, 20° angle from vertical, distal to proximal)	Nondisplaced fracture—cast immobilization including distal interphalangeal (DIP) joint of thumb; change every two weeks; switch to short-arm thumb spica (DIP of thumb not included) at six weeks; displaced—screw or wire fixation
Hamate	Hook of hamate due to striking a stationary object (e.g., golf swing hits the ground)	Carpal tunnel view and 45° supination oblique; computed tomography (CT) may be necessary	Excision of fragment in older patient; adolescents—initial trial of cast (short arm cast with fourth and fifth metacarpophalangeal joints in flexion include base of thumb); no union after six weeks, needs excision of fragment
Triquetral	Dorsiflexion or direct trauma; impingement of the ulnar styloid into the triquetrum (second most common carpal fracture)	Routine series including obliques	Nondisplaced fracture—short arm cast with mild extension for four weeks; displaced—open reduction and wired
Capitate	Forced dorsiflexion of the wrist	Routine radiographs; check for associated scaphoid fracture	Nondisplaced fracture—cast immobilization for six to eight weeks; displaced—open reduction and wired
Trapezium	5% of carpal fractures; due to direct blow or forced extension of the transverse arch	Routine wrist views plus carpal tunnel and a Bett's view of the carpometacarpal (CMC) joint; CT may be needed	When associated with a dislocation or subluxation of the CMC joint reduction, excision of any fragments and casting are required
Pisiform	Direct trauma to the hypothenar eminence	Pisiform view (lateral view with wrist in 30° of supination); check for injury to distal radius	Immobilization in short arm cast; 30° of flexion and mild ulnar deviation for four to six weeks
Kienbock's	Shear stress due to ulnar minus variance leads to avascular necrosis of the lunate from repetitive activity or direct trauma in a young patient	Visible on routine views; gradual progression to lunate sclerosis with collapse and intercarpal arthritis	Surgery is an option; cast immobilization considered useful in some cases. Ulnar lengthening or radial shortening is used. All surgical correction leads to restricted wrist motion.
Distal radius: Galeazzi	Distal radial fracture with dislocation or subluxation of the distal radioulnar joint (6% of forearm injuries)	Radiographic clues are fracture at ulnar styloid base, dislocation/subluxation of ulna on true lateral view, and shortening of the radius 5 mm relative to the distal ulna	Compressive plate fixation with a minimum of five screws
Distal ulnar: Monteggia's	Fracture of the ulna with associated dislocation of the radial head; fall on an outstretched hand with forearm forced into pronation or a direct blow	AP and true lateral elbow; radial head dislocation is missed 16% to 52% of the time	Closed reduction and long arm cast with forearm in supination with children. Adolescents and adults require internal fixation of ulna with a compression plate; radial head is a closed reduction.
Capitellum	Often associated with a medial collateral ligament injury	AP and true lateral view	Open reduction and internal fixation; if more severe, excision of fragments
Coronoid	Rare	Best seen on a true lateral	Surgical fixation
Radial head	Common fracture; fall on an outstretched hand with the forearm pronated	Radial-capitellum view is the most specific	Immobilization sometimes requires surgical fixation

- When the injury is nontraumatic, challenge the musculotendinous attachments with stretch, contraction, and a combination of contraction in a stretched position.
- When trauma or overuse is not present, evaluate the patient's wrist for swelling and deformity (discrete nodules are likely ganglions, deformities are likely arthritides: osteoarthritis [OA] or rheumatoid arthritis [RA]).

## **Management**

- If radiographs are negative for fracture or dissociation but there is a high level of suspicion, place a soft cast on the patient for two to three weeks and reradiograph in two weeks to determine callus status.
- Refer fracture/dislocation and dissociation for orthopaedic management.
- All other soft tissue and articular disorders may be managed for a two- to three-month trial treatment period if necessary.

## **Relevant Anatomy and Biomechanics**

The wrist, as the connection between the hand and the forearm, requires a demanding degree of sophisticated movement. As always, this tradeoff of increased movement is somewhat compromised by lack of strong muscular support. Although there are many interosseous ligaments that support and connect individual carpal bones, there is relatively little or no muscular support, save the support provided by tendons on their way to finger/hand attachment. As a result, when the ligamentous support is

damaged, muscular support is less effective than it might be in other joints.

There is an inherent imbalance of the muscles controlling the hand and wrist. The flexors are stronger than the extensors. Few movements require the strength of the extensors; however, the flexors are required for gripping, and from an evolutionary protective standpoint, for survival. As a result, activities that do require extensor activity often result in strain.

The carpal bones have been functionally divided various ways by different investigators, yet the basic division is into a distal row (trapezium, trapezoid, capitate, and hamate) and a proximal row (scaphoid, lunate, triquetrum, and pisiform). Extrinsic (connection between the radius/ulna and carpals or metacarpals) and intrinsic (carpal to carpal) ligaments provide support.<sup>5</sup> The primary extrinsic support is from the volar intracapsular ligaments. Posterior intracapsular ligaments are thinner and less supportive. Intrinsic support is an intricate overlapping of different length ligaments. The short intrinsic scapholunate, lunotriquetral, and capitoulunate are the most important. Disruption of any of these ligaments will result in a destabilizing effect, allowing independent movement of other carpals. Because these intrinsic ligaments are shorter than the extrinsic ligaments, the reserve ability for stretch is less, leaving them more likely to be damaged.<sup>6</sup> The radius absorbs approximately 80% of an axial load; the ulna, 20%.<sup>7</sup>

The proximal and distal rows of carpal bones function together to provide a variety of precision maneuvers of the hand and fingers. With ulnar deviation, the triquetrum moves under the lunate, which dorsiflexes, taking the lunate with it; the scaphoid follows. With radial deviation, the scaphoid, lunate, and triquetrum move into palmar (volar) flexion while the distal carpal row dorsiflexes. Coupling between the proximal and distal carpal rows is guided by the scaphoid. With ligamentous damage, carpal bones are

uncoupled, allowing some bones to become intercalated (unconnected).

The triangular fibrocartilage complex (TFCC), which consists of the triangular fibrocartilage (articular disc), the meniscus, the ulnar collateral ligament, the dorsal and volar radioulnar ligaments, and the extensor carpi ulnaris tendon, stabilizes the ulnar side of the wrist.<sup>8</sup> Although anatomically on the ulnar side, this complex is extremely important for stability of the radiocarpal joint. The TFCC is usually an intact structure well into age 30 years or older; however, in gymnasts the rate of degeneration is quite high.<sup>9, 10</sup>

TFCC perforations (traumatic or degenerative) and avulsions may occur with repetitive weight-bearing or, more rarely, in a single traumatic event. A predisposition to TFCC injury appears to be related to ulnar length. *Ulnar variance* is the term used to describe the relationship between the distal ends of the radius and the ulna. When the ulna extends past what is in essence a parallel line drawn across the distal radius, positive variance is demonstrated. Palmer and Werner<sup>11</sup> found that 81% of subjects with a positive variance had perforations of the TFCC whereas only 17% of those with negative variance had perforations. Fatigue fractures and Kienbock's disease (avascular necrosis) of the lunate have been associated with a negative ulnar variance. Hypermobility and forceful repetitive wrist motions seem to be the other significant cofactors.

Muscular control of the wrist is dependent on a muscle mass that arises from the elbow and proximal forearm (**Figures 9-1 A, B, and C; Figure 9-2**). Because of the need for carpal bone mobility, the insertion of the extensors is primarily on the metacarpals. The primary flexors of the wrist are the flexor carpi ulnaris and flexor carpi radialis. Each also will assist in deviating the wrist toward the named direction (i.e., radialis toward the radial direction). The rotatory movements of pronation and supination are primarily forearm movements, with the wrist along for the

ride. The primary pronators are the pronator teres and pronator quadratus. Pronation is more effective with the elbow straight, due to prestretch, and therefore there is a mechanical advantage for the pronator teres. Supination is accomplished by the supinator muscle and the biceps brachii. Supination is more effective with the elbow flexed because of the mechanical advantage of the biceps with flexion and the prestretch of the supinator with flexion.

**Figure 9-1** The three layers of the flexor muscles of the forearm.

**Figure 9-2** Extensor muscles of the forearm.

Neural control of wrist movement is via the radial, median, and ulnar nerves. Wrist extension and supination are due primarily to the radial nerve. Flexion of the wrist is divided between the ulnar and median nerves. Pronation is primarily dependent on median nerve innervation. Entrapment of each of these nerves or its branches will result in weakness of related muscles, numbness/tingling, or pain in the distribution of the respective nerve. The classic entrapment neuropathy of the wrist is carpal tunnel syndrome; however, entrapment may occur proximal to the

carpal tunnel, mimicking carpal tunnel syndrome. Patients who complain of numbness/tingling, weakness, or forearm pain should be suspected of having peripheral nerve entrapment, or if bilateral, a systemic neuropathy (e.g., diabetic neuropathy).

## Evaluation

### History

Careful questioning of the patient during the history taking can point to the diagnosis (**Table 9-2**).

### Pain Localization

The following are possible causes of pain based on location (**Figure 9-3** A, B, and C; **Table 9-3**):

- Anterior
  1. Traumatic—lunate dislocation, radial fracture, hook of hamate fracture, or distal forearm fracture
  2. Nontraumatic—median or ulnar nerve entrapment
- Posterior
  1. Traumatic—navicular fracture (anatomic snuffbox), carpal dissociation, or distal forearm fracture
  2. Nontraumatic—de Quervain's syndrome, intersection syndrome, extensor tendinitis, carpal subluxations, radial nerve entrapment

### Traumatic and Overuse Injuries

With trauma, the main concern is ruling out fracture or dislocation. This requires various radiographic imaging approaches. Determining which standard radiographic views to include is based in large part on the specific area of pain, swelling, or deformity. In addition, the mechanism of injury may suggest a specific possibility. Following are some common injury patterns and potential sites of damage (also see [Table 9-1](#)):

**Table 9-2** History Questions for Wrist and Forearm Complaints

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Did you fall on an outstretched hand?	Fracture, dislocation, ligamentous instability	Is there pain on the thumb side of your wrist? Is there any painful popping or clicking? Is there any swelling or deformity at the wrist?	Scaphoid fracture likely Ligament instability Distal radial or ulnar fracture; lunate dislocation
Did the pain begin after repetitive activity?	Tendinitis, peripheral nerve entrapment, trigger points	Do you have any associated numbness, tingling, or sense of weakness? Is the pain on the thumb side of the wrist?	Peripheral nerve entrapment de Quervain's or intersection syndrome is likely
Is the complaint mainly stiffness or restricted movement?	QA, other arthritides such as pseudogout	Is there swelling in the joint? Have you had any past injuries or surgeries to the wrist? Is the pain worse in the morning and improved with activity?	Synovitis, traumatic or arthritic Posttraumatic or surgical adhesion or accelerated OA OA likely
Is there a chief complaint of weakness?	Painful process, neurologic cause	Does it hurt to grip objects?  Are there associated signs of numbness or tingling?  Is the weakness worse with overhead activity?	Often associated with fracture and TFC damage Neural involvement may be local at carpal tunnel, entrapment of motor nerve such as anterior interosseous, or from nerve root compression at the neck Thoracic outlet syndrome or shoulder instability likely
Do you have any known disorders such as diabetes, hypothyroidism, or arthritis?	Diabetes or hypothyroidism may predispose the patient to carpal tunnel syndrome	Do you have a diagnosis of any arthritis or pain in other joints?	Bilateral or symmetric joint involvement suggests an RA or connective tissue problem

- Fall on an outstretched hand. Axial loading usually occurs to the ulnar, palmar side of the wrist, creating compressive and shearing forces. Common injuries

include scaphoid and distal radius fractures, scapholunate and lunotriquetral ligament damage leading to varying degrees of instability, and triangular fibrocartilage injury at the ulnar side of the wrist.

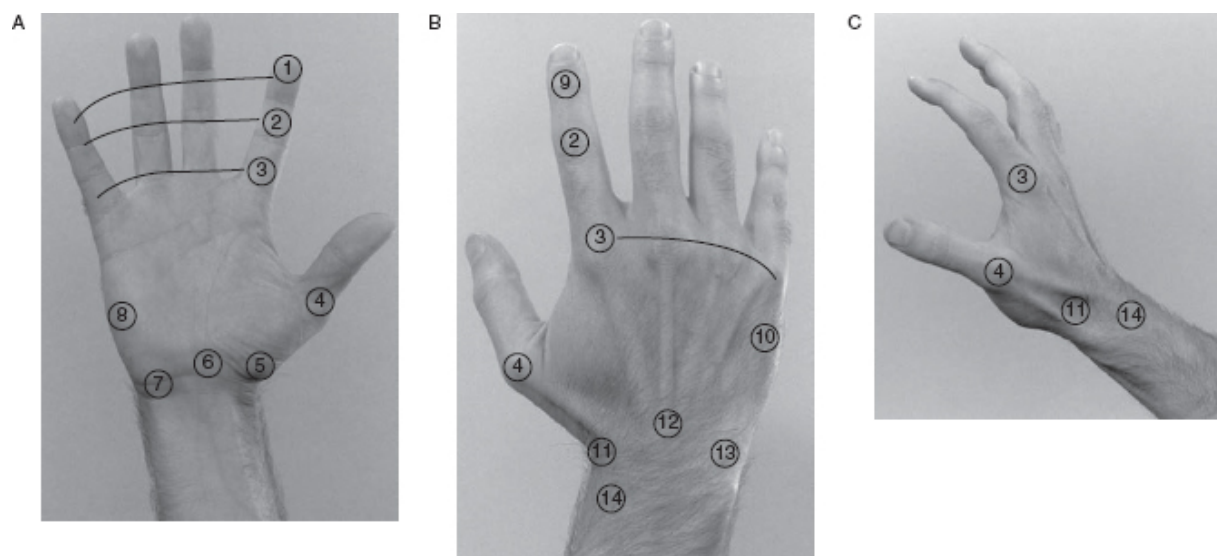

- Fall on a flexed hand. Compression injury occurs to the flexor (palmar) wrist with avulsion or stretch injury to the dorsal wrist. Structures involved are similar to those involved in dorsiflexion injuries, with slightly different fracture patterns; in addition, dorsal capsule avulsion may occur.

Accumulative trauma may occur when the wrist is used as a weight-bearing or partial weight-bearing joint. Commonly, the dorsal aspect of the wrist is irritated, leading to various degrees of dorsal impaction syndromes. Local synovitis, hypertrophied and/or pinched synovium, and osteocartilaginous fracture are possible with dorsal impaction.

## **Weakness**

Weakness may be present for several reasons. Most commonly, a patient will report pain as the limiting factor with gripping. If the pain is well localized or a specific movement other than gripping is weak and painful, a specific anatomic structure may be detected through palpation and specific testing.

**Figure 9-3** (A) Anterior wrist and hand; (B) posterior wrist and hand; (C) radial wrist and hand.

**Table 9-3** Wrist and Hand Pain Localization

#	Structures	Overt Trauma	Insidious or Overuse
1	Flexor digitorum profundus (FDP) insertion	Avulsion of FDP, fracture of distal phalanx	Psoriatic arthritis
2	Proximal interphalangeal (PIP) joint	Capsular sprain or dislocation at PIP	RA, OA, psoriatic arthritis, Reiter's syndrome
3	Metacarpophalangeal (MCP) joint	Dislocation, collateral ligament sprain, capsular sprain	Mild capsular sprain, OA, trigger finger (on palmar surface)
4	First MCP joint	Dislocation, gamekeeper's thumb (ulnar collateral ligament sprain)	OA, bowler's thumb (digital neuritis), trigger thumb
5	First metacarpal base, abductor pollicis longus insertion	Bennett's fracture/dislocation	de Quervain's tenosynovitis
6	Carpal tunnel, lunate	Lunate dislocation, dissociation, subluxation	Carpal tunnel syndrome (palpation/pressure point)
7	Flexor carpi ulnaris, ulna	Distal ulna fracture or dislocation	Tendinitis
8	Pisiform/hamate, tunnel of Guyon	Hook of hamate fracture	Tunnel of Guyon compression of ulnar nerve
9	Distal interphalangeal (DIP) joint and distal phalanx	Fracture of distal phalanx, mallet finger (avulsion of extensor tendon)	Psoriatic arthritis
10	Metacarpals	Metacarpal fracture	Subluxation or extensor tendinitis
11	Anatomic snuff-box, abductor pollicis longus (APL), extensor pollicis brevis (EPB) of the thumb	Scaphoid fracture, radial styloid fracture	de Quervain's, Wartenberg's syndrome (entrapment of radial sensory nerve)
12	Lunotriquetral joint, extensor tendons	Lunotriquetral dissociation, dislocation, distal	Ganglion, lunate subluxation, extensor tendinitis
13	Ulnar styloid process, extensor carpi ulnaris (ECU) tendon	Ulnar styloid fracture	ECU tendinitis or tendon subluxation
14	Intersection of extensor tendons and APL, EPB	Distal radial fracture	Intersection syndrome, RA

*Note:* See [Figure 9-3](#) for localization of numbered areas.

Most patients with a complaint of weakness will indicate some difficulty with gripping activities. Reid<sup>12</sup> categorized these activities. The two main grip maneuvers are power grip and precision grip. Each grip maneuver requires the strength and coordination of specific joints and muscles. By determining the specific grip that feels weak (often painless), the examiner may focus on potential neural involvement. A list of specific grip patterns and the main muscle/nerve control for that grip follows (also consider nerve root involvement when associated with neck and arm pain):

- Power grip includes grasping a ball, bat, bottle, or briefcase. The ulnar nerve is important for this grip as the primary innervation for the ulnar aspect of the wrist, for both flexion and sensation.
- Precision grip includes holding a pen, a key, or fingertip-to-thumbtip maneuvers. The median nerve is important for this grip as the primary innervation to the radial side of the wrist.

The thumb may be important for stability with both grip patterns and is supplied by both the median and ulnar nerves. Opening of the hand from the grip position or extension is largely dependent on the radial control of extensor action.

## **Instability**

Instability may be associated with a sense of weakness. It may also be the misinterpretation of a sense of clumsiness that is more suggestive of a neural cause. Finally, the patient may assume instability exists because of constant popping and clicking about the wrist; however, clicking and

popping are not necessarily pathologic unless accompanied by pain.

## **Restricted Motion**

Restriction of both active and passive range of motion should raise the suspicion of joint effusion. With trauma, the suspicion is fracture or dislocation as the underlying cause. Without a history of trauma, it is more likely that an inflammatory arthritis is the cause. End-range passive restrictions are suggestive of subluxation.

## **Superficial Complaints**

One of the most common superficial complaints is the presence of painful nodules on the dorsal or volar wrist. A history of chronic repetitive motion is often found, which suggests the mostly likely diagnosis—ganglions. It is also common to find a history of fluctuation in size over time. A classic presentation with established RA is multiple nodules and swelling over the dorsum of the wrist associated with wrist pain and stiffness.

Skin lesions, when isolated to the wrist, are more likely an indication of a systemic process such as rheumatic fever (erythema marginatum) or RA. Associated signs or symptoms of each disease should be sought.

<b>Examination</b>
--------------------

## **Wrist**

Examination of the wrist is a standard procedure involving observing for deformities and swellings, palpating for areas of tenderness, stressing of ligamentous structures for instability, testing range of motion with overpressure, testing muscle, and palpating accessory motion. By combining these findings with the history, a preliminary working diagnosis can usually be determined.

Orthopaedic testing of the wrist focuses mainly on carpal instability due to stretching or disruption of interosseous ligaments. Positive test results include a combination of popping or clunking with pain. Painless pops and clicks are common and do not represent pathologic damage or a source of a patient's wrist pain. Tests include the following:

- Watson's test (**Figure 9-4**) for scapholunate stability. The examiner presses the scaphoid from anterior (volar) to posterior (dorsal) with the wrist first in ulnar deviation. By moving the wrist passively into the radial direction, a painful clunk or pop may be produced, indicating that the proximal pole of the scaphoid subluxated over the posterior rim of the radius.
- Lunotriquetral ballottement (**Figure 9-5**) test. The examiner stabilizes the lunate between the thumb and index finger and does the same with the triquetrum. A shearing between the bones is accomplished by moving the bones in opposite directions (i.e., the lunate is forced posteriorly while the triquetrum is forced anteriorly). A painful clunk or pop is indicative of lunotriquetral joint instability.
- Midcarpal instability. By having either the patient actively or the examiner passively pronate and ulnar deviate the wrist, a painful pop is felt on the ulnar aspect of the wrist. This indicates midcarpal instability.
- Axial load testing. The examiner applies an axial load through the first metacarpal of the thumb and the trapezium while adding a shear force. Fracture or joint

arthrosis often will result in painful crepitus with this maneuver.

- **Dynamometer testing.** Although the dynamometer is most often used when trying to measure the degree of strength loss with a nerve root or peripheral nerve entrapment or compression, when a past history of wrist trauma is elicited, dynamometer testing may reveal weakness due to instability.

**Figure 9-4** Watson's test for scapholunate dissociation. The radius is stabilized while the tubercle of the scaphoid is pushed from anterior to posterior. The wrist is then passively moved from ulnar deviation into radial deviation. A painful clunk or pop is a positive finding.

**Figure 9-5** The ballottement test for lunotriquetral dissociation. The examiner stabilizes the lunate while shearing the triquetrum. A positive finding is the production of a painful clunk or pop.

Soft tissue assessment of the wrist is based on a combination of palpation at the sites of insertion of major tendons, coupled with contraction, stretch, and contraction in a stretched position. For example, for the extensors carpi radialis longus and brevis, one or a combination of the following will usually increase the patient's pain complaint:

- Stretching into flexion and ulnar deviation
- Contraction from the above position into radial deviation and wrist extension
- Palpation over the second and third metacarpals dorsally

By simply applying this approach to the remainder of tendons crossing the wrist, soft tissue involvement of a specific tendon is usually made apparent. A specific test involving the stretching concept is Finkelstein's test (**Figure 9-6**) for de Quervain's syndrome.<sup>13</sup> The patient is asked to clench the fingers over the thumb. The examiner then

passively ulnar deviates the wrist, taking care not to press on the metacarpophalangeal joint of the thumb. Although this maneuver is uncomfortable, it is usually not painful. Compare results with those for the opposite (hopefully uninvolved) side. This maneuver illustrates some general orthopaedic testing principles. Although the intent is to stretch the abductor pollicis longus and the extensor pollicis brevis, the position also stretches the superficial branch of the radial nerve (Wartenberg's syndrome), the flexor carpi radialis (tendinitis), and the extensors carpi radialis longus and brevis (intersection syndrome) and compresses the scaphoid (scaphoid fracture) and the metacarpophalangeal joint of the thumb (arthritis). Localization of pain and tenderness coupled with mechanism of injury should differentiate among these possibilities.

**Figure 9-6** Finkelstein's test for de Quervain's tenosynovitis. The patient grasps the thumb while the examiner passively ulnar deviates the wrist. Pain at the radial wrist is a positive finding when it is notably more than the opposite wrist pain response.

---

## Forearm/Wrist

Patients who present with either forearm pain or forearm pain with associated hand or wrist numbness/tingling or weakness should be evaluated for peripheral nerve entrapment. Each of three peripheral nerves (median, ulnar, and radial) may be compressed or entrapped at several sites. Depending on the site of entrapment, motor weakness or sensory abnormalities may be found specific to the nerve. In addition, if the site of entrapment is a fibrous band or hypertrophied muscle, provocative maneuvers focused on these contractile and noncontractile structures may reproduce or worsen the patient's subjective complaints. Following are some common tests, structural sites of entrapment, and findings specific to a peripheral nerve or its branches.

## **Median Nerve Pronator Syndrome**

The median nerve may be compressed or entrapped at several locations proximal or local to the pronator teres. The most proximal site is the ligament of Struthers, an anomalous ligament that connects to the supracondylar process of the distal medial humerus. This is a rare anomaly occurring in only 1% of individuals.<sup>14</sup> Another site is entrapment at the lacertus fibrosus (bicipital aponeurosis) as it attaches to the pronator teres muscle. The most common entrapment sites are between the two heads of the pronator teres and also at the arch of the flexor digitorum superficialis. Hypertrophy or fibrous bands are the cause in most cases. Each site may be localized with specific positional testing.

- Lacertus fibrosus or ligament of Struthers: Symptoms of proximal forearm aching pain with possible hand

pain may be provoked by resisted elbow flexion at 120° to 130° with supination.<sup>15</sup>

- Pronator teres: Resisted pronation with wrist flexion may increase symptoms of proximal forearm pain; passive stretching of the proximal forearm with the elbow and wrist extended or direct deep palpation of the pronator teres may provoke symptoms.<sup>16</sup>
- Flexor digitorum superficialis: Resisted flexion of the middle finger may increase forearm pain symptoms.

## Anterior Interosseous Syndrome

Compression of the motor branch of the median nerve may cause proximal forearm pain and thumb and finger weakness.<sup>17</sup> Numbness and tingling complaints and objective sensory loss are not found. Weakness may occur in the flexor pollicis longus, pronator quadratus, and flexor digitorum profundus of the second and third fingers. The result is an inability to perform the “OK” sign of tip-to-tip apposition of the thumb and index finger.<sup>18</sup> With weakness the patient presses pulp to pulp and cannot flex enough to contact the thumb and fingertips. Motor nerve compression can cause an aching pain because these peripheral nerve branches carry sensory fibers to the joints and muscles, and occasionally to skin receptors. Entrapment may be due to anomalous vessels or muscle slips; however, the most common sites are at the pronator teres and flexor digitorum superficialis muscles after the median nerve has given off the anterior interosseous motor branch.

*Carpal tunnel syndrome:* The median nerve passes through the carpal tunnel formed by the transverse carpal ligament superiorly, the pisiform-hamate bones medially, and the navicular-trapezium bones laterally. The carpal

tunnel contains the flexor tendons for the fingers and thumb and occasionally anomalous vessels or muscles such as the palmaris longus. Pressure in the tunnel is increased with swelling in the tunnel or the extremes of flexion or extension. Symptoms include numbness and paresthesias over the radial three and one half digits with sparing of the thenar eminence. Weakness or clumsiness in gripping may be reported. Eventually thenar atrophy may occur. Sensory symptoms are reproduced with several provocative tests:

- Tinel's sign: Tapping over the carpal tunnel at the wrist may elicit distal feelings of numbness or paresthesias (sensitivity, between 60% and 74%; specificity, 80%).<sup>19</sup>
- Phalen's test: Forced passive flexion at the wrist (pressing the backs of the hands together) or reverse Phalen's with forced passive extension (palm to palm) may elicit symptoms (sensitivity, between 49% and 64%; specificity, 55%).
- Pressure provocative test: Instead of tapping, direct pressure with a cuff or with thumb pressure at the carpal tunnel will elicit symptoms (sensitivity, close to 100%).<sup>20</sup>

## **Ulnar Nerve Cubital Tunnel Syndrome**

The ulnar nerve is rarely trapped in the fascia covering the triceps and an aponeurosis called the arcade of Struthers or at the ulnar groove. Entrapment more frequently occurs in the tunnel just distal to where the ulnar nerve travels through the posterior condylar groove on the medial epicondyle of the humerus.<sup>21</sup> The floor consists of the medial trochlea and the ulnar collateral ligament; the roof consists of the triangular arcuate ligament that bridges the

origins of the flexor carpi ulnaris (FCU). With flexion the arcuate ligament stretches, narrowing the tunnel, and the proximal edge of the FCU tightens; the ulnar collateral ligament can then bulge into the tunnel.<sup>22</sup> Excessive valgus angulation from throwing or acute trauma may stretch the nerve. Provocative tests<sup>23</sup> include the following:

- Holding the elbow flexed between three and five minutes
- Tinel's tapping sign at the posterior elbow (this is inconsistent; however, it is occasionally helpful if compared with the opposite side)
- Possible snapping or popping of the nerve with rapid extension or flexion (subluxating the ulnar nerve)

## **Ulnar Tunnel or Tunnel of Guyon Syndrome**

At the wrist the ulnar nerve (and artery) pass through an osseofibrous tunnel formed by the groove between the pisiform and hook of the hamate. The floor is the pisohamate ligament; the roof is an extension of the FCU tendon. The ulnar nerve divides into a superficial nerve that is primarily sensory and a deep nerve that is exclusively motor. Sensory supply is to the fifth and ulnar half of the fourth digit. Motor supply is primarily to the hypothenar muscles, all the interossei, two medial lumbricals, the deep head of the flexor pollicis brevis, and the abductor pollicis.<sup>24</sup> Anastomosis between the ulnar and median nerve may lead to mixed findings. Provocation testing is with Tinel's sign or pressure at the pisiform hamate area (just distal/medial to the pisiform). Sensory testing also should be performed.

*Radial Nerve. Radial tunnel syndrome (RTS):* At the elbow the radial nerve lies on the anterior capsule just lateral to the lateral epicondyle. It then passes between the two heads of the supinator muscle. Prior to entering the supinator muscle the radial nerve can be compressed by

fibrous bands off the anterior radial head, the sharp medial edge of the extensor carpi radialis brevis (ECRB), a fan-shaped vascular arcade, and the arcade of Frohse (the thickened edge of the superficial head of the supinator).<sup>25</sup> Provocative maneuvers and related sites of entrapment include the following:

- ECRB—resisted middle-finger extension with the elbow extended (positives found also with lateral epicondylitis) or extreme forearm pronation with passive wrist flexion
- Radial head—resisted elbow flexion and forearm supination
- Arcade of Frohse—extreme forearm pronation with passive wrist flexion

## **Posterior Interosseous Nerve Syndrome (PINS)**

The literature often overlaps the description of RTS and PINS. RTS is considered more a mixed-nerve syndrome, with wrist or forearm pain as the main patient complaint. PINS is considered a pure entrapment of the motor branch of the radial nerve.<sup>26</sup> Testing is specifically searching for weakness in wrist extension or thumb and index finger extension. Compression of the posterior interosseous nerve may also occur at the distal radius.<sup>27</sup> Pain is often reproduced with forceful wrist extension or palpating the forearm with the wrist flexed.

*Cheiralgia paresthetica (Wartenberg's syndrome).*<sup>28</sup> The superficial radial nerve is susceptible to trauma between the tendons of the extensor carpi radialis longus (ECRL) and the brachioradialis. Trauma or repetitive pronation and supination may cause irritation. The patient's complaints are mainly numbness and paresthesia over the dorsolateral wrist and hand. Finkelstein's test is usually negative;

however, Tinel's test performed over the dorsolateral wrist may reproduce the symptoms.

---

## Imaging

Radiographic decision making for the wrist is dictated by the degree of trauma or whether there is any suspicion of arthritis involvement based on the history and physical examination. Some common examples follow:

- A combination of anatomic snuff-box tenderness in a patient with a history of a fall on an outstretched hand suggests scaphoid injury. A scaphoid series includes a posteroanterior (PA) view, a true lateral view, a 45° pronation PA view, and an ulnar deviation PA view.<sup>29</sup> Another view that may be helpful is the Stecher view.<sup>30</sup> This is a PA shot with an angle of 20° to the vertical, angled from distal to proximal. When suspicion is high but no fracture is evident, additional angled views may help catch the fracture line. Initially, radiographs are often unrevealing even when a fracture is present. When the suspicion is high yet radiographs are negative, immobilization for two to three weeks in a thumb spica cast is recommended, followed by a second radiographic evaluation. Most fractures become apparent at this time. If immediate determination is necessary because of a particular patient's high level of use (e.g., professional athlete) a bone scan should be performed at three days postinjury. A negative bone scan rules out fracture.<sup>31</sup> Computed tomography (CT) scans may also be beneficial in equivocal presentations.
- If a patient has joint line tenderness coupled with a history of a fall on a dorsiflexed hand and a positive Watson's test (scapholunate dislocation or subluxation), ballottement test (lunotriquetral

dissociation), or midcarpal stability test (midcarpal instability), respectively, is likely. The lateral view will show a disrelationship between the radius, lunate, capitate, and third metacarpal. Two patterns may be evident: the dorsal intercalated segmental instability (DISI) pattern or the volar intercalated segmental instability (VISI) pattern (sometimes called PISI). These instability patterns are based on the position of the lunate in relationship to the radius. Several angles can be measured; however, the most common is the scapholunate angle, which normally ranges between 30° and 60°; greater than 70° indicates scapholunate dissociation. If not evident statically, stability or stress views should be added. These include the clenched fist (AP) view or a traction view, lateral views in flexion and extension, and anteroposterior (AP) views in radial and ulnar deviation.<sup>32</sup>

- A combination of trauma to the pisiform with local tenderness coupled with any sensory abnormalities into the fourth and fifth fingers is suggestive of a hook of hamate fracture. The PA view may demonstrate subtle signs such as absence of the hook or cortical ring or sclerosis in the area of the hook.<sup>33</sup> A carpal tunnel view and/or a 45° supinated oblique view is suggested.<sup>34</sup> When these views are unrevealing yet the suspicion is high, referral for a CT scan is warranted.<sup>35</sup>

## Management

- Referral for orthopaedic consultation or management is necessary for fractures, dislocations, and carpal dissociations.
- Entrapment or compression syndromes may benefit from a conservative approach employing myofascial

release and/or bracing and patient education regarding modification of the inciting activity.

- Tendinitis not associated with an inflammatory arthritis is best managed with conservative care emphasizing rest, ice, cross-friction massage to the tendon, or myofascial release to the respective muscle. On occasion, splinting may be necessary. An eccentric exercise program may also be useful.
- Caution should be exercised when using soft-tissue approaches to inflammatory arthritis problems. Referral to a rheumatologist may be necessary.

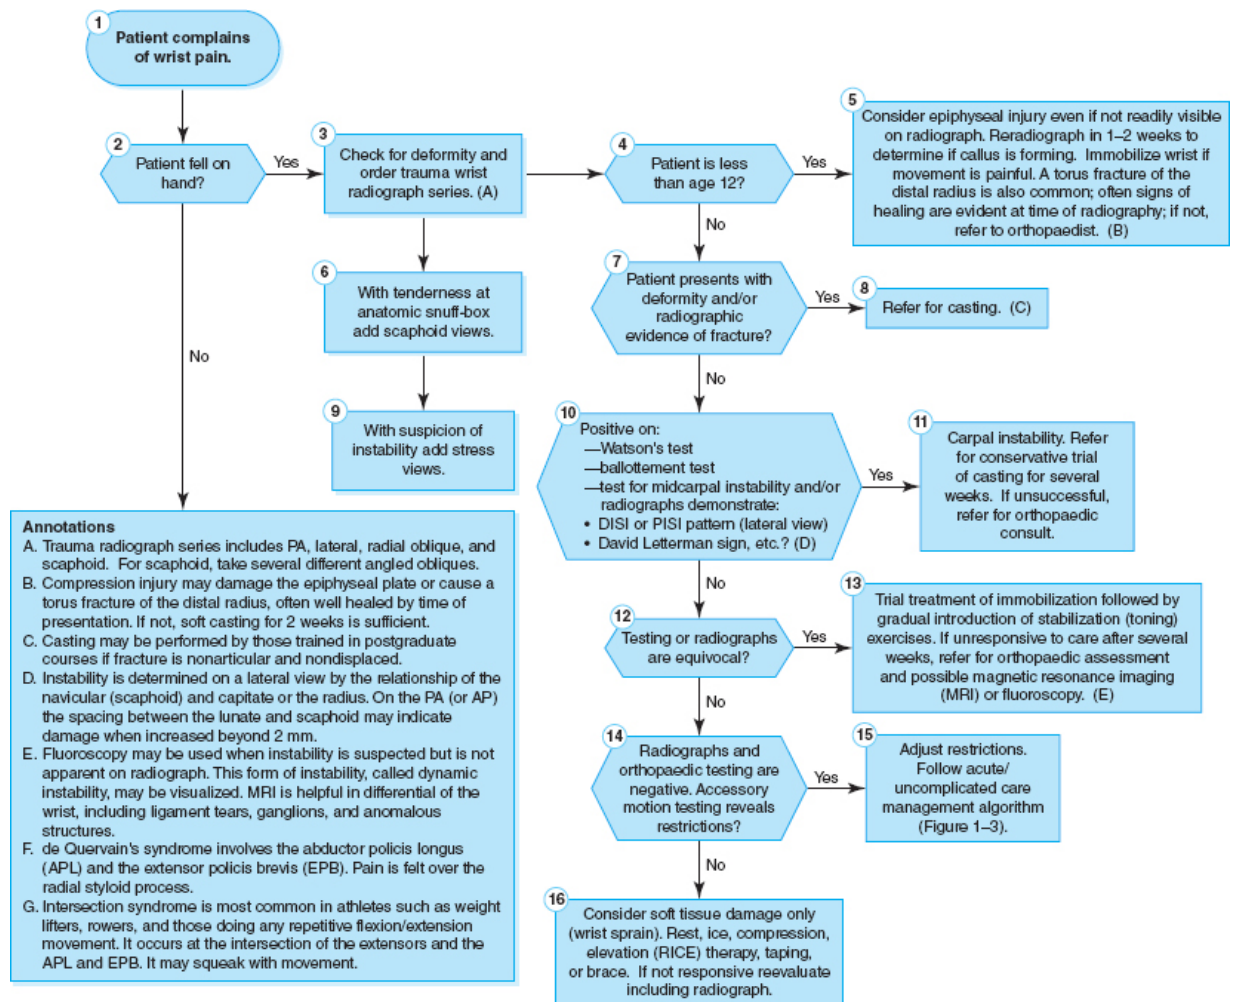

The CCGPP Upper Extremity Team expert opinion supports the use of high-velocity, short-amplitude (HVSA) manipulation (adjustment) of the wrist with some recommendations for use that include avoidance of risk. Further evaluation and/or management is required for patients who fail to respond to treatment within a reasonable period of time.

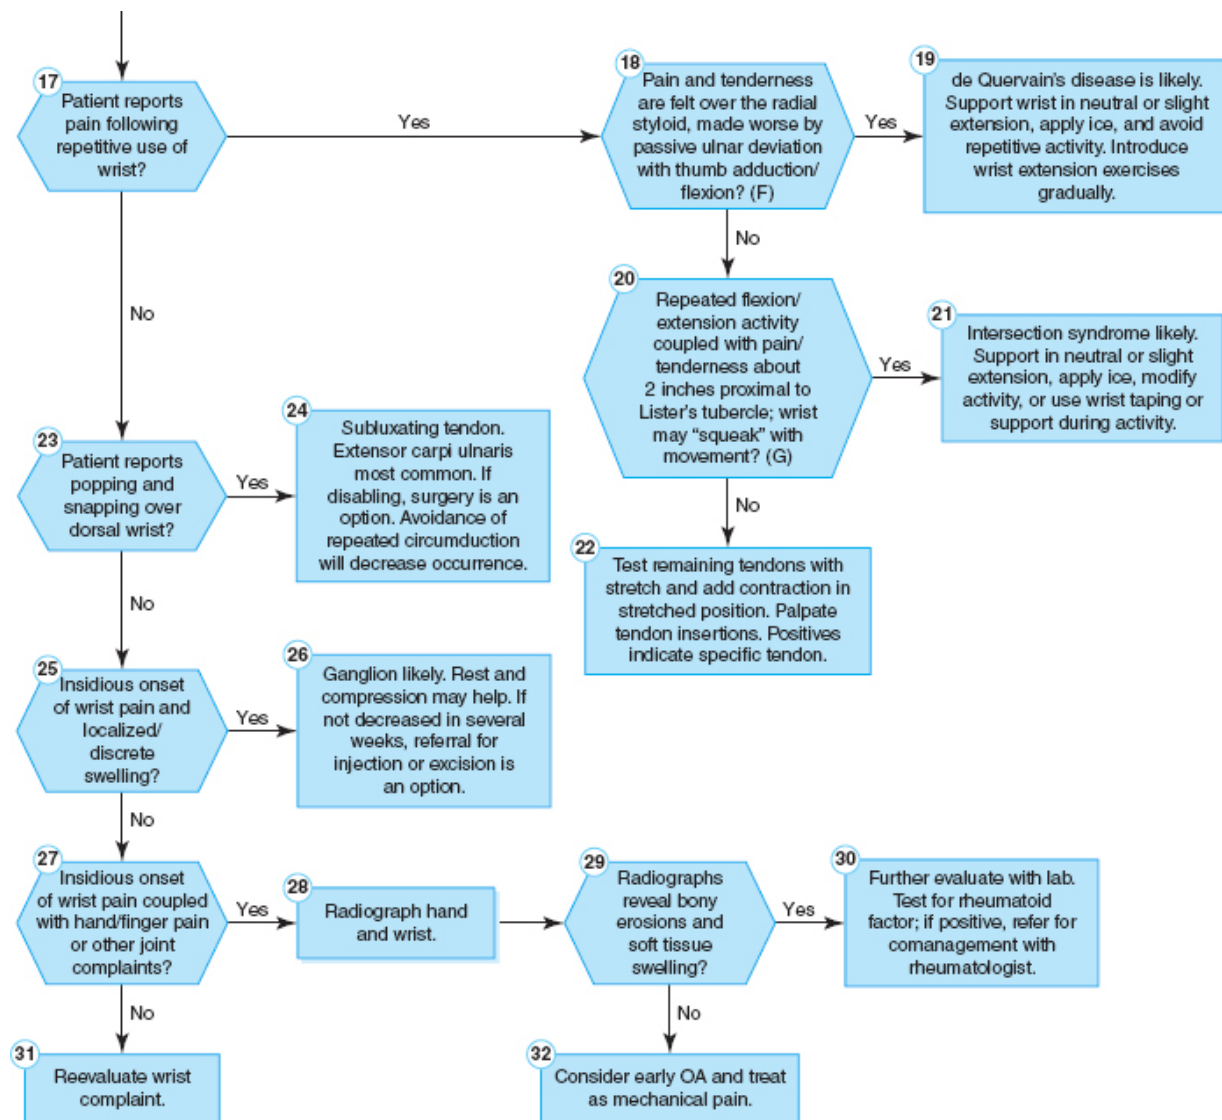

- For all patients who have fracture, suspected fracture, dislocation, active hemarthrosis or extensive swelling, severe generalized or localized osteoporosis, infection, or tumor HVSA manipulation is contraindicated.
- For patients who have had surgery of the wrist/hand, consider date of surgery, extent of surgery, type of procedure, and other related factors in making decisions about the use of HVSA manipulation.
- For all patients, an evaluation of joint stability must be performed. Based on the findings, it is recommended that no HVSA manipulation be used for patients with dissociation (i.e., instability), hypermobility syndromes (e.g., Marfan's, Ehlers-Danlos syndrome), or gross looseness indicating multidirectional instability. Mobilization such as applying a Maitland Grade I-IV

type of translational movement may be appropriate in these case settings.

## Algorithm

An algorithm for the evaluation and management of wrist pain is presented in **Figure 9-7**.

**Figure 9-7** Wrist Pain—Algorithm

# Selected Disorders of the Wrist and Forearm

## INSTABILITY

### Scapholunate Dissociation

## Classic Presentation

The patient complains of radial or dorsal wrist pain following a fall on an outstretched hand.

## Cause

By falling onto the thenar eminence, the wrist is forced into hyperextension, ulnar deviation, and intercarpal supination, which forces the capitate between the scaphoid and lunate.<sup>36</sup> The result is tearing or stretching of the scapholunate interosseous and radioscaphoid ligaments, which leads to various degrees of instability.

## Evaluation

The standard stability test is Watson's.<sup>37</sup> With the patient's arm relaxed, the wrist is taken passively into ulnar deviation. The examiner presses the distal pole posteriorly as he or she passively moves the wrist into radial deviation. A painful pop or click will occur as the proximal pole is forced to subluxate dorsally. This subluxation occurs because the dorsal force of the examiner on the scaphoid prevents its normal ability to move into a vertical position.

When evaluating instability of the wrist radiographically, AP, lateral, and oblique views are supplemented with an AP clenched-fist view and, if needed, a lateral view taken in flexion and extension.<sup>38</sup> Scapholunate dissociation appears on the PA or AP as a 3-mm or greater space between the lunate and the scaphoid; it is sometimes referred to as the Terry Thomas<sup>39</sup> or David Letterman sign. In addition, there is a vertical orientation to the scaphoid that also creates a cortical overlap, referred to as the signet ring sign. On the lateral view, a DISI pattern may be visible.<sup>40</sup> Normally, the scaphoid is angled between 30° and 60°. Angulation greater than 65° to 70°, coupled with a

dorsiflexed lunate, indicates dissociation (lack of stability between the scaphoid and lunate).

## Management

Surgery is usually necessary.

### Triquetrolunate Dissociation

## Classic Presentation

The patient may report a fall on either a palmar-flexed or hyperpronated wrist. Some patients present with only dorsal ulnar wrist pain and a nontraumatic history.

## Cause

Stretching or disruption of the lunotriquetral ligaments allows palmar subluxation of the lunate.

## Evaluation

The standard orthopaedic evaluation involves the ballottement test.<sup>41</sup> This test is performed by stabilizing the lunate or triquetrum and “shucking” or shearing the other bone against the stabilized bone. A painful pop is considered a positive test.

Radiographic evaluation is usually normal. However, with a static instability a PISI (also known as VISI) deformity on the lateral wrist view is seen. The PISI pattern is palmar subluxation of the lunate and scaphoid with a dorsiflexed triquetrum. When the radiographs are negative for instability, either fluoroscopic evaluation or an arthrogram is necessary to reveal an underlying dynamic instability.

## Management

If the ballottement test is positive, but radiographs are negative, initial treatment is immobilization in a long arm cast for six to eight weeks (wrist in ulnar deviation and dorsiflexion). If instability is radiographically evident (static instability), there is some disagreement as to management. Some

practitioners suggest surgery; others suggest repositioning of the lunate and scaphoid followed by immobilization.

## **Triquetrohamate Instability (Midcarpal)**

### **Classic Presentation**

A patient may present with a history of a fall or blow to the medial (anatomic) side of the hand with hyperpronation. Some patients may have wrist pain without a specific traumatic event.

#### **Cause**

Ligamentous tearing disrupts the osseous coupling between the hamate and triquetrum.

### **Evaluation**

Reproduction may occur on either passive or active pronation coupled with ulnar deviation. Unfortunately, a host of other ulnarsided problems may also respond with a painful click,<sup>42</sup> including TFCC damage, lunotriquetral ligament tears, and distal radioulnar subluxation. Axial compression may also produce a click with midcarpal and other instabilities. Radiographic evaluation is usually normal. With a static instability, a DISI pattern may be visible. Videofluoroscopic evaluation is most sensitive, often revealing a sudden movement of the proximal carpal row from the normal PISI pattern in radial deviation to a DISI pattern near the end-range of ulnar deviation.

### **Management**

Initially, immobilization may be effective for six weeks. If ineffective in reducing instability or pain, various forms of surgery are recommended.

## **Triangular Fibrocartilage Injury**

### **Classic Presentation**

A patient presents with pain on the ulnar side of the wrist made worse by pronation and supination. She or he may have a traumatic history such as a fall on an outstretched hand or no obvious trauma.

# Cause

The TFCC is the fibrocartilaginous structure at the distal end of the ulna. It is part of the complex that supports the ulnar side of the wrist. The TFCC is injured through several mechanisms that result in either perforations (traumatic and degenerative) or avulsions. Degenerative changes occur by the third decade. Other factors include the poor blood supply limited to the peripheral 15% to 25% of the disc<sup>43</sup> and the association of ulnar positive variance (along ulna) that causes compression and thinning of the TFCC.

# Evaluation

To differentiate between damage to the distal radioulnar joint (DRUJ) and the TFCC, the examiner may stabilize the radius and ulna by compressing them together proximal to the DRUJ. Passive movement of the forearm into pronation and supination should be uneventful if only the TFCC is involved. Second, ulnar deviation, axial loading, and shearing distal to the DRUJ often will produce pain and crepitus when the TFCC is damaged. Radiographic evaluation is largely an attempt to determine whether the patient has positive ulnar variance. For standardization it is recommended that the PA film be taken with 90° of elbow and shoulder flexion with the hand as flat as possible.<sup>44</sup> A line drawn perpendicularly across the distal end of the radius should be even with the distal ulna. Referral for an arthrogram or magnetic resonance imaging (MRI) may confirm the diagnosis of TFCC damage.

# Management

Initial management is to immobilize the wrist in neutral for several weeks, obviously avoiding any ulnar deviation or compression maneuvers subsequent to splint removal. Failure to resolve requires arthroscopic evaluation and repair that includes resection of the distal ulna.

## TENDINITIS/TENDINOSIS

### de Quervain's Tenosynovitis

## Classic Presentation

A patient presents with a complaint of radial wrist pain with a history of activities that require either forceful gripping with ulnar deviation or repetitive use of the thumb.<sup>45</sup>

## Cause

Stenosing tenosynovitis of the abductor pollicis longus (APL) and extensor pollicis brevis (EPB) occurs as a result of chronic microtrauma to either the tenosynovium or sheath.<sup>46</sup>

## Evaluation

Pain is reproduced with resisted thumb extension with the wrist in radial deviation or with the standard Finkelstein test.<sup>47</sup> The Finkelstein test begins by having the patient grasp his or her thumb with the same side fingers. The examiner passively deviates the wrist ulnarly. Tenderness is often found 1/2 inch proximal to the radial styloid.

### Management

Initially, a conservative trial of activity modification, ultrasound, and nonsteroid anti-inflammatory drugs (NSAIDs) should be attempted. Failure to improve within two to three weeks requires immobilization with a thumb spica for another two to three weeks. If ineffective, referral for local steroid injection should be made. Rarely, surgery is needed.

## Intersection Syndrome

## Classic Presentation

A patient (often an athlete) presents with a complaint of pain and crepitus two inches or so above the wrist on the dorsoradial aspect. There is usually a history of repeated flexion/extension movement with either occupational or sports activity.<sup>48</sup>

## Cause

An inflammatory response and possible adventitial bursitis occur at the crossing of two groups of tendons: the APL and EPB crossing over the wrist extensors. This condition is more common in canoeists, weight lifters, and recreational tennis players.

## Evaluation

There is usually tenderness and swelling 4 to 6 cm proximal to Lister's tubercle.

## Management

Rest, NSAIDs, and ice may help initially. Myofascial release techniques applied proximal to the tendon crossing may also be of benefit. If unsuccessful, splinting for two weeks may help enforce a rest period. Prevention includes modification or elimination of the inciting activity.

## Other Tendinopathies

Following is a list of tendinopathies/tendinosis and the patient population most often associated with each:

- Extensor pollicis longus tendinitis/tendinosis—seen in drummers, athletes involved in racquet sports, and patients with rheumatoid arthritis.
- Extensor indicis proprius syndrome and extensor digiti minimi tendinitis/tendinosis—due to trauma and overuse.
- Extensor carpi ulnaris tendinitis/tendinosis—relatively common tenosynovitis found in occupations or sports requiring repetitive wrist movement such as racquet sports, rowing, golf, and baseball. The tendon has its own sheath separate from the extensor retinaculum, which may rupture following forced supination, flexion, and ulnar deviation. This will lead to a painful snapping over the back of the wrist.

## Evaluation

Palpation of the tendon or its insertion is usually painful, and there may be associated swelling. Full stretching of the tendon or contraction in a stretched position may reproduce the patient's complaint.

## Management

Avoidance of the inciting activity coupled with myofascial release of the involved muscle may be helpful. If ineffective, a short period of soft cast immobilization may be necessary. For patients with RA, referral for medical management is prudent.

## PERIPHERAL NERVE ENTRAPMENTS MEDIAN NERVE

# Carpal Tunnel Syndrome

## Classic Presentation

The patient presents with a complaint of pain and numbness/tingling in the palmar surface of the thumb and radial two and one half fingers; the symptoms are worse at night that may be relieved by shaking the hand (Flick sign). The patient typically complains of clumsiness with precision gripping.

## Cause

The median nerve runs through an osteofibrous tunnel created by the transverse carpal ligament and carpal bones. Although direct compression from ganglions, fractures, and dislocations is possible, it is more common to have a history of direct external pressure on the tunnel or a history of prolonged wrist use in full flexion or extension. Pressure inside the tunnel increases in these extreme positions. Additional factors may have to do with fluid retention, as in pregnancy, RA, diabetes, and connective tissue disorders. Patients deficient in B vitamins may be predisposed. The prevalence of CTS is not entirely clear. The most often quoted percentage is 3.7% from a population-based study by Atroshi et al.<sup>49</sup> One of the lowest reported prevalence is by Katz et al.<sup>50</sup> and Levine et al.<sup>51</sup> at 1%. The range, however, is between 0.7% to 9.2% for women and from 0.4% to 2.1% for men in the general population.<sup>52-54</sup> Certainly in some high-risk populations, this percentage is higher<sup>55-57</sup> with a prevalence as high as 61%. Tanka's<sup>58</sup> study on self-reported CTS indicated that approximately 0.5% of the population has been diagnosed with CTS. Atroshi<sup>49</sup> found that obesity is associated with an increased incidence of CTS. They found that women in their forties and fifties are four times more likely to suffer from CTS than men. Further confusing the identity, and therefore management, of CTS is the variable and unpredictable course. Some studies<sup>59</sup> indicate a cyclic, unpredictable occurrence of "silent" periods alternating with periods of exacerbation. Other studies<sup>60</sup> indicate spontaneous improvement without management. There is strong evidence for an association between exposure to a combination of risk factors and CTS. Carpal tunnel syndrome is an important contributor to work-related healthcare costs. There was some concern when the U.S. Department of Labor, Bureau of Labor Statistics reported a tenfold increase in the number of disorders "associated with repeated trauma" between 1981-1991.<sup>61</sup> CTS is reported as the most frequent of these disorders.<sup>62</sup> There was some speculation about the introduction of computer use including keyboard and mouse usage. Recent studies contradict the assumption of a causative relationship to keyboard use. The evidence points to a combination of highly repetitive work or, in combination with forceful work, and work involving hand

and wrist vibration. Specifically, risk is high for work that demands intensive manual exertion<sup>58, 63</sup> such as automobile assembly, meatpacking, and poultry processing, but not necessarily frequent computer users (when compared to the general population).<sup>53</sup> There is no evidence in published literature at this time between posture and CTS.

## Evaluation

There is no clear “gold standard” for the diagnosis of CTS. Although the clinical examination is used as a standard which is then often “confirmed” by electrodiagnostic (ED) studies, it is clear that there is overlap among other neurological conditions and that ED studies may produce false positives and false negatives for patients with CTS.<sup>64</sup> A recent study<sup>65</sup> emphasizes that the relationship between ED findings and patient symptoms and function are independent measures and may not be related. More confounding is that the sensitivity and specificity for ED has been based on the standard of a positive clinical evaluation, such as a positive Tinel’s sign. This is worrisome considering the convincing evidence in the Kushner et al.<sup>66</sup> review questioning the value of Tinel’s sign and of Phalen’s test that clearly demonstrated a wide range of sensitivity and specificity. Sensitivity for Phalen’s ranged from 40% to 88% with an overall average sensitivity of 60% or 80% dependent on the inclusion of a study by Posch et al.<sup>67</sup> Specificity was 80% overall. Tinel’s sign had an overall sensitivity of 49% with the Posch<sup>19</sup> data and 64% without. Overall specificity was 55%. On the other hand a more recent review by Lajoie et al.<sup>68</sup> applies a different statistical approach to determine the sensitivity and specificity of these commonly used tests. The authors claim that latent class analysis is necessary if there is no reference standard (gold standard). In other words, if there is an assumption that the reference test is 100% sensitive and specific, underestimation may occur when evaluating other tests in comparison. With that approach, these authors reevaluated Tinel’s and Phalen’s and found them to be highly sensitive (0.97 and 0.92, respectively) and specific (0.91 and 0.88, respectively). The sensitivity and specificity of nerve conduction velocity testing was 0.93 and 0.87, respectively. A systematic review and narrative review by MacDermid et al.<sup>69, 70</sup> are somewhat intermediate to the conclusions drawn in the Lajoie and Kushner reviews. They agree with Kushner<sup>66</sup> stating that the quality of many of the studies was poor. The overall estimate for Phalen’s was 68% for sensitivity and 73% for specificity. Tinel’s estimated sensitivity was 50% and specificity, 77%. The carpal compression test had estimates of 64% and 83% for sensitivity and specificity, respectively. Specific, but not sensitive, were two-point discrimination testing and atrophy or testing of strength of the abductor pollicis brevis.

A prospective study by Nora et al.<sup>71</sup> demonstrated a wide range of findings that seemed to vary based on overlapping disease and patient subjectivity. Out of a total of 1,528 hands that were diagnosed with CTS, the severity was

considered mild in 42% of cases, moderate in 18%, and severe in 40%. Patients had a female-to-male predominance of 5.6:1. Symptoms were restricted to the hand and wrist in 51.8% of cases with paresthesia and in 18.5% of cases with pain. In 92.5% of the partially affected hands, paresthesia was present in at least one of the three first fingers, while pain affected the three first fingers in 78.8% of these hands. Matching to the Katz's hand diagram revealed a classic pattern in 12.6% of affected hands with a pattern rated as probable CTS in 66.3%. Tinel's and Phalen's sign were positive in 34.2% and 56.3% of these hands, respectively.

- A patient diagram called the Katz diagram is valuable in establishing the location and extent of the patient's hand complaint (**Exhibit 9-1**).<sup>72</sup> There are three diagrams that the patient can match including classic, probable, and unlikely. The classic is not what most would assume based on the classic description. It illustrates symptoms that are quite diffuse involving all fingers and thumb on both surfaces and forearm involvement also on posterior and anterior aspects. Classic is >2 out of digits 1, 2, 3; no palm involvement but radiation into forearms allowed as part of description. Probable is >2 out of digits 1, 2, 3; however, the palm is involved. Possible is >1 out of digits 1, 2, 3; palm is involved. Unlikely is 0 out of digits 1,2,3 with possible medial palm involvement. The "unlikely" pattern illustrates more ulnar nerve involvement.

#### **Exhibit 9-1 The Katz Diagram**

Reproduced from Katz JN, Stirrat C, Larson MG, et al. A self-administered hand symptom diagram in the diagnosis and epidemiologic study of carpal tunnel syndrome. *J Rheumatol.* 1990;17:1495-1498.

D'Arcy et al.<sup>73</sup> performed a systematic review of history taking and physical examination for diagnosing CTS, and used ED testing as the comparative standard. In the studies that met the inclusion criteria, the following were indications of the value of history and physical examination findings confirmed by ED testing:

- Hypalgesia in the median nerve territory (LR, 3.1, 95% CI, 2.0-5.1)
- Classic or probable Katz hand diagram<sup>74</sup> results (LR, 2.4, 95% CI, 1.6-3.5)
- Weak thumb abduction strength (LR, 1.8, 95% CI, 1.4-2.3)

Findings arguing against CTS were:

- Unlikely Katz hand diagram results (LR, 0.2, 95% CI, 0.0-0.7)
- Normal thumb abduction strength (LR, 0.5, 95% CI, 0.4-0.7)
- Some standard tests such as Phalen's and Tinel's signs, thenar atrophy, and nocturnal paresthesia had little or no diagnostic value for positive ED test findings.

It is important to note that the degree or severity of CTS in these patients was likely beyond that seen by many primary care physicians or chiropractors. These were patients seen by orthopaedic surgeons, physical therapists, and ED laboratories, further questioning the value of these standard clinical examination approaches in less severe cases. With regard to nerve conduction studies, a sensitivity and specificity analysis was performed in a study by Lew et al.<sup>75</sup> in 2005. The results indicate that measurement of a single short-nerve segment tended to be superior to results obtained by either long-segment studies, or differential subtraction between two segments of the same nerve. Short-segment, onset-latency transcarpal mixed NCV yielded the highest sensitivity (75%).

## Management

Both the surveys by Bernard<sup>63</sup> and Andersen<sup>76</sup> clearly demonstrated no association between keyboard use and CTS. However, there is still some question regarding mouse usage and CTS. On the other hand, the Verhagen et al.<sup>77</sup> Cochrane systematic review indicated some evidence for the effectiveness of some specific types of keyboards for patients with CTS.<sup>78</sup> Evidence for expensive ergonomic interventions was not clearly demonstrated in their review. In Cochrane reviews on nonsurgical management of CTS by Verdugo et al.<sup>79</sup> only two RCTs met the criteria for inclusion. One by Garland<sup>80</sup> was published in 1964 when surgical treatment would be different from current standards. The other study by Gerritsen<sup>81</sup> compared splinting to surgery for the management of CTS. Both studies produced evidence in favor of surgery. However, while the Gerritsen study showed a statistically significant advantage for surgery, it also demonstrated a CI that was quite low and close to nonsignificant with an RR of 1.38 (95% CI 1.08–1.75). The surgery rated in this study was an open carpal tunnel release, which would currently not be the standard.

Newer studies indicate that 90% of CTS patients fully recover within a few weeks after surgical release of the carpal tunnel, whereas only between 30% and 70% of CTS patients fully recover with conservative interventions within a few weeks to a few months.<sup>82</sup> The standard of conservative care is nocturnal neutral splinting or a cock-up splint worn for several weeks to determine effect. It is important to make an early referral for EDS and/or specialist consult if related to the workplace environment if: (1) symptomatic for over 6–12 months prior to claim acceptance, as conservative care is less likely to benefit; (2) time-loss exceeds two weeks; or (3) significant improvement, including ability to work, is not attained within the first several weeks of conservative care.<sup>82</sup>

It is clear that the term manipulation is not synonymous with an “adjustment” or Grade V mobilization. Only one randomized controlled trial by Davis<sup>83</sup> evaluated chiropractic management versus usual medical care. Even this study is not specific to manipulation/adjustment of the wrist including manipulation of the spine as part of the overall management. In both Cochrane reviews on conservative management of CTS by O’Connor<sup>84</sup> and

Verdugo,<sup>79</sup> the Davis study was included, but the conclusions reached were inconsistent. This is partly due to the different outcome measures used, but also because the determination was to focus on whether chiropractic management was of benefit beyond usual medical care. The Davis study, in fact, indicated that in the short term, both approaches were essentially equal. The improvement reported was in perceived comfort and function, and nerve conduction and finger sensation overall, but showing no significant differences between groups. In the Davis study, medical treatment consisted of medication and nocturnal wrist supports. Chiropractic treatment included nocturnal wrist support, myofascial massage/loading, and ultrasonography in addition to “manual thrusts” to the wrist and spine. No other high-quality studies on chiropractic management were found other than case reports.<sup>85</sup>

In addition to manipulation/mobilization for carpal tunnel syndrome, chiropractors may utilize other management approaches including wrist supports/splints, ultrasonography, and/or B6 vitamins (pyridoxine). Other approaches that have been studied include laser therapy, nerve/tendon gliding/stretching, or yoga. In the O’Connor<sup>84</sup> Cochrane systematic review, all of the above approaches were evaluated for evidence. In the Verdugo<sup>79</sup> Cochrane review, only splinting was compared to surgery.

**Table 9-4** Conservative Management of Carpal Tunnel Syndrome

Parameter	Acute Stage	Subacute Stage	Symptom-Free Stage
Criteria	Numbness/tingling in palmar thumb, index, and radial half of middle finger; positive Tinel's, Phalen's, or compression test.	Frequency of numbness/tingling event is decreasing.	No complaints with moderate daily use of wrists; limited work activity does not provoke symptoms.
Goals	Reduce any internal swelling, decrease pain or numbness/tingling frequency.	Gradually retrain patient to perform activities with less stress to carpal tunnel; wean patient off daytime use of support.	Maintain proper ergonomic work environment; wean patient off night support.
Concerns	If condition progresses, atrophy of thenar muscles is likely and the need for surgery increases; patient may have irritation of the median nerve at more proximal sites; patient with diagnosis from other doctor may not have carpal tunnel syndrome.	Patient is unable to avoid aggravating activities or shows signs of progression.	Patient returns to work activities without proper ergonomic support.

<b>Requirements for progression to next stage; approximate time needed</b>	Improvement of frequency and intensity of numbness/tingling complaint; no progressive atrophy of thenar muscles; 1–3 weeks.	Able to perform daily activities (without brace) with minor symptoms; 2–3 weeks.	No symptoms with work activity; 2–3 months.
<b>Manipulation/mobilization</b>	Adjustments of the lunate and radioulnar articulation may help; evaluate the cervical spine for possible fixation.	Adjustments of the lunate and radioulnar articulation may help; evaluate the cervical spine for possible fixation.	Adjustments of the lunate and radioulnar articulation may help; evaluate the cervical spine for possible fixation.
<b>Modalities</b>	Ice, rest, electromyographic stimulation (bipolar for 20 min/d with ice; 80–120 Hz first few days, 1–150 Hz next few days, 1–15 Hz next few days).	Underwater ultrasound at 1.5–2 wt/cm <sup>2</sup> for 5–7 minutes; ice after strengthening exercises for 10 minutes.	Ice after exercises.
<b>External brace, support, etc.</b>	Consider use of splint in neutral or slight extension.	Continue use of splint, gradually decreasing daytime use.	Continue night splinting if necessary; attempt gradual reduction of use.
<b>ROM/flexibility massage</b>	Mild stripping massage to flexor and extensor groups of muscles.	Grade 3 or 4 myofascial release to extensors or flexors based on findings.	Maintain flexibility with mild postisometric relaxation technique.
<b>Open-chain exercise</b>	Mild isometrics in pain-free ranges with focus on extension.	Isometrics progressing to isotonic exercises with a focus on wrist extensors, pronators, and supinators; flexor exercises should be performed but not emphasized.	Continue isotonic exercises on an every-other-day routine for maintaining wrist strength and preventing recurrence.
<b>Associated biomechanical items</b>	Evaluate the patient's work posture, especially with keyboard and mouse positions and padding; attempt to isolate provoking maneuvers or positions.	Follow-up of modification of workstation for patient; gradually introduce patient to activity beginning with short periods of work and frequent rest periods.	
<b>Lifestyle/activity modifications</b>	Avoid activities that compress the anterior wrist, such as wrist-supported typing, use of a mouse, or activities that require lifting; this may require a work restriction request to the patient's employer. Decrease salt intake; consider use of B6 with a B-complex vitamin; consider use of bromelain or NSAIDs.	Continue to avoid postures that compress the anterior wrist or force the wrist into hyperflexion or extension; avoid carrying heavy objects or repeated pronation supination.	

Splinting has been used as a treatment approach for CTS with the theoretical purposes of both preventing use and also decreasing pressure within the carpal tunnel. Additional variations include neutral/extension splinting and nocturnal versus full-time usage. Braces/splints can be custom-made or stock. The findings in the Verdugo<sup>79</sup> systematic review are similar to other reviews such as Gerritsen,<sup>86</sup> D'Arcy,<sup>73</sup> and Feurstein,<sup>87</sup> and RCTs such as Gerritsen<sup>81</sup> that indicate outcomes that favor surgery. Gerritsen's RCT indicated that at the end of an 18-month follow-up, 41% of patients in a splint group had eventually resorted to surgery. However, in this prospective evaluation for splinting, Gerritsen et al.<sup>81</sup> found a 31% success rate for splinting. Only two prognostic indicators were identified. For patients with both a short duration of CTS complaints (one year or less) and a score of 6 or

less for severity of paresthesia baseline at night, the predicted probability of success was 62%. The percentage of patients correctly identified by this model was 78% (95% CI, 69–87%).

Ultrasonography was evaluated in two trials, one by Ebenbichler<sup>88</sup> and the other by Oztas,<sup>89</sup> which demonstrated that two weeks of treatment was not beneficial. However, these trials did demonstrate significant improvement following seven weeks of treatment. A newer study using dexamethasone demonstrated improvement with phonophoresis.<sup>91</sup> Interestingly, O'Connor pooled the data for these studies even though one trial used continuous ultrasound while the other used pulsed-ultrasound. In the Goodyear-Smith<sup>90</sup> systematic review of nonsurgical management for CTS, they conclude that the Ebenbichler and Oztas studies provide conflicting evidence with a high drop-out rate. They state that there is limited evidence for ultrasonography in the short- and medium-term (up to six months). A more recent study supports this finding.<sup>93</sup> Numerous approaches may be included in the conservative management of CTS. The evidence is limited for each.

- B6—Two RCTs on the effects of 10–12 weeks of vitamin B6 therapy have been evaluated.<sup>94,95</sup> There is limited evidence for improvement of finger swelling and movement discomfort with 12 weeks of treatment. However, there is also limited evidence that B6 does not improve any of the symptoms or signs of CTS.
- One study by Akalin et al.<sup>95</sup> on nerve/tendon gliding exercises compared these exercises to wrist splint only, or wrist splint combined with the exercises. Although there was some improvement with static two-point discrimination, there was no advantage over wrist-splint-only treatment for improving hand symptoms and signs.
- One study by Garfinkel et al.<sup>96</sup> evaluated yoga stretching as compared to wrist splinting for CTS. There was limited evidence that yoga improved pain and decreased Phalen's sign findings better than wrist splinting. There was limited evidence that yoga and wrist splinting were similar in providing short-term improvement with Tinel's sign, grip strength, and nocturnal awakening.
- There is limited evidence that low-level laser treatment has not been shown to have an advantage over a sham laser treatment.<sup>98</sup> More recent studies show mixed results in other joints.

## **Pronator Syndrome**

### **Classic Presentation**

The patient presents with a complaint of volar forearm pain. There is usually no history of trauma; however, there is often a history of repetitive pronation and wrist flexion such as incurred by carpenters, assembly line workers, and weight lifters.

# Cause

Compression may occur at several sites, including the bicipital aponeurosis (lacertus fibrosus) that connects with the pronator teres, between the two heads of the pronator teres, and at the flexor digitorum superficialis by a thickened, fibrotic arch. Compression between the heads of the pronator is often due to hypertrophy. Other (rarer) sites are beneath the ligament of Struthers (supracondylar arch), the median artery, and a bicipital tuberosity bursa.<sup>99</sup>

# Evaluation

- Reproduction of the patient's complaint is based on a direct or an indirect search for the compression site.
- Provocation with resisted elbow flexion and supination with maximum elbow flexion implies the lacertus fibrosus or less often the ligament of Struthers.
- Provocation with resisted pronation, keeping the elbow extended and the wrist flexed, suggests pronator teres compression (hypertrophy common).
- Provocation with resisted middle finger flexion suggests that the site of compression is the flexor digitorum superficialis. When the lacertus fibrosus is involved, active pronation may reveal indentations in the pronator teres. Direct pressure over the pronator teres often will reproduce symptoms. Electrodiagnostic studies are of little value.

# Management

Initial management involves a trial of myofascial release and/or rest. If unresponsive to myofascial release after two to three weeks, splinting for two to three weeks may be necessary. If symptoms persist beyond six months, surgical exploration may be necessary.

## Anterior Interosseous Syndrome

# Classic Presentation

The patient presents with a complaint of anterior proximal forearm pain that occurred either acutely after a single violent forearm muscle contraction or from repetitive activity. There is an associated complaint of weakness, usually

isolated to pinch of the thumb and index finger and usually within 12 to 24 hours after the onset of pain.

### **Cause**

Compression sites are similar to those for pronator teres syndrome; however, they are most commonly at the flexor digitorum superficialis or deep head of the pronator teres. At these sites, the anterior interosseous nerve, a motor branch of the median nerve, is compressed or entrapped. It may also be seen with stingers (acute stretch injuries to the brachial plexus) or after an interscalene block.

## **Evaluation**

Inability to pinch the tips of the thumb and index finger together results in a pulp-to-pulp pinch. This is due to weakness of the flexor pollicis longus (FPL) and index finger flexor digitorum profundus (FDP). The pronator quadratus may be weak when tested with resisted forearm pronation with full elbow flexion. On occasion, there may be weakness of the hand intrinsics due to a Martin-Gruber anastomosis, which is found in 15% of the population (connection between median and ulnar nerves). Electrodiagnostic studies are considered the gold standard with denervation of the FPL and index finger FDP and pronator quadratus.

## **Management**

Conservative treatment should be attempted for up to eight weeks, at which time surgery should be considered. Conservative care involves myofascial release, rest, and anti-inflammatory medication.

### **ULNAR NERVE**

#### **Cubital Tunnel Syndrome**

## **Classic Presentation**

The patient presents with a complaint of medial forearm pain and paresthesia into the ring and little finger. There is often a history of activities, such as throwing, that medially stretched the elbow.

### **Cause**

Compression or stretch may cause irritation of the ulnar nerve. Stretch is usually due to valgus force to the elbow. Compression may be at the two heads of the flexor carpi ulnaris or may be due to osteophytes in the cubital tunnel. Less common causes include lipomas, ganglions, and anomalous soft tissue structures. Pressure in the tunnel is increased with elbow flexion and wrist extension (threefold), and the cocking position of throwing (sixfold).<sup>100</sup>

## Evaluation

The symptoms are often reproduced by passive or resisted elbow flexion with the elbow in a maximally flexed position. The Tinel's sign is variable and somewhat unreliable. Electrodiagnostic studies are rarely necessary but may be helpful in differentiating among other medial forearm pain syndromes.

## Management

Conservative management includes rest, ice, and anti-inflammatories. In addition, if entrapment is at the flexor carpi ulnaris, myofascial release may be of help. Night splinting with the elbow flexed to 45° in neutral rotation is recommended. Failure of conservative care should warrant a surgical consultation.

## Tunnel of Guyon

## Classic Presentation

The patient complains of numbness/tingling or pain in the fourth and fifth digits.

## Cause

The ulnar nerve may be compressed in the tunnel of Guyon, which is an osseofibrous tunnel formed by the groove between the pisiform and the hook of the hamate. Activities that cause chronic compression at this site may result in ulnar nerve dysfunction. Constant compression on handlebars, as with cyclists, may cause this problem (handlebar or cyclist's palsy). Other causes include vascular abnormalities, fractures of the hook of the hamate, and ganglions.<sup>101</sup>

## Evaluation

Provocation testing includes either Tinel's or pressure at the pisiform hamate area (just distal and medial to the pisiform). Compression may occur at several areas, causing either mixed motor and sensory findings or isolated motor or sensory findings. Sensory testing may reveal abnormalities in the fourth and fifth digits. Two-point discrimination may be affected in the same region. Motor involvement may be evident by testing grip strength. Weakness of the adductor pollicis may be evident with Froment's sign. Grasping a piece of paper between the thumb and the index finger, the patient flexes the distal thumb to substitute for the weak adductor pollicis. Wartenberg's sign is positive when the patient cannot fully adduct all fingers.

## **Management**

Protection with padding and modification of any inciting activity that adds pressure to the area, such as a change in handlebar or bicycle position with cyclists, are usually sufficient. If there is an obvious neural deficit, refer to an orthopaedist when the problem persists for longer than a few weeks.

### **RADIAL NERVE**

#### **Radial Tunnel Syndrome**

## **Classic Presentation**

The patient complains of a dull, aching pain over the lateral forearm.

## **Cause**

There is a disagreement with regard to whether radial tunnel syndrome (RTS) should be considered an entity separate from posterior interosseous nerve syndrome (PINS).<sup>102</sup> The distinction is mainly clinical when entrapment occurs at a site where the PIN is selectively affected, leading to motor findings with no sensory deficits. As the radial nerve enters and traverses the forearm, it may be compressed or entrapped at several locations, including the radial head, the medial edge of the ECRB, a fan-shaped vascular arcade, the arcade of Frohse (thickened edge of the superficial head of the supinator), and the two heads of the supinator muscle.

## **Evaluation**

Tenderness is distal to the lateral epicondyle (approximately four fingerbreadths below the lateral epicondyle). Provocative maneuvers are based on the site of entrapment: ECRB—resisted middle finger extension with the elbow extended; radial head—elbow flexion; supinator muscle—resisted, repeated supination with the forearm flexed; arcade of Frohse—extreme forearm pronation with wrist flexion. Weakness of the wrist extensors is often found when the PIN is involved.

## **Management**

If the syndrome is due to repeated pronation/supination, rest from the activity and modification of the activity are required. Myofascial release technique is particularly helpful when the entrapment is at the supinator muscle. Adjusting the radial head may be of benefit in some cases.

## **Cheiralgia Paresthetica (Wartenberg's Syndrome)**

### **Classic Presentation**

The patient complains of numbness or tingling over the dorsolateral aspect of the wrist and hand.

### **Cause**

The superficial branch of the radial nerve is susceptible to trauma between the tendons of the ECRL and the brachioradialis. Repetitive movements such as pronation and supination are often the cause. Wearing a wrist band or a brace or taping may cause compression. Direct blows to the dorsolateral forearm/wrist may also cause this disorder.

### **Evaluation**

Tinel's sign is often positive over the point of compression at the dorsolateral wrist. Pain may be caused by passive ulnar deviation and flexion of the wrist.

## **Management**

If there is a compressive culprit such as a wrist brace, support, or taping, modify use to avoid compression. If there is a repetitive movement cause, initially rest from the activity and modify the movement to avoid further

irritation. Myofascial release above the area may be helpful; however, release at the area often reproduces the problem.

## **FRACTURES**

### **Scaphoid**

## **Classic Presentation**

The patient presents with pain at the anatomic snuff-box after a fall on an outstretched hand. The patient often is seen three to six months after the trauma.

### **Cause**

An impact injury with the wrist in maximum dorsiflexion (greater than 90°) will fracture the scaphoid. The radial styloid may impact the midportion of the scaphoid. The vascular supply to the scaphoid runs distal to proximal and therefore distal fractures generally heal without incident. Proximal pole fractures, however, usually result in avascular necrosis. Proximal pole fractures account for about 20% of all scaphoid fractures.

## **Evaluation**

The clinical examination is often more revealing than radiographs. There are several tests, including axial compression of the index or middle finger, percussion on the extended thumb, forced dorsiflexion, and resisted pronation. One of the most sensitive tests is to stretch the patient's pronated hand carefully into maximum ulnar deviation. A positive test result is obtained when pain is produced at the anatomic snuff-box. The positive predictive value is 52%.

Although it may appear that radiographs are the definitive tool for detecting a scaphoid fracture, initial films are often negative. In addition, follow-up films (two to three weeks postinjury) are not always helpful. One study<sup>103</sup> indicated an interpretation error of 40%. However, it is prudent to use multiple views, including several oblique films at the time of injury and in two to three weeks. A scaphoid series includes the standard PA, lateral, right and left obliques, and a PA view with radial and ulnar deviation with the fingers flexed. When the suspicion is high but films are unrevealing, a bone scan or CT scan is usually diagnostic.

## **Management**

Initial treatment of nondisplaced fractures is cast immobilization, which includes the forearm and the proximal interphalangeal joint of the thumb. If there is no visible fracture line on initial radiographs, the patient should be managed as if a scaphoid fracture is present when there is a positive scaphoid fracture test, especially if there is any associated swelling at the dorsal radial wrist. Follow-up films are taken in about two weeks with the cast removed. If a fracture is evident, cast immobilization is continued to 8 to 12 weeks. Out-of-cast films are taken in 6 and 12 weeks. If further healing is necessary, continue immobilization for two to four weeks. Referral is necessary if healing is not progressing or if there is a displaced fracture. Another referral scenario is an associated perilunar dislocation where the capitate dislocates off the lunate.

## **Hook of Hamate**

### **Classic Presentation**

The patient presents with pain just distal and radial to the pisiform following impact to the area from a fall, a bat, racquet, or golf club.

### **Cause**

The hook of the hamate is susceptible to direct trauma. A fall on or blow to the hypothenar eminence may result in fracture. The fracture is unstable because of the pull from the flexor carpi ulnaris (through the pisohamate ligament), the opponens digiti and flexor digiti quinti, and the transverse ligament.

### **Evaluation**

Pain is felt 1 to 2 cm distal and radial to the pisiform. Radiographs include the carpal tunnel view and 20° supinated view. When a fracture is not visible but suspected, a bone scan or CT scan may be valuable.

### **Management**

Fragment excision is usually successful, followed by a short arm cast for three to four months.

## **Kienbock's Disease**

# Classic Presentation

The patient presents with a stiff and painful wrist. Often there is no history of trauma.

## Cause

Kienbock's disease is avascular necrosis of the lunate due to a stress or compression fracture. Repetitive minor trauma is suspected as the common initiator.

## Evaluation

Diagnosis is usually difficult until the lunate becomes more radiopaque than the surrounding carpal bones. CT or MRI is more sensitive, yet should be used only when the suspicion is high and radiographic confirmation is equivocal.

## Management

If Kienbock's disease is detected, cast immobilization for about eight weeks is necessary to allow revascularization. When this fails, surgery is used to decompress the area before collapse of the lunate. This may also include osteotomy of the radius to equal out a relatively short ulna. Following collapse, replacement with a prosthetic or autogenous material is used. Intercarpal fusion is the least desirable procedure. One study indicated that conservative care may provide a similar long-term outcome compared to surgery.

## FOREARM

Following is a list of forearm fractures. These fractures are usually due to a fall on an outstretched hand or a blow to the area.

- Monteggia—shaft fracture of the ulna with an associated dislocated radial head.
- Galeazzi—fractured distal radius and dislocated ulna.
- Greenstick—an incomplete fracture, often of both the radius and the ulna, in a skeletally immature patient; healing usually occurs in six to eight weeks.
- Colles'—distal radial fracture with dorsal and radial angulation.
- Smith's—distal radial fracture with volar (palmar) angulation.

## MISCELLANEOUS CONDITIONS

## **Dorsal Impaction Syndrome**

### **Classic Presentation**

The patient presents with a complaint of dorsal wrist pain. There is a history of repeated forced dorsiflexion with some component of concomitant weight-bearing (the two groups most commonly affected are gymnasts and chiropractors).

### **Cause**

Repeated dorsiflexion causes compression of the dorsal wrist structures, leading to a capsulitis and a number of reactive changes, including localized hypertrophic synovitis (meniscoid of the wrist) and osteocartilaginous changes in the dorsal rim of the scaphoid, lunate, capitate, or radius.

### **Evaluation**

Tenderness is found at the middorsal aspect of the wrist, specifically at the lunocapitate area. Unfortunately, unless radiographic changes are evident, there are no indicators other than the history.

### **Management**

Essentially an overuse (and misuse) condition, the dorsal impaction syndrome is managed by avoidance of the offending position, forced dorsiflexion. Blockage of forced passive dorsiflexion can be accomplished by the use of a wrist brace with a limiter such as taping the front of the wrist and forearm or placing padding on the back of the wrist (thick felt or multiple layers of moleskin). Flexion exercises also may be helpful. If ineffective, splinting in a soft cast for two to three weeks may allow healing. For the chiropractor, use of non-weight-bearing adjusting techniques or substitution with other soft techniques for a period of time may be the final answer.

### **Ganglions**

### **Classic Presentation**

The patient presents with a complaint of dorsal wrist pain. Passive dorsiflexion often makes it worse. The patient may have found a small tender nodule or knot. There is usually a history of a repetitive wrist activity occupationally or with sports. Most often, the patient is under age 35 years.

## **Cause**

Ganglions are soft tissue tumors that arise from either the capsule or tendon sheaths. They are most common at the dorsal scapholunate ligament or at the metacarpal heads. Ganglions represent mucinous degeneration into multiple intraligamentous cysts or larger, sometimes palpable cysts.

## **Evaluation**

Unfortunately, not all ganglions are palpable. It has been observed that often the more occult (smaller ganglion), the more symptomatic. Radiographs are useless except to rule out other causes. MRI may be useful.

## **Management**

If the ganglion is visible, an initial attempt at compression to rupture the capsule is sometimes made. However, ganglions tend to reappear unless surgically excised. The need for surgery is based on the degree of discomfort and effect on daily activities, occupation, or sport. Ganglions often fluctuate in size.

# **CHAPTER 10**

## **Finger and Thumb Complaints**

### **Context**

Finger and thumb complaints reflect a wide spectrum of disorders ranging from local pathology to distal manifestations of systemic disease. Local pathology is usually due to trauma. Localization of pain or tenderness coupled with mechanism of injury substantially narrows down the possibilities. Radiographs are usually necessary to discover subtle bone damage not accessible through clinical examination. When a history of trauma is not evident, local finger/thumb pain is often associated with clues of systemwide involvement. Conditions such as arthritides, connective tissue disease, or vascular problems such as Raynaud's disease or reflex sympathetic dystrophy must be considered.

When a hand complaint is an extension of pain from another site, a peripheral nerve, nerve root, or spinal cord involvement must be differentiated. When numbness, tingling, or weakness is reported, peripheral nerve entrapment is likely, especially when the forearm or wrist is part of the pattern. When the neck and shoulder are part of the pathway of complaint, nerve root compression by a disc, nerve entrapment by osteophytes, or referral from the cervical facets should be considered. For a more detailed

discussion of each of these possibilities see the specific section for each in this chapter.

The chiropractor's role with hand trauma is clearly to determine the degree of injury. The degree of injury often is not severe and all that is needed is appropriate splinting, taping, or a cast. Articular or displaced fractures; tendon detachments or severage; deep lacerations with risk of infection; and animal, spider, or human bites must be referred. Most nontraumatic complaints reflect chronic processes that may benefit from conservative management.

## **General Strategy**

### **History**

- Localize the complaint and determine whether it is one of pain, stiffness, numbness/tingling, weakness, popping/snapping, coldness, deformity, or a combination.
- If traumatic, determine whether the mechanism was compressive or rotational, or caused by excessive flexion, extension, abduction, or adduction.
- If traumatic, consider radiographs in most cases to determine whether there is any underlying fracture.
- If nontraumatic, determine whether there are associated complaints such as other joint complaints (arthritides), deformities (arthritides), or cervical spine or arm complaints (facet referral, nerve root, brachial plexus, or peripheral nerve).

### **Evaluation**

- If traumatic, test for neurovascular status; examine for lacerations, swellings, or deformity; test ligamentous stability.
- If nontraumatic, examine for sites of local tenderness over joints and tendon insertions; test for accessory motion.

## Management

- Displaced or articular fractures, severed or avulsed tendons, and infection should be referred for orthopaedic consultation and management.
- Many ligament injuries can be managed with taping or splints unless there is an associated articular fracture.
- Rheumatoid and connective tissue disorders may require comanagement.

## Relevant Clinical Anatomy

The fingers and thumb participate in not only simple survival functions such as gripping but also complex actions that require amazing dexterity. The mechanical and neurologic integration necessary for this high functional demand is complex (**Figure 10-1**, A and B). An ingenious system of pulleys, redundant muscular and neural support, and varying joint design allows for an enormous degree of subtlety of motion. The general arrangement of the hand is similar to that of many joints, with a system of muscles that allows for flexion, extension, abduction, and adduction. Rotational movements are largely due to elbow/forearm and thumb movement.

## Fingers

Flexion of the digits is accomplished mainly through extrinsic muscle control provided by the flexor digitorum superficialis (FDS) and flexor digitorum profundus (FDP) with assistance from the intrinsic lumbricals and interossei. The lumbricals, in fact, originate off the radial side of the FDP tendons. The FDS tendon splits at the proximal end of the first phalanx, allowing the FDP to pass through and insert onto the distal phalanx.<sup>1</sup> The FDS then reunites and splits again to insert on either side of the middle phalanx. The volar interossei originate off the radial side of the fourth and fifth metacarpals and the ulnar side of the second and first metacarpal, allowing adduction of the fingers (in relation to the middle finger). The dorsal interossei originate off the metacarpals and abduct the fingers. The second and third dorsal interossei abduct toward the thumb. This is important for pinch-grip stability. A complex system of annular pulleys allows the flexor tendons to generate the greatest amount of force. There are five of these with one at each joint (MCP, PIP, and DIP) and two approximating the proximal and middle phalanx. The three at the joints are numbered proximal to distal A1, A3, and A5. The two fibro-osseous pulleys are numbered A2 and A4 proximal to distal. There are also three cruciform pulleys: two at the middle phalanx and one at the proximal phalanx. The cruciforms are not often injured or damaged; however, the A pulleys, in particular A2 and A4, are often partially or completely torn in rock climbing injuries.

Extension of the fingers is accomplished by the extensor digitorum (ED) muscle/tendons. The fifth finger is assisted by the digiti quinti and the index finger by the extensor indices. The primary insertion of the ED is onto the dorsum of the proximal phalanx. As the tendon continues distally it connects to lateral bands that are the continuation of the interossei and lumbrical muscles. The lateral bands continue distally to unite into a combined insertion into the distal phalanx. The ED tendon also inserts into the middle

phalanx. Although there is an insertion into each distal phalanx, the primary functional insertion is at the proximal phalanx. When the ED tendon pulls, most of the action is at the proximal phalangeal insertion. When the proximal phalanx is extended, the interossei and lumbrical connections to the lateral bands cause these intrinsic muscles to be the primary extensors of the middle and distal phalanges. When the ED relaxes, these same muscles act as flexors. With the metacarpophalangeal (MCP) joint flexed to  $90^\circ$ , tension on the ED pulls the distal interphalangeal (DIP) and proximal interphalangeal (PIP) joints passively into extension without the aid of the interossei.<sup>2</sup>

**Figure 10-1** (A) Tendons of the thumb; (B) tendons of the finger.

The index and middle fingers are stable, whereas the fourth and fifth fingers are mobile (the fifth being the most mobile). This is in large part due to the unique articulation at each joint. In particular, the articulation between the fifth metacarpal and the hamate is similar to the saddle configuration at the thumb and, like the thumb, allows for greater mobility.<sup>3</sup> This is visible while observing the metacarpal heads during flexion and extension. The heads

are in alignment with extension, allowing the palm to rest flat. With full flexion (clenched fist), the fourth and fifth heads flex beyond that of the second and third, creating a curved arch. Clinically, this is important with fracture management where more rotational or varus/valgus angularity is allowed with fourth and especially fifth metacarpal fractures. Additionally, the overlap of support provided by the intrinsic ligaments and interossei muscles makes the metacarpals quite stable even with fracture or ligament injury.

## **Thumb**

The thumb's mobility is due to its position and the articular configuration at the carpometacarpal and MCP joints. Nine muscles act on the thumb to allow not only flexion/extension and abduction/adduction, but also opposition (abduction, rotation, and flexion). Although flexion and extension may occur at all the thumb joints, abduction and adduction occur mainly at the carpometacarpal joint (some at the MCP joint).

Flexion, extension, and abduction of the thumb are accomplished through a muscle couple made up of a long extrinsic muscle/tendon and a short intrinsic muscle. Flexion is due to the flexor pollicis longus (FPL) and the flexor pollicis brevis (FPB). Extension is accomplished with the ED and the extensor pollicis brevis (EPB) muscles. Abduction is governed by the abductor pollicis longus (APL) and abductor pollicis brevis (APB). The short muscles are part of the thenar group and are joined by the adductor pollicis and opponens pollicis muscles. Adduction is controlled by the first palmar interosseous muscle and adductor pollicis. The tendons of the EPB and the APL outline the anatomic snuff-box, a common location of tenderness with scaphoid fractures. These tendons may be involved in de Quervain's

disease. Ligamentous support is provided by two collateral ligaments (similar to the other phalanges), one on each side, with assistance by paired accessory ligaments. The collateral ligament on the inside web is the ulnar collateral ligament. This is often injured with a hyperextension or abduction injury referred to as gamekeeper's thumb. Support at the MCP joint is provided by the volar ligaments and plate.

## Evaluation

## History

Careful questioning of the patient during the history taking can point to the diagnosis (**Table 10-1**).

---

### Pain Localization (see **Figure 9-3, A-C**) Finger

- Metacarpophalangeal (MCP) joint
  1. Traumatic—dislocation, collateral ligament sprain or rupture
  2. Nontraumatic—capsular sprain, osteoarthritis (OA)
- Proximal interphalangeal (PIP) joint
  1. Traumatic—dislocation (coach's finger), boutonnière deformity (hyperflexion injury)
  2. Nontraumatic—rheumatoid arthritis (RA), Reiter's syndrome, psoriatic arthritis, or OA
- Distal interphalangeal (DIP) joint
  1. Traumatic—mallet finger (hyperflexion), flexor digitorum avulsion (jersey finger)
  2. Nontraumatic—psoriatic arthritis

**Table 10-1** History Questions for Finger and Thumb Complaints

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Was there an injury?	Fracture, dislocation, ligament sprain, tendon avulsion, capsular sprain	<p>Hit on end of finger?</p> <p>Finger bent back?</p> <p>Thumb pulled back?</p> <p>Finger forced into flexed position?</p> <p>Hit an object with a clenched fist?</p>	<p>Fracture</p> <p>PIP joint dislocation</p> <p>Capsular sprain</p> <p>Sprain</p> <p>Volar plate tear</p> <p>Avulsion of FDP (jersey finger)</p> <p>PIP or MCP joint dislocation</p> <p>Gamekeeper's thumb (injury to DIP)</p> <p>Mallet finger (injury to DIP)</p> <p>Boutonniere deformity (tearing of central slip)</p> <p>If thumb is involved rule out metacarpal fracture</p> <p>If hand is involved rule out metacarpal fracture</p>
Does your finger feel stiff?	Arthritis (OA or RA), capsular effusion or adhesion, subluxation, trigger finger	<p>Does your finger get stuck in a flexed position?</p> <p>Can't close finger(s)?</p> <p>Worse in morning; better with mild activity?</p> <p>Associated swelling or deformity?</p>	<p>Trigger finger likely (check for nodule)</p> <p>Capsular effusion or adhesion</p> <p>Retinacular tightness</p> <p>OA</p> <p>RA</p> <p>OA</p> <p>Psoriatic arthritis</p>
Is there a sense of weakness?	C8-T1 nerve roots, peripheral nerve entrapment	<p>Associated neck pain and/or radiation into hand?</p> <p>Associated elbow or forearm pain?</p>	<p>Cervical disc, tumor, or spondylosis</p> <p>Peripheral nerve entrapment (distinguish by which muscles)</p>
Do you routinely perform repetitive activity with your fingers?	Tendinitis, peripheral nerve entrapment	Is the pain at your thumb or slightly above?	<p>de Quervain's disease</p> <p>Intersection syndrome</p>

## Thumb

- Traumatic—gamekeeper's thumb (ulnar collateral ligament [UCL] sprain or rupture), Bennett's fracture (first MCP base)
- Nontraumatic—OA, bowler's thumb (digital neuritis)

## Traumatic Finger Pain

As distal joints, the fingers are vulnerable to all order of outside forces. Hand and finger injuries are particularly common in sports.<sup>4</sup> General patterns of injury occur with “hyper” movements:

- Hyperextension may simply strain the palmar surface of the fingers or hand or result in tendon avulsion of the flexor digitorum profundus, volar plate damage, or dislocation or fracture.<sup>5</sup>
- Hyperflexion may cause dislocation, central extensor tendon slip damage at the PIP joint, or extensor tendon avulsion at the DIP joint.
- Rotational or valgus/varus forces will often result in collateral ligament damage. With more force a dislocation or fracture is possible.
- Direct axial forces to the extended fingers may cause a synovitis or fracture. An axial force to the knuckles often results in a metacarpal fracture or simply a local contusion to the knuckle (boxer’s knuckle). The examiner may need to be persistent in determining whether the patient, in a fit of anger, punched an inanimate (or animate) object.
- When the patient has a cut or laceration, a tendon or nerve may be severed. Wounds are open to infection, and questions about animal, insect, or object penetration, and recent tetanus shots should be asked.

## Weakness

Weakness in the fingers may be a generalized or local problem. Clarify whether the patient feels pain with movement or gripping. Pain localization when associated with a weakness complaint may be helpful; however, a complaint of weakness with pain is itself nonspecific because of the reflex or voluntary inhibition that occurs with

painful movement. The patient should be asked about weakness that relates to a specific movement. It is important to remember that a perception of weakness may be due to stiffness or inflexibility at a joint or joints. Passive range of motion testing will often reveal this component.

Weakness in a single digit following trauma should suggest tendon avulsion, especially if associated with deformity. Weakness with specific finger/thumb gripping or pinching suggests a peripheral nerve entrapment or damage. Gross weakness with hand gripping is possible with any number of problems; however, the problem usually is neural. Ulnar or median nerve involvement will affect grip strength, as will nerve root compression. Radiation of a complaint from the forearm suggests peripheral nerve entrapment, whereas pain or paresthesia radiating from the neck suggests nerve root or a referral phenomenon. Weakness in grip may also be the result of instability at the wrist. Remember that grip strength is usually decreased with the use of thick gloves. Grip strength is also position-dependent. Gripping is most efficient in neutral or slight wrist extension (less than  $30^\circ$ ). Beyond these limits the mechanical advantage of the finger flexors is reduced.

## **Restriction in Movement**

Movement restriction in the fingers should be divided into posttraumatic or insidious. Stiffness, especially with flexion, is not uncommon after an axial load injury to the finger with a resultant capsular sprain and reactive synovitis. Because of the inability to immobilize the fingers as easily as more proximal joints, the fingers are constantly stressed. As a result, capsulitis of the digits often takes two months or more to resolve.

An insidious onset suggests an arthritis. The two most common are OA and RA. Historically, there is often a

distinction between the two. OA often causes the patient to complain of early-morning stiffness that improves after 20 to 30 minutes of activity. RA is often more restrictive and takes several hours to improve. Exacerbations with movement are more common with RA. A search for corroborative evidence includes the age of the patient, family history, and involvement of other joints. In an elderly patient with unilateral complaints of knee or hip pain, OA is more likely. In a middle-aged woman with a positive family history and bilateral, diffuse involvement of the PIP joints, RA is more likely.

Restriction to movement may be localized to the fourth and fifth fingers with an associated flexion contracture evident. This is likely to be Dupuytren's contracture.<sup>6</sup> Questioning regarding alcohol consumption or possible diabetes should be included. A unique restriction complaint is snapping of a finger or thumb upon extension. This is often due to a trigger finger or thumb. Initially, the patient may report the ability to overcome an extension restriction actively. As the condition progresses, she or he may have to extend the finger passively past the restriction, often with an audible snap.

## **Superficial Complaints**

As the distal point of the upper extremity, the fingers and hands are often indicators of more proximal and often systemic conditions. Complaints range from numbness/tingling, coldness, skin and nail lesions, and burning sensations. If one or two fingers appear blanched and cause the patient pain when exposed to cold, Raynaud's disease or phenomenon is likely. Nail lesions are often indicators of various systemic processes. Longitudinal nail lines are seen with anemia, clubbing with chronic pulmonary disorders, and pitting with psoriasis. Many

complaints of numbness or tingling are connected to a wrist, forearm, or neck complaint. See the related section in this text for a more thorough discussion. When there is localized numbness in the thumb, compression of the ulnar digital nerve of the thumb is often the cause; it is called bowler's thumb. A "sausage finger" (swelling of the PIP joint) suggests psoriatic arthritis or Reiter's syndrome.

## **Examination**

# **Traumatic Injury**

When evaluation is immediately posttraumatic, a quick check of neurovascular status is warranted.<sup>7</sup>

## **Vascular**

- Allen's test for radial and ulnar arteries: The patient is instructed to open and close the hand several times. He or she is then instructed to keep the hand tightly closed in a fist. The examiner occludes both the radial and ulnar arteries at the wrist. The patient is then asked to open the hand. The examiner releases pressure on the artery and observes for filling; the distal hand reddens within a few seconds. Repeat with the opposite artery. This test may also be used for the digital arteries at the fingers: The examiner gently squeezes the radial and ulnar sides of the volar tip with finger and thumb, sliding them proximally while maintaining the squeeze. The finger should become pale. Release pressure with the finger to determine whether the finger fills. Repeat with release of thumb pressure to check the patency of the other artery.

# Neural

- Two-point discrimination: This is the minimal distance at which a patient can discriminate between two points of stimulation. A paper clip bent to expose two points 4 mm apart may be used (testing is on the palmar surface). The two points must touch the skin simultaneously. Although the distance varies over the hand, an average of 4 to 5 mm is used for a quick check.
- Sensory testing (use a pin; check for pain perception)
  1. Ulnar nerve—volar tip of little finger
  2. Radial nerve—dorsum of thumb web
  3. Median nerve—volar tips of index and middle fingers
- Motor (gross check)
  1. Ulnar nerve—cross middle finger over the back of the index finger
  2. Radial nerve—extend thumb
  3. Median nerve—point thumb toward ceiling (palm up on table)
- Muscle/tendon check (inability to perform may indicate a severed or avulsed tendon)
  1. Flexor digitorum profundus—with MCP and PIP joints held in extension (or held down with the patient's palm up), ask the patient to flex the DIP (often the result of a hyperextension injury).
  2. Flexor digitorum superficialis—with patient's palm up, hold down all untested fingers into extension and ask the patient to flex the unrestrained finger.
  3. Flexor pollicis longus—with the thumb held in extension at the MCP joint, ask the patient to flex the IP joints.
  4. Extensor digitorum—with the wrist in extension, ask the patient to extend at the MCP and IP joints.

Observation should focus on a search for deformity and swelling. This search is occurring as the above neurovascular check is being performed. Note that if there is an apparent dislocation, depending on the joint involved, an attempt at relocation should be made. See specific joints in the selected disorders section. Next, check for a rotational deformity of a finger, best seen with flexion of the fingers to the palm. Rotational or angular deformity is an indication of fracture. Tapping on an extended finger often will increase the pain if a fracture is present.<sup>8</sup> Further evaluation with radiographs is necessary. Tapping at the knuckle with the fingers flexed to the palm may reveal a metacarpal fracture. Swelling localized to a joint may indicate ligamentous rupture or capsular sprain with an associated synovitis. Stability testing of the PIP and MCP joints is performed in two positions: 30° and 70° of flexion. In each of these positions, a varus and valgus stress is applied to the joint.

Radiographic evaluation is necessary with most finger injuries. Standard anteroposterior (AP) and lateral views will reveal most fractures or dislocations. It is important to search for an associated dislocation when a fracture is evident. This is often best seen on a lateral view. For fractures of the metacarpal, it is useful to add a lateral view with the hand pronated about 20°. Otherwise, metacarpal fracture lines may be obscured.<sup>9</sup> For the thumb, AP and lateral views are required. Stress views (pulling the thumbs into abduction) are often necessary to determine the degree of injury with a gamekeeper's thumb. Greater than 30° difference between the two sides indicates rupture of the ulnar collateral ligament, as does an avulsion fracture of the proximal base.<sup>10</sup>

---

## **Nontraumatic**

Observation of the fingers may reveal deformities or swellings. Deformities at the distal and proximal joints are

most commonly associated with two arthritides, OA and RA. DIP joint involvement is referred to as Heberden's nodes; PIP involvement is referred to as Bouchard's nodes when associated with OA or RA.<sup>11</sup>

Involvement with either arthritis is often bilateral and involves more than one digit. MCP joint involvement is rare with OA but may occur with RA and psoriatic and gouty arthritis. Psoriatic arthritis affects mainly the DIP joint and is usually associated with skin lesions on the extensor surfaces of the extremities and pitting and ridging of the nails. Swelling and tenderness of the entire involved finger (sausage finger) is found with psoriatic arthritis and Reiter's syndrome (check for associated sacroiliac pain). Clubbing of the fingers may occur with a variety of pulmonary diseases, including tuberculosis and bronchogenic carcinoma.

Severe RA will present with fusiform swelling of the PIP joints, ulnar deviation of the fingers at the MCP joints, interosseous muscle atrophy, extensor tenosynovitis, and subcutaneous nodules over the extensor surfaces of the forearm and wrist. Laboratory testing is most useful for RA, checking for rheumatoid factor (immunoglobulin [Ig] M and anti-IgG) and increases in the erythrocyte sedimentation rate. However, rheumatoid factor is found in only 70% to 80% of patients with RA.

Observation and palpation of the fingers/hand may reveal vascular compromise.

- Reflex sympathetic dystrophy—A combination of shiny, swollen skin is present (the whole arm is often involved in shoulder-arm-hand syndrome).
- Raynaud's phenomenon or disease—Often one or two fingers are "white" compared with other fingers; the condition is worse upon exposure to cold. Raynaud's disease is idiopathic; Raynaud's phenomenon is associated with an identifiable connective tissue

disorder such as scleroderma or systemic lupus erythematosus.

When stiffening is the main complaint, it is important to distinguish between intrinsic muscle and capsular/collateral ligament tightness. This is accomplished by joint positioning that either tightens or relaxes these structures. For the PIP joint, the Bunnel-Littler test (**Figure 10-2**) is used.<sup>12</sup> With the MCP joint held in slight extension, the PIP joint is passively flexed toward the palm. Inability to flex fully is indicative of either joint capsule contracture or tight intrinsic muscles. If the PIP joint can be flexed after moving the MCP joint into slight flexion, the intrinsic muscles are tight. If the PIP joint cannot be flexed with MCP joint flexion, joint contracture is likely the cause. For the DIP joint, the retinacular test is used. Here the distinction is between the retinacular ligaments and the joint capsule. The retinacular test (**Figure 10-3**) is the distal extension of the Bunnel-Littler concept. While the PIP joint is held in neutral, the examiner attempts to flex the DIP joint passively. If it cannot be flexed, either retinacular or capsular tightness is the cause. If after flexion of the PIP joint the DIP joint can be passively flexed, retinacular tightness is the cause. If the DIP joint still cannot be passively flexed, a joint capsule contracture is likely.

**Figure 10-2** Bunnel-Littler test. With the MCP joint stabilized the examiner attempts to flex the PIP joint. If not flexible, the MCP joint is flexed and the test is repeated. Ability to flex indicates tight intrinsic muscles. Inability to flex in the second position indicates joint contracture or swelling.

**Figure 10-3** The Retinacular test. With the PIP joint held in neutral, the examiner attempts to passively flex the DIP joint. If unable to flex, the DIP is flexed slightly and the DIP is again flexed. If unable to flex in the second position, a joint contracture is present; able to flex indicates retinacular tightness.

Radiographic evaluation of the hand is often a search for either fracture or typical clustered findings suggestive of each arthritis.<sup>13</sup>

- RA: Early signs are of soft tissue swelling; progression results in periarticular demineralization, loss of joint space, erosions of the joint margins (rat-bite lesions), and malalignment of the fingers (especially ulnar deviation at the MCP joints).
- OA: Joint space narrowing, sclerosis, subchondral cysts, and osteophytes are the hallmarks of OA. Bony enlargement of the DIP joints is typical (Heberden's nodes) and occasionally at the PIP joints (Bouchard's nodes). The CMC joint of the thumb is also often affected.
- Psoriatic: Bone resorption of the tufts of the distal phalanges may be seen; progression to the rest of the phalange may occur with the most severe form of psoriatic arthritis, arthritis mutilans.

There is some overlap between wrist, hand, and forearm complaints and testing. See the specific sections for each. Neurologic involvement from a proximal source is described in [Chapters 2](#) and [9](#).

## Management

### Acute Traumatic Injury

Management of acute injury is as follows:

- Dislocations of the PIP and DIP joints should be relocated if possible; clinical testing for instability and radiographs for associated fracture should be performed.
- Fractures involving more than 20% to 30% of the articular surface should be referred for orthopaedic consultation.

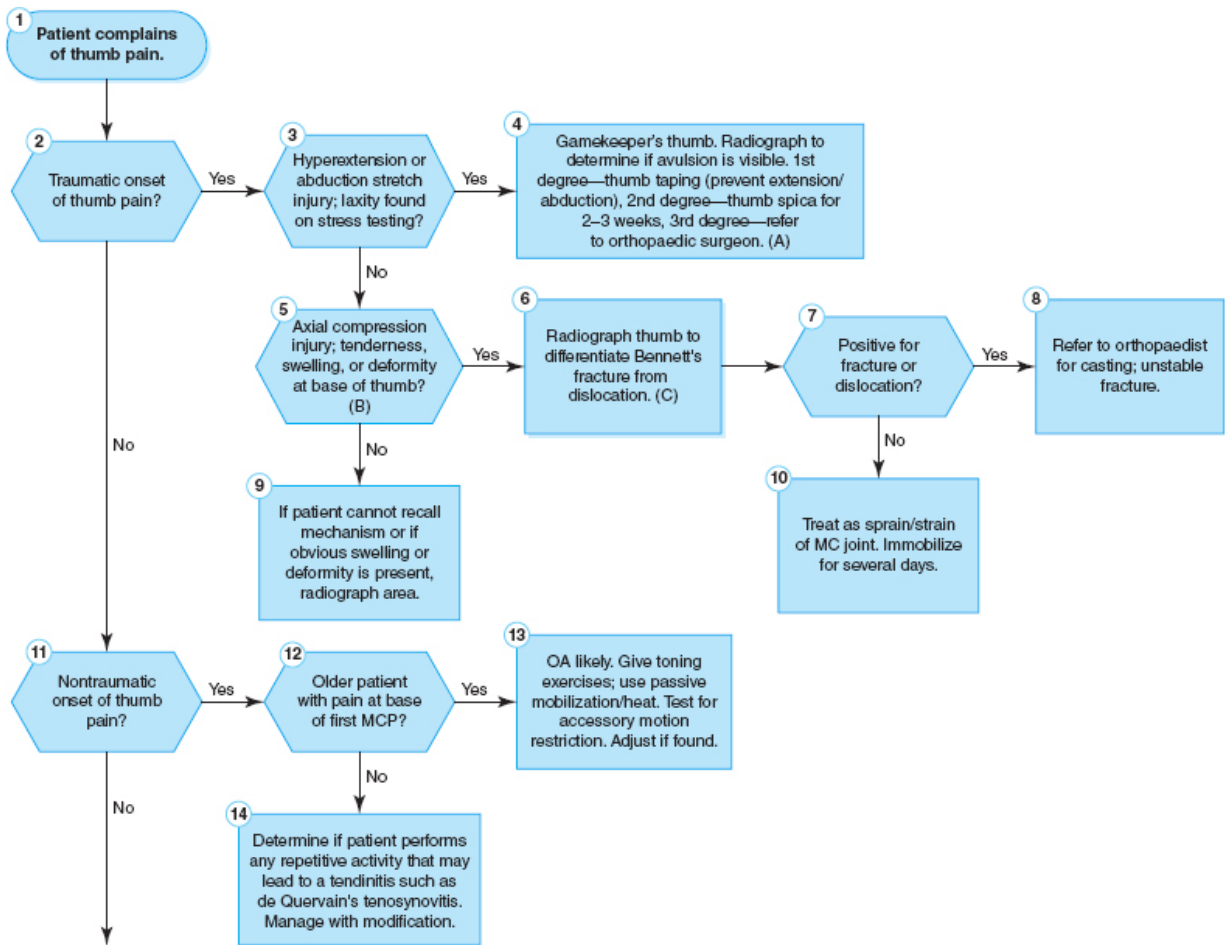

- Nondisplaced fractures are casted (specific position-dependent on joints involved).
- Displaced fractures are referred for surgical stabilization.
- Flexor tendon avulsion (mallet finger) or a suspected severed tendon requires orthopaedic referral.
- Ligament damages to the volar plate, central extensor slip, or collateral ligaments are splinted (see Related Conditions section for specifics).

## **Nontraumatic Conditions**

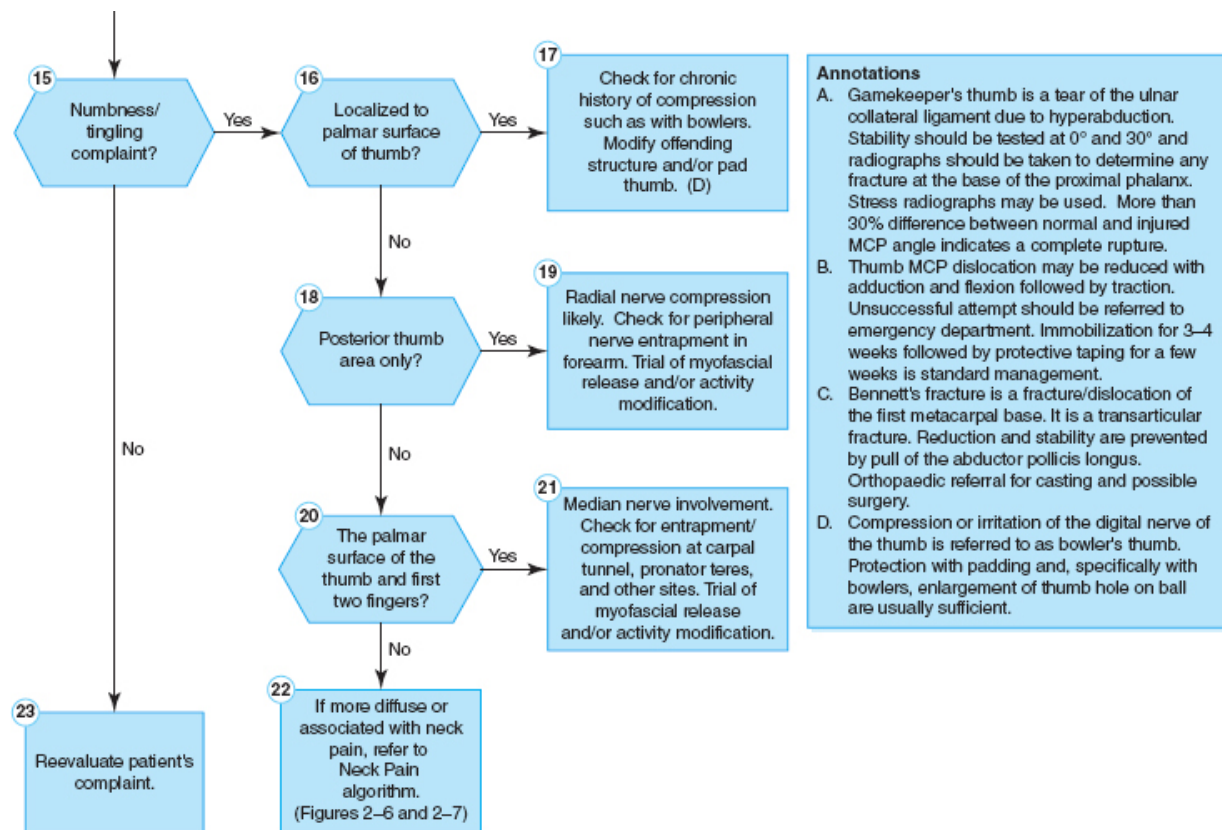

- Rheumatoid or connective tissue disorders warrant comanagement with a rheumatologist.
- Osteoarthritic involvement requires a mild finger/hand strengthening program; physical therapy heating modalities may be transiently beneficial; mobilization and manipulation of the involved joints when performed cautiously may also be of benefit.
- Peripheral nerve causes of numbness/tingling or pain should first be treated with a myofascial release approach for two to three weeks to determine treatment effectiveness, modification of any identifiable inciting activity, and, when necessary, splinting or soft casting for a short course of imposed rest.
- Soft tissue contracture of the intrinsic muscles may also benefit from postisometric relaxation and myofascial release.
- Joint contracture may benefit from mobilization and deep heat with passive stretching when subacute or chronic.

## **Algorithms**

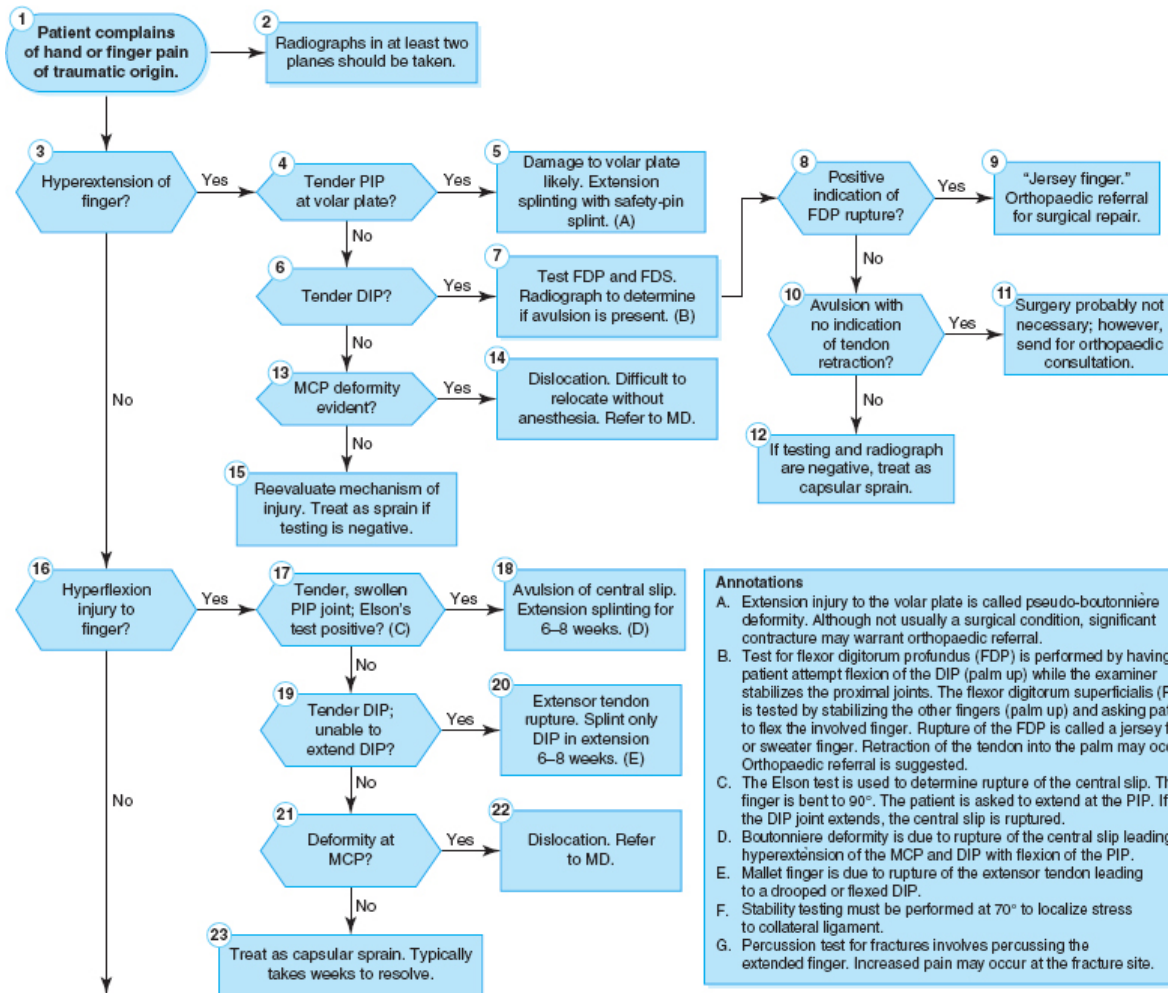

Algorithms for evaluation and management of thumb pain, traumatic hand pain, and nontraumatic hand pain are presented in **Figures 10-4** to **10-6**.

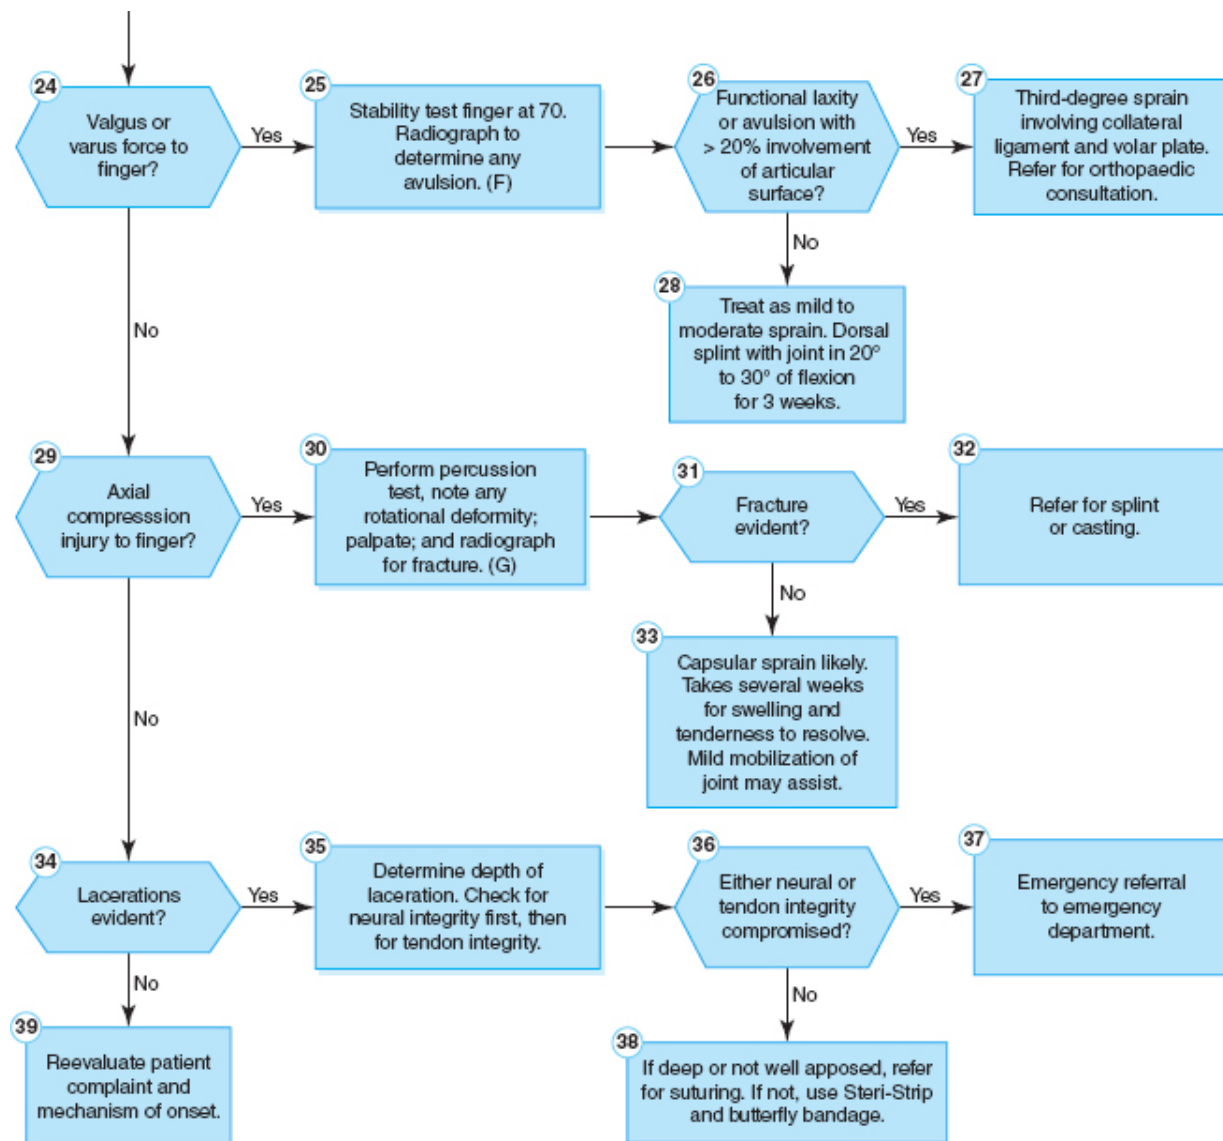

**Figure 10-4** Thumb Pain—Algorithm

**Figure 10-5** Traumatic Hand Pain—Algorithm

1 Patient presents with a nontraumatic onset of finger or hand pain.

2 Difficulty extending finger from flexed position?

Yes

3 Fourth and fifth fingers affected most with thickening or nodules in flexor tendons at palm?

Yes

4 Dupuytren's contracture. Early treatment involves stretching and ultrasound (US). Soft-cast in neutral may help. Refer for possible Botox injection. (A)

6

"Trigger finger," a form of stenosing tenosynovitis. Early treatment includes US, NSAIDs, and cross-friction. Progression may require referral for steroid injection or surgery.

5 Middle finger, ring finger, or thumb snaps from flexion to extension?

Yes

No

7 Movement difficulty associated with finger swelling that improves after several hours? (B)

Yes

8 Possible RA or other inflammatory arthritide. Check for deformity, order lab for rheumatoid factor, and radiograph to determine any bony involvement.

No

9 If chronic, check for bony deformity suggestive of OA; otherwise, treat for flexion contracture. (C)

No

10 Difficulty flexing finger?

Yes

11 Hold proximal joint in slight flexion while trying to flex next distal joint.

12

Distal joint does flex?

Yes

13 Retinacular tightness of DIP or tight intrinsic at PIP. (C)

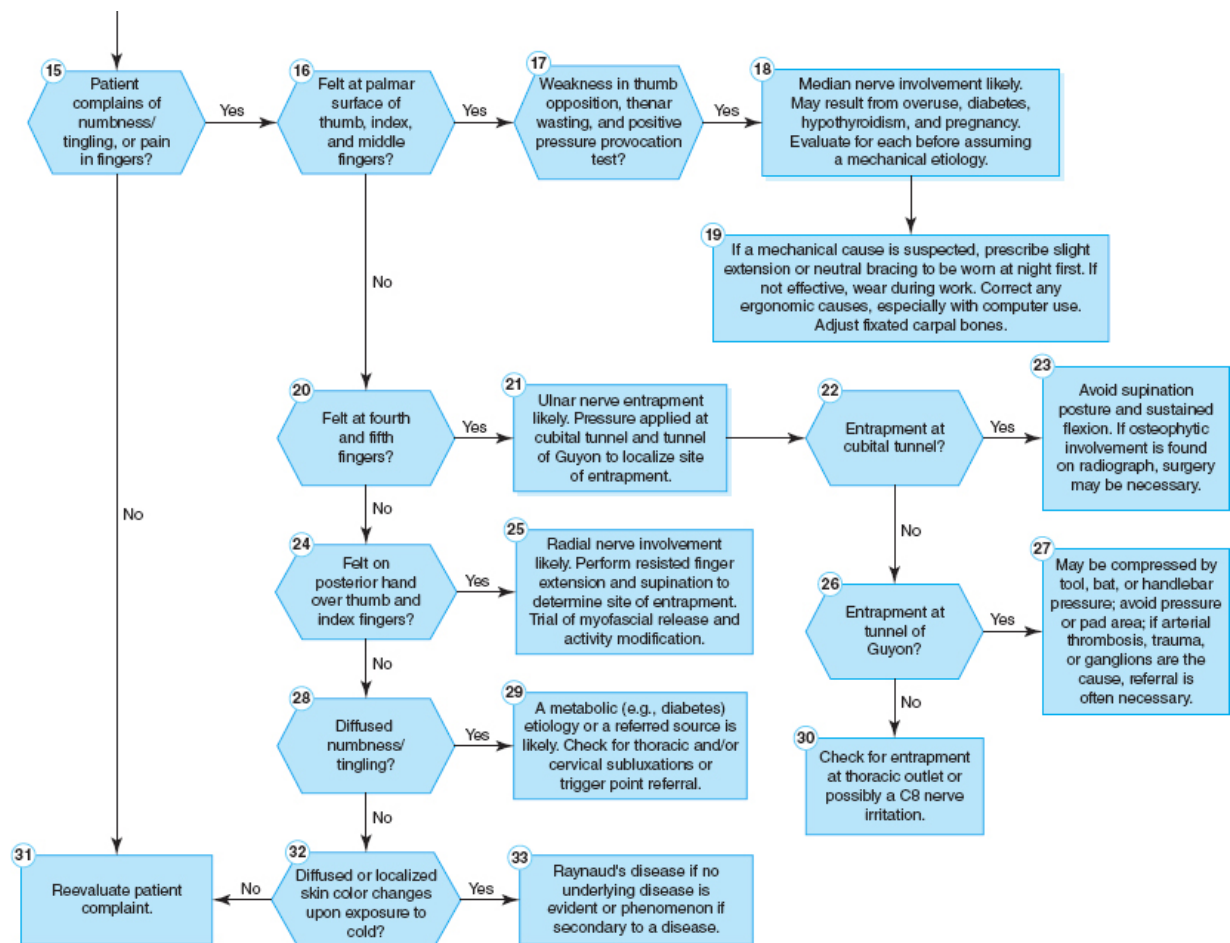

No

14

Joint contracture; mild manipulation may assist increase in range of motion; gradual stretching over several weeks may help.

#### Annotations

- A. Dupuytren's contracture is more common in alcoholics, epileptics and those with diabetes or pulmonary tuberculosis.
- B. Finger swelling should be differentiated first between bony deformity and soft tissue involvements. DIP and PIP involvements are suggestive of OA, while PIP & MIP involvements suggest inflammatory arthritide. Soft tissue swelling and stiffness that resolve quickly imply OA, while that taking several hours is more characteristic of inflammatory arthritide.
- C. Joint contracture, intrinsic muscle tightness, or retinacular tightness should be addressed with gentle passive stretching, PNF stretching, and underwater ultrasound.

**Figure 10-6** Nontraumatic Hand Pain—Algorithm

# Selected Disorders of the Finger, Thumb, and Hand

A summary of the disorders discussed below is presented in [Table 10-2](#).

## FINGER

### DISTAL INTERPHALANGEAL JOINT

#### Mallet Finger: Extensor Tendon Avulsion

## Classic Presentation

A patient complains of distal finger pain after being hit on the end of the finger with a ball. The distal finger is dropped into a flexed position.

## Cause

A compressive force on the tip of an extended finger, forcing it into flexion, causes avulsion of the extensor digitorum tendon. Commonly, this is due to a ball hitting the finger; often called “baseball finger.”<sup>14</sup> Because of the drooping deformity, another pseudonym is drop finger.

**Table 10-2** Summary of Hand Conditions

Name of Condition	Injury	Treatment
Boutonnière deformity	Flexion injury of PIP, tearing central slip; deformity is hyperextension of MCP and DIP with flexion of PIP.	PIP is splinted in extension for several weeks.
Pseudoboutonnière	Extension injury of DIP	Extension splinting;

deformity	with damage to volar plate.	safety-pin splint.
Jersey finger	Avulsion of flexor digitorum profundus; hyperextension injury.	Usually surgery.
Mallet finger (baseball finger)	Hyperflexion injury to DIP.	Extension splinting of DIP for six to eight weeks.
Collateral ligament injury	Usually ulnar stress to a flexed MCP.	Remember to stress test at 70° and radiograph for possible fracture fragment. Splint PIP at 30° of flexion.
PIP joint dislocation (coach's finger)	Axial or extension force to middle phalanx.	Immobilize at 20° -30° of flexion for several weeks.
MCP dislocation	Dorsiflexion injury, usually tearing the volar plate.	Difficult to reduce; often requires anesthesia. Immobilize for three to four weeks.
Gamekeeper's thumb	MCP joint sprain of ulnar collateral ligament, usually due to hyperabduction or extension.	Tape with a cinch between thumb and first finger for several weeks.
Bennett's fracture	Fracture/dislocation of first metacarpal base.	Difficult to reduce due to pull of abductor pollicis longus. Usually need open reduction with fixation of fracture fragment.
Boxer's fracture (overlap definition with bar-room fracture dependent on source)	Hitting an object with an unprotected fist, usually fracture of the fifth or fourth metacarpal. Look for rotation or angular deformity. Percuss distal end of finger.	Gutter splint or hand cast for six weeks.

## Evaluation

Active extension of the DIP joint is impossible; however, passive extension is usually accessible with some associated tenderness over the dorsum of the

joint. Radiographic evaluation must include two planes of view to visualize clearly any degree of avulsion or epiphyseal fracture in immature athletes. The lateral view may also demonstrate subluxation (medial) at the joint. Two points of caution are, first, that the DIP joint may also be injured (central slip damage) and should always be included in the examination, and second, if a large piece of bone is avulsed, surgery may be necessary.

## **Management**

Treatment involves splinting of the DIP joint in extension (not hyperextension) for up to six weeks.<sup>15</sup> Gradual active and passive range of motion exercises may then begin. This is followed by another six weeks of night and, if applicable, athletic splinting.<sup>16</sup> The PIP joint must not be included in the splinting to prevent contracture. It is imperative that the patient always keep the DIP joint in extension. He or she must remember this when changing finger splints.

### **Football or Jersey Finger: FDP Rupture**

## **Classic Presentation**

A patient complains of distal finger pain after getting his or her finger forcefully extended while grabbing a moving object.

## **Cause**

Hyperextension of the DIP joint may result in rupture of the FDP tendon. Because of a common mechanism, this is often referred to as football or jersey finger, in which the finger (often the ring finger) is caught in an opponent's jersey.<sup>17</sup> While the athlete is grabbing the jersey, the opponent pulls away, exerting an extension force on the flexing finger. The degree of injury is based in part on how far the tendon has migrated, which may be as far as the palmar crease.

## **Evaluation**

Acute evaluation requires testing of FDP function. This is accomplished by asking the patient to flex the DIP joint fully while the PIP joint is held in extension by the doctor. Inability to flex is diagnostic for rupture.

# Management

Unlike many finger injuries, this injury requires immediate referral for surgical repair. Surgery has a better prognosis within the first three to four days postinjury.

## Dislocation

## Classic Presentation

A patient reports having the distal finger pulled out of place by a hyperextension injury. Pain and some deformity may be evident at the DIP joint. If the patient is an athlete, he or she may have had the dislocation reduced prior to presentation.

## Cause

Disruption of the volar plate allows dorsal dislocation of the distal phalanx. Associated tendon or collateral ligament damage is possible.

## Evaluation

Tenderness and dorsal deformity of the distal phalanx are seen in the acute presentation. Radiographs should always be taken to rule out any associated fractures. After reduction, it is imperative to check for damage to the collateral ligaments and for flexor/extensor tendon function.

## Management

Reduction is accomplished with long-axis traction while gently increasing the deformity. After reduction, immobilization in a dorsal or volar splint (not including the PIP joint) for two to three weeks is sufficient. There is debate as to whether to splint in 30° of flexion or full extension. Following splinting, flexion exercises are begun while maintaining protective splinting during any sporting activities.<sup>18</sup>

## PROXIMAL INTERPHALANGEAL JOINT

## **Central Slip Tear (Boutonnière Deformity)**

### **Classic Presentation**

The patient presents with pain at the PIP joint and an associated deformity after having an injury that involved forced flexion of the finger.

#### **Cause**

A hyperflexion injury of the PIP joint may result in tearing of the central slip of the extensor digitorum tendon. The lateral bands drop anteriorly and maintain the PIP in flexion while the DIP joint is extended.

### **Evaluation**

There is pain and point tenderness at the PIP with associated swelling. Functionally, the PIP joint cannot be actively extended. Eventually, a boutonnière deformity occurs as hyperextension of the DIP and flexion of the PIP. At this point the DIP cannot be actively extended. Due to volar slippage of the lateral bands, active and passive flexion is not possible at the distal joint.<sup>19</sup>

### **Management**

It is imperative that the PIP joint be immobilized with a finger splint in full extension for approximately six weeks. If not splinted properly, there will be no apposition of the torn ends of the central slip and deformity will result. This is often the case when loss of active extension is attributed to pain and the athlete is splinted in flexion for a collateral ligament sprain by an inexperienced coach/trainer/doctor. Due to the severity of the injury, an additional four to six weeks of splinting is necessary at night and during athletic activity (if applicable). When 45° of flexion and full extension are attained, the splinting may be discontinued.

#### **Volar Plate Injury**

### **Classic Presentation**

The patient (often an athlete) complains of finger pain after his or her finger was pulled back or overextended by a ball or from a fall on an outstretched finger.

## Cause

The volar plate on the anterior surface of the PIP is injured by a hyperextension injury to the finger.<sup>20</sup>

## Evaluation

Pain and tenderness are found at the PIP joint. If chronic, a pseudoboutonnière deformity may result due to scar tissue formation and subsequent contracture with the PIP joint held in flexion. The distinction between a boutonnière and a pseudoboutonnière deformity is that normal mobility is present at the DIP with pseudoboutonnière deformity.<sup>21</sup>

## Management

The PIP joint is splinted in 30° of flexion for four to five weeks. If unsuccessful, surgical referral should be made.

## Dislocation

## Classic Presentation

The patient complains of middle finger pain following a hyperextension injury (often in ball-handling sports). It is not unusual for a coach or trainer to reduce the joint with an assumption that the individual simply “jammed” the finger.

## Cause

Hyperextension with some axial loading while the PIP joint is in extension causes volar plate rupture and often an avulsion fracture of the base of the middle phalanx.

## Evaluation

Tenderness and deformity are found at the PIP joint if acute. After reduction, the MCP joint should be tested for active and passive range of motion. Static stability testing for collateral ligament and volar plate integrity must also be

included. Radiographs are requisite to rule out associated fractures (especially when associated with an axial load or rotation injury).

## Management

Reduction is accomplished by long-axis traction with gentle hyperextension of the PIP joint. If unsuccessful, refer for reduction with a local digital nerve block. Following reduction, ice and splint. A volar splint is applied with the finger held in 20° to 30° of flexion for two to three weeks. This is followed by buddy-taping for an additional two weeks, especially if participating in sports. Gentle active range of motion should be prescribed after the initial three weeks of splinting.

### Collateral Ligament Sprain

## Classic Presentation

A patient presents with a sports-related injury whereby the finger was pulled sideways (usually ulnar). The patient often reports that the finger “went out,” but it either reduced spontaneously or was reduced by the patient.

### Cause

A varus or valgus force stretches and tears the collateral ligament support at the PIP. The index finger is most often involved. The force is often sufficient to subluxate the joint medially; however, it often reduces spontaneously or is reduced by the patient, a coach, or a trainer.<sup>22</sup> Associated partial or complete rupture of the volar plate is possible depending on the magnitude of force.

## Evaluation

Tenderness is found over the PIP collateral ligament and volar plate. Swelling is often rapid, leaving little time to test for stability. Stability testing should include varus and valgus attempts at two positions of flexion, 30° and 70°. Like all ligamentous injuries, there are varying degrees of damage. Radiographic demonstration of an avulsion fracture involving the volar plate is indicative of a rupture.

## Management

With first- and second-degree sprains, the PIP is immobilized with a dorsal splint for two to four weeks in a 20° to 30° flexed position and may be buddy-taped to an adjacent finger for more stability. If a volar plate avulsion involves more than 20% of the articular surface, surgery may be indicated.<sup>23</sup>

## **Flexor Pulley Injuries (Rock Climber's Finger)**

### **Classic Presentation**

Patients present with a sudden onset of finger pain while rock climbing using a “crimp” position or shock-loading the fingers when they lost their footing.

### **Cause**

A complex system of annular pulleys allows the flexor tendons to generate the greatest amount of force. There are five of these with one at each joint (MCP, PIP, and DIP) and two approximating the proximal and middle phalanx. These two fibro-osseous pulleys are designated A2 and A4 numbered from proximal to distal. These are loaded the most with climbing, and more eccentrically when the climber uses a crimp position of 90° to 100° of PIP flexion with hyperextension of the DIP. The A2 is the strongest able to withstand up to 400 N; however, strains can exceed 450 N when climbers fall and catch their weight by their fingers.

### **Evaluation**

There is a report of sudden pain and swelling with occasionally a report of a pop at the time of injury. Tenderness is found over the involved areas. Like all soft tissue injuries, there are varying degrees of damage from partial tears to full rupture. Bowstringing, meaning the tendon has popped out of its restraining sleeve, will present as swelling on the flexor (palmar) surface usually of the proximal phalanx. There are no orthopaedic tests in-office to perform. MRI is not very useful; however, diagnostic ultrasound is and has become the gold standard allowing dynamic evaluation of movement of the tendon.

### **Management**

Injuries have been classified into a system of Grade I through Grade IV.<sup>24</sup> Following is a description of each with the associated recommended treatment approach:

- Grade I—a pulley strain with no dehiscence of the tendon from bone (< 2 mm). Circumferential wrapping (or an H-type taping) around the distal end of the proximal phalanx with gradual return to full climbing over six weeks although continued taping up to three months is recommended.
- Grade II—either a complete rupture of the A4 pulley or partial rupture of the A2 or A3 pulleys. The same management approach as Grade I injuries is recommended.
- Grade III—complete rupture of the A2 or A3 pulleys. Immobilization in a thermoplastic splint or soft-cast ring for 10–14 days. This is followed by mild mobilization and protective taping with a return to climbing in six to eight weeks after injury using protective taping for up to six months.
- Grade IV—complex injuries involving ruptures and associated lumbrical muscle or collateral ligament injury. These require surgical repair that either includes a palmaris tendon graft or extensor retinaculum grafts. The latter are more difficult to perform and there appears to be no difference in outcome.

## **METACARPAL PHALANGEAL JOINT**

### **Collateral Ligament Sprain**

## **Classic Presentation**

The patient presents with a complaint of pain at the MCP joint after a fall on the hand that stretched the associated finger to the side. The patient initially may not have sought help. Persistent pain and swelling usually prompt the patient to seek advice.

### **Cause**

Tearing of the radial collateral ligament of the ulnar three digits is most common. When the ligament is most taut, the finger is in flexion. The finger is deviated away from the side of injury.

## **Evaluation**

The MCP joint is most lax in full extension. Tautness increases with flexion; therefore, stress testing of the collateral ligaments with a varus and a valgus force is best accomplished at 70° of flexion. Radiographs should be taken to determine any associated fractures at the base of the proximal phalanx.

## **Management**

Because of the support provided by the intrinsic muscles of the hand, lateral instability is not a strong concern. Immobilization in flexion for three weeks is followed by buddy-taping to the adjacent fingers for an additional three weeks. It is important not to splint in extension, which would allow shortening of the collaterals and a residual functional deficit in active and passive flexion.

## **Dislocation**

### **Classic Presentation**

The patient presents with pain and deformity at the MCP joint and proximal phalanx (dorsally positioned) following a hyperextension accident, often a fall on an outstretched hand.

### **Cause**

Dislocation usually involves volar displacement of the metacarpal head through a rent in the volar plate. The metacarpal head is caught between the lumbricals, long flexors, and other soft tissue structures. Reduction is usually impossible because of this soft tissue blockage.<sup>25</sup> The little finger and index finger are most often involved.

### **Evaluation**

Because of the volar displacement of the metacarpal head, the proximal phalanx is dislocated dorsally. This deformity, coupled with a prominence at the MCP joint on the palmar surface of the hand, is indicative of dislocation. Radiographs may demonstrate widening of the joint space (volar plate caught in the joint) or articular fracture at the MCP.

### **Management**

MCP subluxations may be converted to a dislocation by an attempt at reduction. This occurs when using the standard procedure for dislocation of a phalanx; distraction with increasing the deformity into hyperextension. MCP dislocations should be referred for reductions.

### **Metacarpal Fractures**

# Classic Presentation

The patient presents with pain and often swelling over a metacarpal joint following either a direct blow or an axial compression force such as punching a wall with an unprotected hand. (*Author's note:* Patients often are embarrassed by the mechanism and often will give a fictitious history. The fracture is sometimes the result of taking out anger on an inanimate object.)

## Cause

Fractures may be transverse, spiral, or oblique and may involve the base, neck, or shaft. Direct blows or axial compression forces are most common. Fracture of the neck of the fifth metacarpal is called a boxer's fracture.<sup>26</sup> There is some disagreement about the definition of and distinction between a boxer's fracture and a bar-room fracture. The lines have blurred and they seem to be used interchangeably.

## Evaluation

Observation should include a search for rotational deformity evident at the MCP joint and with finger flexion. This is determined by noting nail alignment. Additionally, percussion of the extended finger or of the metacarpal with the fingers flexed often will increase pain. Radiographs usually indicate the type and extent of injury.

## Management

Depending on the scope of practice in a given state, management with casting or stock appliances may be acceptable if there is no fracture displacement. If not within the scope of practice and experience of a chiropractor or if there is displacement, referral for reduction and possible wire or screw fixation should be made. In general, third and fourth metacarpal fractures are inherently more stable than first and fifth. A 40° volar angulation is often considered an acceptable "functional" deformity.

## Dupuytren's Contracture

## Classic Presentation

The patient complains of stiffening in his or her hand so that the little and ring fingers are progressively kept in a flexed position. The patient may be a musician, often a guitarist.

## Cause

The cause is unknown. However, nodular thickening occurs in the flexor tendon, usually the fourth or fifth fingers. Eventually, the fingers become flexed at the MCP and PIP joints with the DIP joint held in extension. One predisposition that has been suggested is alcoholism.<sup>27</sup>

## Evaluation

Inspection and palpation reveal a flexion deformity with nodularity and flexor tendon/fascial thickening on the palmar aspect of the hand. Early in the course, passive stretch into extension is possible.

## Management

Early management includes avoidance or modification of any possible inciting activity. Constant stretching may be of benefit. One easy stretch is to sit on the hands. If not effective, immobilization at night with a soft cast to hold the fingers in neutral has been reported to be helpful. Failure of conservative care may require surgery if the contracture is significantly affecting activities of daily living or occupation. The surgery is technically difficult, however, and should be performed by a specialist.

## Trigger Finger or Thumb

## Classic Presentation

The patient presents with a complaint of his or her fingers getting “stuck” when trying to extend from a flexed position. She or he often reports having to extend the involved finger or thumb passively. The patient may have a history of chronic occupational overuse, especially grasping maneuvers.<sup>28</sup>

## Cause

The flexor tendons of the fingers or thumb pass through a soft-tissue pulley system at the base of the proximal phalanx of the thumb or finger. Through inflammation, trauma, or congenital variation, the tendon sheath enlarges proximal to the pulley system and is caught as the finger or thumb moves into extension.<sup>29</sup> This is a form of stenosing tenosynovitis.

## Evaluation

A discrete nodule is palpated at the base of the proximal phalanx of the involved finger or thumb. The nodule may be tender to pressure or gripping. Active extension is blocked and when possible causes a snapping action. If active extension is not possible, passive movement can accomplish extension accompanied with a snap as the nodule clears under the pulley.

## Management

Conservative approaches include underwater ultrasound with stretching, cross-friction massage, and avoidance of aggravating activities. Failure of conservative care (trial of several months) should result in a referral for cortisone injection. The cure rate with one to two injections is 91% according to one study.<sup>30</sup> Failure with cortisone injection requires a referral for surgical release under local anesthesia.

## THUMB

### Gamekeeper's Thumb

## Classic Presentation

The patient presents with pain at the base of the thumb and reports having fallen on the thumb, bending it back.

## Cause

Abduction or hyperextension causes tearing of the ulnar collateral ligament at the MCP joint of the thumb (medial side of the thumb). Common scenarios include a fall on the hand or a ski pole injury whereby the strap pulls the thumb back. Athletes who are hit on the thumb by a ball (such as in volleyball, basketball, or football) may have the thumb hyperextended.

# Evaluation

Tenderness and swelling are often found at the inside web space of the thumb. Stressing the thumb into extension or abduction is painful. The pain may be too great to allow stability testing. If stability testing is possible, pull the thumb into abduction, with the thumb in extension and also with slight flexion. Then test extension again with the thumb in extension and flexion.<sup>31</sup> If a complete tear is present, pinch strength between the thumb and index finger is lost. Radiographs should be taken with stress applied. If stress views demonstrate more than 35° abduction (subtracting starting position of abduction from stress position of abduction), a rupture is likely.<sup>32</sup> With physical examination and radiographs, always compare with the uninjured side.

# Management

First-degree and mild second-degree tears are managed with immobilization and stabilization with thumb taping, including a cinching between the thumb and index finger for a few days to a week.<sup>33</sup> Bad second-degree tears are immobilized with a thumb spica for two to three weeks. Complete tears are referred as soon as possible for surgery.

## Bowler's Thumb

# Classic Presentation

The patient complains of pain, numbness, or tingling on the palmar surface of the thumb. He or she is often a bowler.

# Cause

Constant irritation of the ulnar digital nerve of the thumb leads to perineural fibrosis. The irritation is from the edge of the thumb hole in the bowling ball of bowlers, or any utensil or tool that chronically compresses the nerve. Other mechanisms include overstretch of the thumb into extension acutely or chronically.<sup>34</sup>

# Evaluation

Tapping of the nerve causes pain and sensory symptoms in the distal thumb. Tenderness of the proximal joint is often found. Passive extension may increase symptoms.

## **Management**

Padding of the volar thumb area will decrease any compressive force. Enlargement of the thumb hole on a bowling ball may help. Taping or bracing the thumb to prevent extension of the thumb may help if the underlying mechanism is stretch. Modification of any inciting activity is the main goal.

## **Dislocation**

## **Classic Presentation**

The patient presents with pain and deformity at the base of the thumb following a hyperextension injury.

## **Cause**

Hyperextension tears the volar plate, allowing proximal phalanx dislocation dorsally.

## **Evaluation**

Tenderness and deformity are found at the base of the thumb with posteriority of the proximal phalanx. Radiographs are necessary to determine any associated fracture.

## **Management**

Reduction may be possible, avoiding straight traction, which may cause the volar plate to be caught in the joint. Push the dorsal aspect of the proximal phalanx in a volar direction while pushing the metacarpal dorsally to acquire reduction. If unsuccessful, refer for reduction under local block or open reduction. Postreduction, the joint is immobilized in a gutter splint or thumb spica for two to three weeks. Cautious range of motion exercises are then begun and progressively increased to resisted exercise for two to four weeks. Return to play may require a fiberglass cast for two weeks if allowed by the specific sport rules.

## **Bennett's Fracture**

### **Classic Presentation**

A patient presents in acute, severe pain following a fall or blow that caused axial compression to the thumb. There is deformity and rapid swelling.

### **Cause**

Axial compression causes a transarticular fracture at the first metacarpal base. A triangular fragment of bone is held in place by the volar ligament while the shaft dislocates over it. The dislocated section is held out of place by the action of the abductor pollicis longus.

### **Evaluation**

Deformity and swelling are usually severe, warranting immediate radiographic examination.

### **Management**

Referral is required for open reduction and pinning.

## **ARTHRITIDES**

### **Rheumatoid Arthritis**

### **Classic Presentation**

The patient is often a woman (aged 20 to 40 years) who complains of finger or wrist pain. She says that the joints are swollen and that in the morning it takes over an hour for her to be able to move her fingers comfortably. There is often an associated complaint of fatigue and possible weight loss.

### **Cause**

RA is an autoimmune disorder causing an inflammatory arthritis characterized by bilateral distribution often beginning in the hand (PIP and MCP joints). At the joint a reactive pannus forms, causing swelling and eventual erosion.

Genetic predisposition is based on the patient's possessing the class 2 human leukocyte antigen (HLA).

## Evaluation

When the disease is active, the joints are often warm, swollen, and tender. Finding symmetric involvement adds weight to the suspicion of RA. Other joints commonly involved include the wrists, knees, ankles, and toes. Later changes include flexor contractures and ulnar deviation of the fingers. Laboratory findings include a positive rheumatoid factor (IgM antibody found in 75% of patients), elevated erythrocyte sedimentation rate (ESR), C-reactive protein, and an associated anemia (often hypochromic and normocytic). Radiographic findings usually confirm the diagnosis; however, these are not evident in the early stages of the disease. The early changes include soft tissue swelling and juxta-articular demineralization. Eventually, uniform loss of joint space and joint erosions become apparent. Particular concern for the chiropractor is involvement of the transverse ligament at the dens of C2. This may lead to instability and would be a contraindication to upper cervical adjusting. An evaluation of the atlantodental interspace is necessary to determine stability of the C2-C1 articulation visible on a lateral view.

## Management

It is important to remember two factors regarding the natural course of RA in patients: (1) those with active disease have periods of exacerbation and remission that are usually unpredictable, and (2) 50% to 75% of patients presenting with RA will experience a remission within two years.<sup>35</sup> Various medical approaches are used during acute RA episodes, including aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), methotrexate, sulfasalazine, antimalarial drugs (Plaquenil), and—in difficult cases—gold salts (chrysotherapy) (e.g., Aurolate). Injectable gold is now seldom used due to high toxicity potential. A short course of corticosteroid (prednisone) treatment often will dramatically improve the symptoms; however, it will not alter the course of the RA. A special class of medications used in the management of rheumatoid and rheumatoid-like inflammation are disease-modifying antirheumatic drugs (DMARDs). DMARDs are prescribed either as sequential monotherapy, step-up therapy, induction therapy, or a more individually targeted approach of tight control. There are two classifications: biologics and nonbiologics. The older nonbiologics include drugs such as methotrexate, cyclosporine, and sulfasalazine. The biologics work off different principles. Delivery is either through self-injection subcutaneously (SQ) or through infusion therapy. Biologics are genetically engineered proteins used to address one of several aspects of immune regulation. The most common are anti-TNF inhibitors such as Cimzia, Enbrel, Humira, Remicade, and Simponi.

Conservative approaches involve passive mobilization of the joints through a pain-free range of motion. Avoidance of thrusting into inflamed joints is crucial in preventing aggravation of RA.

## **Psoriatic Arthritis**

### **Classic Presentation**

The patient complains of unilateral finger pain and swelling of nontraumatic origin. The patient may also complain of sacroiliac pain. The patient will have either a past diagnosis of psoriasis or a secondary complaint of skin lesions on the extensor surfaces of the arms and/or legs or scalp.

#### **Cause**

Psoriatic arthritis is a seronegative arthritis, meaning it is negative for rheumatoid factor (as are Reiter's syndrome and ankylosing spondylitis). There is a genetic predisposition associated with various HLA subtypes. Only 20% of patients with psoriasis have arthritis associated with their condition.<sup>36</sup> The arthritis can be mild or fulminant (arthritis mutilans).

### **Evaluation**

A search for skin lesions should be made in patients with a new, nontraumatic arthritis. Eighty percent of psoriatic arthritis patients have skin lesions prior to the onset of arthritis. The skin lesions may be quite obvious as silvery scales on the extensor surfaces of the arms and legs or subtle patches in the gluteal cleft, scalp, or umbilicus. In general, the more pronounced or involved the skin lesions, the worse the arthritis (when associated with arthritis). Involvement of the fingers or toes may create a "sausage" appearance. Laboratory evaluation is negative for rheumatoid factor (seronegative). ESR and uric acid levels may be elevated during the active phase. HLA B-27 is found in almost half of patients; however, it is nonspecific, given that ankylosing spondylitis may coexist with psoriatic arthritis. HLA B-17, Bw38, and Bw39 are also found. Radiographically, marginal erosions, especially of the DIP and PIP joints, are common with tuft erosion causing a sharpened pencil appearance. Fluffy periosteal bone may be visible along the shafts of the metacarpals and phalanges. The sacroiliac involvement may be evident in 15% to 20% of patients. Atypical syndesmophytes appearing on the anterior vertebral body may be evident also.

### **Management**

Medical treatment is similar to that for RA except that antimalarial agents may exacerbate psoriatic arthritis. Drugs used to treat both RA and the seronegative disorders like psoriatic arthritis are called DMARDs. If dermatologically more severe (measured by the Psoriasis Area Severity Index [PASI]) or when arthritis is present, cyclosporine, methotrexate, and acitretin are used with a 75% improvement in skin lesions. Methotrexate is associated with hepatic toxicity, cyclosporine with hypertension and nephrotoxicity, and acitretin with elevated serum lipids, mucocutaneous toxicity, and teratogenicity.<sup>37</sup> As a result, 40% of patients feel frustrated by the inadequacy of treatment, with 32% considering the treatment too aggressive.<sup>38</sup> Highly promising new drugs are being marketed, but they are extremely expensive, costing as much as \$26,000 annually. These drugs are part of a new class of medications called immune modulators (also known as biological response modifiers or “biologics”).<sup>39</sup> Their advantage may be the avoidance of adverse effects on organs or adverse drug reactions; however, their long-term effect on immunosuppression is unknown. Examples are alefacept and etanercept.<sup>40</sup> The ending of “-cept” is an indication of the drug’s effect, which is fusion of a receptor to the Fc portion of human IgG1. Finally, drugs designed to prevent T-cell activation with CTLA4Ig are being developed. Delivery is either through self-injection subcutaneously (SQ) or through infusion therapy. Biologics are genetically engineered proteins used to address one of several aspects of immune regulation:

- Anti-TNF inhibitors—Cimzia, Enbrel, Humira, Remicade, and Simponi
- T-cell inhibitors—Orencia
- IL-6 inhibitors—Actemra

There are no studies discussing the chiropractic management of this arthritis.

# Wrist and Hand Diagnosis Table

Wrist and Hand Diagnosis Table					
Diagnosis	Comments	History Findings	Positive Examination Findings	Radiography/Special Studies	Treatment Options
Subluxation or Fixation of: Carpometacarpal Joint Metacarpal/Phalangeal Joint Interphalangeal Joint	<ul style="list-style-type: none"> <li>Should be used when chiropractic manipulation is used as Tx for any wrist/hand problem/Dx.</li> <li>Can be primary Dx if patient is asymptomatic or mildly symptomatic (e.g., mild stiffness or pain level &lt; 2/10).</li> <li>Must indicate chiropractic exam findings to support Dx.</li> </ul>	<i>Nonspecific</i>	<p><i>Palpation</i>—Local tenderness or other signs of subluxation</p> <p><i>Ortho</i>—None</p> <p><i>Neuro</i>—None</p> <p><i>Active ROM</i>—Variable restriction</p> <p><i>Passive ROM</i>—End-range restriction</p> <p><i>Motion palpation</i>—Specific articular restriction or symptoms produced on end-range</p>	<ul style="list-style-type: none"> <li>Radiography not required for the diagnosis of subluxation.</li> <li>Radiographic biomechanical analysis may assist in treatment decisions.</li> </ul>	<ul style="list-style-type: none"> <li>Chiropractic adjustive technique</li> <li>Decisions regarding specifically which technique(s) is/are applied and modifications to the given approach will be directed by the primary Dx and patient's ability to tolerate preadjustment stresses.</li> </ul>
Carpal Sprain/Strain Carpometacarpal Joint Sprain Metacarpal/Phalangeal Joint Sprain Interphalangeal Joint Sprain Note: Sprain/strain is not synonymous with spasm or hypertonicity.	<ul style="list-style-type: none"> <li>Codes are used for either strain of a muscle/tendon or sprain of a ligament.</li> <li>Note, however, that tendon overuse generally would fall under general tendinitis or insertional tendinitis.</li> </ul>	<i>Mechanism</i> —Overstretch or over-contraction acute event; often a fall on hand/wrist or direct blow to area	<p><i>Ortho</i>—Each joint is tested by testing stability (often reproduces mechanism of injury); positives include pain and/or instability. Specific tests for carpal bones include Watson's, Ballotement, and shuck tests.</p> <p><i>Active ROM</i>—Pain or weakness may be reported</p> <p><i>Passive ROM</i>—Pain on end-range stretch of ligament</p>	<ul style="list-style-type: none"> <li>Radiography generally recommended to rule out any associated fracture.</li> <li>Stress radiographs may be needed.</li> <li>CT, fluoroscopy, or MRI may be needed to detect degree of damage when instability or pain is persistent.</li> </ul>	<ul style="list-style-type: none"> <li>With severe sprains, referral to orthopaedist may be required; for less severe, the following is applicable: <ul style="list-style-type: none"> <li>—Orthotic support (taping or brace)</li> <li>—Ergonomic advice</li> <li>—Strengthening and preventive exercises</li> <li>—Myofascial therapy</li> </ul> </li> </ul>
Carpal Tunnel Syndrome	<ul style="list-style-type: none"> <li>Carpal tunnel is one site of compression of the median nerve. It is important to differentiate from other sites of entrapment.</li> </ul>	<i>Onset</i> —Usually insidious onset of numbness and tingling on palmar surface of thumb and first 2 1/2 digits; paresthesias are often worse with sleeping	<p><i>Ortho</i>—Positives for reproduction of complaint with Tinel's or compression testing, Phalen's, reversed Phalen's; weakness of pinch and/or grip strength</p> <p><i>Neuro</i>—Possible hypoesthesia in palmar area of thumb and first 2 1/2 digits; thenar atrophy in chronic cases</p> <p><i>Motion palpation</i>—Possible restriction of lunate or distal radioulnar joint</p>	<ul style="list-style-type: none"> <li>Radiography not used for Dx unless traumatic in onset.</li> <li>Electrodiagnostic testing will demonstrate a decrease in nerve conduction velocity with an increase in latency.</li> </ul>	<ul style="list-style-type: none"> <li>Myofascial therapy may be helpful.</li> <li>Nutrition advice may include B6.</li> <li>Neutral or cock-up splint worn initially at night to relieve symptoms.</li> <li>Address any ergonomic considerations such as keyboard or mouse usage.</li> </ul>
Tendinitis of Wrist	<ul style="list-style-type: none"> <li>Usually a result of overuse.</li> </ul>	<p><i>Mechanism</i>—Often no Hx of trauma; chronic repetitive microtrauma is most common cause; establish causative activity</p> <p><i>Worse with specific ROM</i>—ROM that uses tendon action most is painful (e.g., active extension is painful with extensor carpi radialis tendinitis)</p>	<p><i>Palpation</i>—Tenderness found at insertion point or origin.</p> <p><i>Active ROM</i>—Resisted testing of involved muscle/tendon pattern reproduces complaint</p> <p><i>Passive ROM</i>—End-range stretch in opposite direction of contraction pattern may elicit pain</p>	<ul style="list-style-type: none"> <li>Radiography not usually necessary initially except to rule out fracture/dislocation with acute trauma.</li> </ul>	<ul style="list-style-type: none"> <li>Limited orthotic support.</li> <li>Physiotherapy for pain and swelling control.</li> <li>Herbal recommendations for pain and swelling.</li> <li>Modify inciting activity.</li> <li>Strengthen tendon with emphasis on eccentric movements.</li> </ul>
de Quervain's Tenosynovitis	<ul style="list-style-type: none"> <li>May be confused with intersection syndrome with involvement of extensor tendons proximal to wrist.</li> </ul>	<i>Mechanism</i> —Tenosynovitis of the abductor pollicis longus and extensor pollicis brevis; due to repetitive activities involving ulnar deviation of the wrist; also seen in pregnancy	<i>Ortho</i> —Finkelstein's test is positive for pain at anatomical snuff-box	<ul style="list-style-type: none"> <li>Radiography not usually indicated.</li> </ul>	<ul style="list-style-type: none"> <li>In early stages, ice, immobilization, and electrotherapy may be helpful.</li> <li>In later stages when stenosis occurs, conservative care is less effective.</li> </ul>

Trigger Finger	<ul style="list-style-type: none"> <li>• May be secondary to a chronic tendinitis or develop insidiously.</li> <li>• Considered a form of stenosing tenosynovitis.</li> </ul>	<p><i>Mechanism</i>—Nodule develops in flexor tendon and is caught in soft-tissue pulley on flexor surface</p> <p><i>History</i>—Gradual development of difficult movement of finger, in particular into extension that may be blocked</p>	<p><i>Palpation</i>—Often a tender nodule is palpable at base of proximal phalanx</p> <p><i>Active ROM</i>—Flexion may be limited; however, extension is blocked or snapping occurs during movement</p>	<ul style="list-style-type: none"> <li>• Radiography not used for diagnosis.</li> </ul>	<ul style="list-style-type: none"> <li>• Mild, constant stretching.</li> <li>• Physiotherapy may assist in decreasing size of nodule.</li> <li>• Nodules that do not resolve may respond to a cortisone injection.</li> <li>• If an underlying mechanism can be established, modify or eliminate.</li> </ul>
Extensor Tendon Rupture Mallet Finger	<ul style="list-style-type: none"> <li>• It is important to not dismiss the problem as a simple sprain due to mallet finger complications associated with tendon rupture or fracture.</li> <li>• Also check for possible central slip tearing of PIP joint.</li> </ul>	<p><i>Mechanism</i>—Compressive force on tip of extended finger forcing it into flexion causing avulsion of extensor digitorum tendon</p>	<p><i>Observation</i>—Distal joint may be in a flexed or “dropped” position</p> <p><i>Ortho</i>—Active extension of DIP joint is impossible</p>	<ul style="list-style-type: none"> <li>• Radiographs are required, with two planes of view to visualize any bony avulsion or epiphyseal fracture in younger patients; large bony avulsion usually is an indication of the need for surgical correction.</li> </ul>	<ul style="list-style-type: none"> <li>• Splinting of DIP joint in extension for up to six weeks.</li> <li>• Gradual active and passive ROM exercises may then begin.</li> <li>• Follow with six weeks of night and/or athletic splinting.</li> </ul>
Central Slip Tear	<ul style="list-style-type: none"> <li>• Avulsion of tendon at PIP will eventually result in Boutonnière’s Deformity if not managed appropriately.</li> <li>• Caution that injury is not misdiagnosed as simple finger sprain.</li> </ul>	<p><i>Mechanism</i>—Hyperflexion injury of PIP joint tears central slip of ED tendon as lateral bands drop anteriorly; the PIP joint is held in flexion with DIP joint extended</p>	<p><i>Palpation</i>—Tenderness at PIP joint; possible swelling</p> <p><i>Ortho</i>—Active extension of PIP not possible</p>	<ul style="list-style-type: none"> <li>• Radiographs should be ordered to rule out any bony avulsion or epiphyseal injury.</li> </ul>	<ul style="list-style-type: none"> <li>• PIP joint splinted in extension for six weeks.</li> <li>• Additional four to six weeks of night and/or athletic splinting.</li> </ul>
Flexor Digitorum Tendon Rupture (Football or Jersey Finger)	<ul style="list-style-type: none"> <li>• Caution that this injury results in tendon migration as far as into the hand.</li> </ul>	<p><i>Mechanism</i>—Hyperextension of DIP joint resulting in rupture of the FDP rupture</p>	<p><i>Ortho</i>—Patient unable to actively flex the DIP joint</p>	<ul style="list-style-type: none"> <li>• Radiographs should be ordered to rule out any bony avulsion.</li> </ul>	<ul style="list-style-type: none"> <li>• Refer for surgical reattachment (best results in three to four days post-injury).</li> </ul>
Volar Plate Injury	<ul style="list-style-type: none"> <li>• Caution that injury is not misdiagnosed as simple finger sprain and not properly splinted, leading to a pseudoboutonnière’s deformity (flexion at PIP with normal DIP).</li> </ul>	<p><i>Mechanism</i>—Hyperextended finger causes tearing of volar plate on palmar surface of PIP joint</p>	<p><i>Palpation</i>—Tenderness on volar plate of involved finger</p> <p><i>Ortho</i>—No consistent finding; however, resisted flexion or passive extension may increase pain</p>	<ul style="list-style-type: none"> <li>• Radiographs should be ordered to rule out any bony avulsion or epiphyseal injury.</li> </ul>	<ul style="list-style-type: none"> <li>• PIP joint is splinted in 30° of flexion for four to five weeks.</li> <li>• If unsuccessful, surgical referral may be needed.</li> </ul>
Ganglion	<ul style="list-style-type: none"> <li>• Ganglions have a tendency to increase and decrease in size regardless of treatment approach.</li> </ul>	<p><i>Cause</i>—It is thought that repetitive microtrauma causes ganglions to develop in either the capsule or tendons of the wrist or dorsal scapholunate ligament</p>	<p><i>Palpation</i>—A tender nodule may be evident on palpation (most common on dorsum of wrist)</p> <p><i>Ortho</i>—Passive dorsiflexion may make pain worse</p>	<ul style="list-style-type: none"> <li>• Radiographs not recommended.</li> </ul>	<ul style="list-style-type: none"> <li>• Attempts at compression to rupture the capsule of the ganglion should be applied cautiously.</li> <li>• Surgical excision if persistent or unresponsive.</li> </ul>
Raynaud’s Syndrome	<ul style="list-style-type: none"> <li>• May be associated with other disorders (Raynaud’s disease) or may be idiopathic (Raynaud’s phenomenon).</li> </ul>	<p><i>Cause</i>—Abnormality of sympathetic NS affecting vascularity in fingers; exposure to cold leads to pain</p>	<p><i>Signs/Symptoms</i>—Exposure to cold results in a triphasic response of pallor, cyanosis, and reactive redness (hyperemia)</p> <p><i>Test</i>—Allen’s test may show occlusion of radial artery if due to disease</p>	<ul style="list-style-type: none"> <li>• Radiographs not recommended.</li> </ul>	<ul style="list-style-type: none"> <li>• Treatment based on underlying cause; if due to a known disease, treatment of disease is recommended.</li> <li>• Avoidance of sympathetic stimulation and exposure to cold with appropriate protection are conservative options.</li> <li>• Failure to respond should result in medical referral.</li> </ul>
Gamekeeper’s Thumb	<ul style="list-style-type: none"> <li>• Patients have pain on the inside of the thumb.</li> </ul>	<p><i>Mechanism</i>—Hyperextension or hyperabduction of thumb may result in tearing of the ulnar collateral ligament</p>	<p><i>Ortho</i>—Passive extension or abduction recreates pain on the medial aspect of the thumb and may indicate laxity</p>	<ul style="list-style-type: none"> <li>• Radiographs should be ordered to determine if there are any associated avulsion fragments; stress radiographs may also be ordered.</li> </ul>	<ul style="list-style-type: none"> <li>• Taping or splinting of mild to moderate injuries for two to three weeks will usually allow sufficient healing.</li> <li>• Injury associated with full rupture (laxity) or bony avulsion may require surgical consult.</li> </ul>

Myofasciitis	<ul style="list-style-type: none"> <li>Used when specific trigger points are identified on physical examination.</li> <li>Also may be used if a strain is not evident from the history but there are indications of muscle tenderness, stiffness, or pain.</li> </ul>	Nonspecific	Trigger points are evident as localized tenderness in a muscle that corresponds to traditional (Travell/Simons) trigger point charts. These points may be local or refer pain when compressed.	<ul style="list-style-type: none"> <li>Not required or recommended.</li> </ul>	<ul style="list-style-type: none"> <li>Myofascial approaches such as myofascial stripping, trigger point massage, or spray and stretch approaches are the standard.</li> <li>Home stretching and modification of activity suggestions.</li> </ul>
Laxity Hypermobility	<ul style="list-style-type: none"> <li>May represent inherent looseness in the joint or acquired secondary to injury.</li> </ul>	A history of a single event, traumatic injury to the joint is not found; however, either overuse (microtrauma) or generalized inherent looseness is evident	Capsular or ligament testing reveals "looseness" that falls within the physiologic range of normal.	<ul style="list-style-type: none"> <li>Not usually recommended unless when differentiating pathological laxity from congenital or overuse acquisition.</li> </ul>	<ul style="list-style-type: none"> <li>Strengthening program</li> <li>Bracing or functional taping during rehabilitation or during strenuous activities.</li> </ul>

# **CHAPTER 11**

## **Hip, Groin, and Thigh Complaints**

### **Context**

Although the hip and shoulder are the most proximal joints of their respective limbs, the hip is unique in several aspects. Unlike the shoulder, the hip is quite stable and requires a major force to cause a dislocation. Although common shoulder problems are often soft-tissue generated, the hip is more prone to bone or joint damage. As a weight-bearing joint it is commonly affected by degenerative changes and fracture in senior patients. Disorders of the hip are probably more age-related than any other joint. Many presentations fit an age-related categorization: congenital disorders in the infant, growth plate and vascular etiologies in the adolescent, trauma in the young adult, and fracture or arthritis in the elderly. The diagnosis of many of these disorders is dependent on radiographic confirmation.

Patients often claim hip pain when, in fact, the pain is in either the low back or buttocks. It is important, as with all pain, to have the patient localize the problem. Hip pain may be due to intrinsic pathology of the hip joint or referred from a number of geographically and neurally related structures. Associated pain in the lumbopelvic or abdominal areas often will identify the source, but not always. The overlap with groin pain extends the diagnostic list substantially. Pain in

the groin also may be caused by local pathology or referred from the hip, pelvis, genitals, or abdomen. Associated signs or symptoms will usually help differentiate between mechanical and visceral sources.

A common traumatic history is a fall onto the hip. This often results in soft tissue injury such as a contusion or a trochanteric bursitis. Fracture should be ruled out, in particular in the senior patient. An insidious onset of hip pain is suggestive of osteoarthritic changes in the middle-aged or senior adult. In the child or adolescent, avascular necrosis, slipped epiphysis, or a reactive synovitis should be considered. With children it is important to remember that the knee is a common referral site for hip disorders.

Thigh pain is often differentiated on the basis of a history of either direct trauma (contusion) or sudden-movement onset (strain). When anterior numbness, paresthesias, or weakness are complaints, femoral nerve involvement should be evaluated. Lateral sensory complaints usually represent lateral femoral cutaneous nerve (meralgia paresthetica) involvement or trigger point referral. Posterior neurologic complaints suggest sciatic nerve irritation, referral from trigger points, or lumbar/sacral facet problems.

## **General Strategy**

### **History**

- Determine what the patient means by “hip” pain (groin, buttocks, hip, pelvis, etc.).
- Localize the pain to a quadrant of lateral, medial, anterior, or posterior pain.
- Determine whether any overt trauma occurred such as a fall on the hip (in younger patients, suspect a slipped

epiphysis or an avascular process; in the elderly, a fracture).

- If there was trauma, determine whether the patient can bear weight; if not, radiographs including anteroposterior (AP) and lateral (frog-leg) views are essential.
- If there was a sudden onset with sporting activity, determine the mechanism (in younger patients consider an apophysitis).
- Determine whether there is a history of overuse (suspicion of a stress fracture in a high-level athlete; myofascial problems in all patients).
- Determine whether there are any associated visceral complaints (radiation of pain from the back to the groin is suggestive of renal disease; from the groin to the hip suggests genitourinary disease or hernia).

## Evaluation

- Determine whether there is a range of motion (ROM) restriction suggestive of capsular involvement of the hip (internal rotation and extension), a positive FABER (flexion, abduction, external rotation) test, or increased pain by axial compression into the joint (found with synovitis of various causes and with osteoarthritis [OA]).
- Determine whether there is associated anteversion/retroversion or asymmetric restrictions in either passive external or internal rotation.
- If groin pain is the complaint, test adductors and hip flexors to determine strain, palpate for tenderness at attachment sites of muscles, and palpate for hernias in patients with chronic pain made worse with straining; if pain is radiating to the groin from the back, perform

a kidney punch test; palpate lymph nodes if genital complaints or lesions are present.

- If snapping around the hip is the complaint, determine the location and determine on which ROM the snapping or popping occurs (adduction for iliotibial band syndrome snapping, abduction for iliopectineal or psoas snapping).
- Determine whether there are other musculoskeletal complaints (may be a clue to hip pain being the result of accommodation to other lower extremity or low back problem).
- Radiographs of the hip should be ordered if an obvious soft tissue cause is not evident or if pain is trauma-induced; include AP and frog-leg (lateral) views.
- Determine whether further imaging techniques are appropriate (bone scan with suspicion of stress fracture or synovitis; magnetic resonance imaging [MRI] if there is a suspicion of tumor or infection; computed tomography [CT] scan if there is a suspicion of a pelvic fracture).

## Management

- Refer cases to the appropriate medical specialist if any of the following are found: fracture, avascular necrosis, dislocation, tumor, infection, or hernia.
- Management of soft tissue problems involves stretching, myofascial release techniques, appropriate exercise, and preventive approaches through correction of any underlying biomechanical faults.
- OA is managed initially with physical therapy modalities and possibly manipulation; long-term management involves a strengthening program for the hip and thigh.

# Relevant Anatomy

As essentially a ball-and-socket joint, the hip shares with the shoulder a great degree of movement capability. Unlike the shoulder, however, the hip is a primary weight bearer and as such is more prone to acute and chronic consequences of trauma such as degenerative changes, fractures, and synovitis. As a weight-bearing joint, the effect of femoral head fit and positioning is crucial to proper function. The angulation of the femoral head is referred to as *version*. When the hip is determined to be anteverted, the femoral head faces forward (with relative posterior positioning of the greater trochanter). With retroversion the angulation of the femoral head faces backward with positioning of the greater trochanter anteriorly. These angulations place a biomechanical demand on the bones and joints below. In growing children and adolescents, these demands may result in compensations that may cause torsion of the femur or tibia and foot compensations of pronation or supination. Another mechanical factor is the angulation of the neck of the femur. An increased angle (coxa valga) or decreased angle (coxa vara) is age-related or may be changed by fracture or pathology of the femoral neck. The angle normally decreases from birth (average of  $160^{\circ}$ ) to adulthood (average of  $120^{\circ}$ ).

The hip is inherently stable because of its articulation with the pelvis and the thick support of musculature. The capsule is supported by the iliofemoral and pubofemoral ligaments anteriorly and the iliofemoral and ischiofemoral ligaments posteriorly (**Figure 11-1**). Ligaments tighten on extension and are more relaxed in flexion. Specifically, the iliofemoral ligament tightens in hip external rotation and adduction, the ischiofemoral ligament tightens in hip internal rotation and abduction, and the pubofemoral ligament tightens in hip external rotation and abduction.

Although these capsular ligaments are substantial enough to require macro trauma to damage them with a single traumatic event, it is becoming evident that repetitive hip external rotation as seen in such activities as ballet, golf, gymnastics, martial arts, and baseball may lead to capsular laxity through microtrauma.<sup>1</sup> This focal rotational laxity, as it is referred to, contrasts with the more global laxity seen with connective tissue disorders such as Down's, Marfan's, and Ehlers-Danlos syndromes among others.

**Figure 11-1** The ligamentous support of the hip. Anterior view showing main ligaments; coronal section showing articular cavity and capsule.

The ligamentum teres is a unique structure that attaches at the fovea capitis of the femoral head and the acetabular notch. It tightens during adduction, flexion, and external rotation.<sup>2</sup> Damage to the ligamentum teres appears to be far more common than once thought, accounting for the

third most common lesion in athletes when viewed arthroscopically.<sup>3</sup>

As with the shoulder, the acetabulum contains a labrum. The labrum helps provide stability to the hip joint. It deepens the acetabulum and acts as a seal to maintain negative intra-articular pressure. It also protects the articular cartilage and provides proprioceptive input.<sup>4</sup> A number of anatomical problems may contribute to labral damage, which can then predispose to degeneration and early osteoarthritis. Damage is also possible through trauma, often extreme external rotation. The articular cartilage of the hip is thicker anterosuperiorly. Although it was generally assumed that degeneration occurred primarily from osteoarthritis and rheumatoid arthritis, it appears that anterosuperior acetabulum chondral lesions are associated with a host of abnormalities such as labrum tears, anterior capsular laxity, and femoroacetabular impingement (FAI).<sup>5</sup> During standing the hips bear approximately one third of body weight. This increases to 2.4 to 2.6 times body weight when standing on one leg. During walking, the hip can bear as much as 1.3 to 5.8 times body weight. Use of a cane can reduce this load by as much as 40%.<sup>6</sup>

Function of the hip may be affected by pelvic motions such as anterior, posterior, or lateral tilt. These motions are affected by the cocontraction or relaxation of various muscle groups. Anterior tilt is caused by the contraction of the hip flexors. Posterior tilt can be accomplished by contraction of lumbar spine extensors, hip extensors, or trunk flexors. Lateral tilt is accomplished through contraction of hip abductors. Excessive weakness or tightness of these muscles may allow or cause abnormal mechanical function through the creation of a functionally short or long leg.

Flexion of the hip is controlled by the iliopsoas and rectus femoris (**Figure 11-2**). Assistance may be provided by the

adductors, tensor fascia lata, and sartorius (L2-L4). Extension is primarily accomplished by contraction of the gluteus maximus, ischial portion of the adductor magnus, and hamstrings (L5-S2). The gluteus medius and piriformis may assist. Internal rotation and abduction are due to the contraction of the gluteus medius, gluteus minimus, and the tensor fascia lata (L4-S1). External rotation is accomplished mainly by the piriformis, gemellus, and obturator muscles (L5-S2), with some posture-dependent assistance from the iliopsoas and gluteus maximus. Adduction is primarily accomplished by the adductor group and the gracilis muscle (L3-L5). The strongest movements are extension, adduction, and external rotation. With walking, the unsupported pelvis is supported by the contralateral hip abductors (primarily gluteus medius).

## Evaluation

## History

Careful questioning of the patient during the history taking can point to the diagnosis ([Table 11-1](#)).

## Pain Localization

By having the patient point to the area of pain and describe whether or not the onset was traumatic, the diagnostic list can be narrowed.

## Iliac Crest

- Anterior superior iliac spine (ASIS)—sartorius strain or, in younger patients, apophysitis or avulsion
- Anterior inferior iliac spine (AIIS)—rectus femoris strain or, in younger patients, apophysitis or avulsion

**Figure 11-2** (A) Quadriceps muscles (anterior view); (B) hamstring and gluteal muscles (posterior view).

**Table 11-1** History Questions for Hip, Groin, and Thigh Complaints

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Did you fall on your hip?	Hip pointer, hip fracture, traumatic synovitis, slipped epiphysis	Are you able to bear weight and walk?	If yes, hip pointer or contusion is likely; unable to bear weight indicates the other possibilities
Was there a blow to your thigh?	Contusion of hamstrings or quadriceps	Were you hit in the front and do you have difficulty flexing your knee?	Quadriceps contusion
		Were you hit in the back of the thigh and does it hurt to bend forward?	Hamstring contusion
Did you feel a sharp pain in your thigh or groin while performing a sport or recreational activity?	Hamstring, adductor, or quadriceps pull; in younger patients apophysitis is possible	Does it hurt to flex the knee or fully straighten the knee?	Hamstring pull
		Does it hurt to lift the leg?	Iliopsoas or adductor strain (pull)
		Does it hurt to extend the knee?	Quadriceps strain (pull)
		Did you have a previous respiratory infection (especially in children)?	Septic or aseptic synovitis (needs special imaging to differentiate)
Do you have any associated signs and symptoms?	Referral from other joints, septic or aseptic synovitis, OA or other arthritides, tumor, Paget's disease	Do you have any menstrual irregularities?	Possibly gynecologic referral
		Is the pain worse at night, and have you lost any weight recently? Any previous history of cancer?	Metastasis or primary tumor
		Is the pain in both hips and do you have any hand or finger pain?	Rheumatoid arthritis is likely
		Have you noticed a change in hat size?	Paget's disease is possible
		Have you had previous trauma or previous disease of the hip?	OA
		Does the pain radiate from the back to groin?	Renal pathology
		Do you have pain in the groin with bearing down or lifting?	Inguinal hernia

- Lateral iliac crest—hip pointer (if due to a direct blow or fall); iliac crest apophysitis; oblique abdominal, tensor fascia lata, or gluteus medius strain
- Posterior iliac crest—Maigne's syndrome (from T12), strain of gluteus maximus or iliac fascia, or referral from the low back

## Groin

- Pubic bone—osteitis pubis, adductor tendinitis
- Inguinal area—hernia, abdominal strain, lymphadenopathy, iliopsoas bursitis, or tendinitis
- Lateral hip—trochanteric bursitis, tensor fascia lata, or gluteus medius trigger points
- Ischial tuberosity—hamstring sprain, ischial bursitis, or avulsion injury
- Generalized deep pain—synovitis, fracture, OA, Paget's disease

It may be frustrating to have forgotten to clarify the location of the patient's complaint. Often patients have a larger target area in mind when they describe their pain as "hip" pain. Many patients mean buttock pain or thigh pain. After it is clear that hip pain is the chief complaint, it is important to distinguish among associated complaints of snapping, crepitus, and decreased ROM or stiffness. Pain is nonspecific; however, snapping suggests a bursa or tendon source. Decreased ROM is found with many conditions; however, the pattern of restriction may be quite revealing, as discussed earlier in the general strategy section. Also, when there is a chief complaint of stiffness without significant pain, the diagnostic list is narrowed.

## **Age and Onset**

By approaching the history from the perspective of age and mode of onset, a high level of suspicion for a specific cause can be gained. Many of these suspicions are quickly confirmed or eliminated with a radiographic evaluation. The following are classic presentations based on age.

### **Pediatric/Childhood Onset**

The earliest indicator of a congenital hip disorder may be a nonpainful limp that is of concern to the parents. This would be suggestive of an undetected hip dysplasia or a congenital hip dislocation.

### **Adolescent/Young Adult Onset**

An insidious onset of pain in the adolescent should raise the suspicion of either a slipped femoral capital epiphysis (or preslip) or an avascular necrosis (Perthes' disease). When the onset is sudden and/or traumatic, a search for a slipped epiphysis should be followed. However, a similar presentation may be found with a transient synovitis, which is not clearly evident on radiographs. When the onset is insidious yet associated with a repetitive activity such as running, marching, dancing, or aerobics, suspicion of a stress fracture should be high.

### **Middle-Aged Adult Onset**

Hip pain in the middle-aged adult is unusual unless the patient has had previous problems as a child or adolescent. The obvious exceptions are pregnancy, during which hip pain may be part of the mechanical discomfort associated with extra weight bearing, and trauma. If pain began subsequent to a physical activity, such as sports, or an unaccustomed activity, such as cleaning the yard, local muscle strain should be considered. Occasionally, the answer to questions regarding the use of orthotics or heel lifts is revealing. The altered mechanics may result in strain or reactive bursitis. In the middle-aged group of patients, it is always important to distinguish between a local joint problem and one that is part of a bigger complex of joint complaints. Arthritides such as rheumatoid arthritis (RA) have their initial noticeable signs/symptoms in middle age, although they are less common in the hip. Crystalline deposition disorders, as well, may begin in middle age.

Although it may appear that the diagnosis of hip pain would be relatively straightforward based on common age-related disorders, insidious hip pain is often a dilemma. When none of the obvious causes are found, a decision as to which imaging tool is most appropriate (and cost effective) must be determined. The other complication is that the hip, more than many other joints, is dependent on proper alignment and functioning of the distal joints of the lower extremity kinematic chain. Disorders in any of these joints may cause adaptive compensation at the hip. Being the primary weight-bearing joint of the lower extremity, impact forces must be attenuated, especially in the straightened leg.

## **Weakness**

Isolated weakness in the hips is usually a patient perception due to restricted ROM. OA or muscle contracture provides resistance to movement attempts. Further differentiation can be made by the findings of strong contractions in the midrange combined with restricted passive ROM findings upon examination. When muscle pathology is present, as in muscular dystrophy, the patient often will develop perceptible muscle weakness first in the proximal muscle around the hip and pelvis. There will be no associated complaints of pain or sensory aberrations. If weakness is associated with pain, it is important to ascertain the movement pattern to determine whether there is a specific muscle or tendon cause. Painless difficulty in standing up is suggestive of muscular dystrophy but is not specific for this disorder.

## **Restriction**

If the patient feels that he or she has restricted movement, age and associated symptoms help distinguish the cause. In older patients, OA or perhaps Paget's disease is possible. In a younger patient, especially in males, ankylosing spondylitis is possible (due primarily to pelvic involvement). If the restriction is less discernible after moving around for a half hour or longer, OA is often the cause in older patients.

## Snapping

Snapping at the hip is usually a benign problem. In addition to tendon snapping, there is often a suction effect that occurs at the hip joint, causing a pop similar to that caused by manipulation. On rarer occasions, a loose body may be present. Tendon snapping is usually evident with localization of the snapping coupled with the type of movement that creates the snapping.

- Anterior snapping with hip abduction or external rotation suggests that the psoas tendon is snapping over the lesser trochanter or iliopectineal eminence.
- Lateral snapping with hip adduction coupled with flexion or extension suggests that the iliotibial band is snapping over the greater trochanter.
- Posterior snapping with flexion or extension suggests that the biceps femoris tendon is snapping over the ischial tuberosity.
- Pubic bone snapping may occur during pregnancy or the postpartum period or, in rare cases, following a traumatic spread-eagle injury (indicates instability).

Further distinction can be made during the physical examination, palpating the area while the patient performs the provocative movement. It is important to remember that

there are interposed bursae at these sites that may be inflamed and cause pain due to the constant snapping.

## **Groin Pain**

The history is particularly important in differentiating the various causes of groin pain. When the pain follows a twisting, sudden, or forceful movement of the hip, adductor strain is often the cause. If the report is that pain occurred after a lifting incident and is made worse with bearing down (Valsalva maneuver), a hernia is likely. If the patient is a man who reports an associated testicular mass, then epididymitis, testicular cancer, a varicocele, or testicular torsion is possible. Testicular torsion usually causes pain severe enough to cause the patient to seek medical attention. Palpation of the testes must be performed to differentiate each. Groin pain in women that is not readily reproducible suggests a gynecologic cause. Questions regarding a relationship to the patient's menstrual period may reveal a connection.

## **Thigh Complaints**

Thigh pain is usually due to direct trauma that results in a contusion or due to overcontraction that leads to either muscle tear or rupture. A history of a direct blow to the quadriceps or hamstrings is highly suggestive of a contusion with subsequent hematoma formation. It is important to question the patient regarding the events following the trauma. If the patient returned to a strenuous activity or applied deep heat or massage, a concern for myositis ossificans is generated.

When sudden pain follows a strenuous activity such as running to first base or sprinting, location of the pain will

usually isolate a quadriceps or hamstring strain. It is important to determine whether the patient stretches or warms up prior to activity.

When the complaint is more of numbness or paresthesia into the thigh, localization to the lateral thigh suggests meralgia paresthetica. Determining whether the patient is obese, pregnant, sits for long periods, or carries keys or other objects in his or her front pockets may unearth the underlying cause. When the numbness is more anterior, the femoral nerve is involved, and it is likely that the patient is a known diabetic or has signs indicating canal stenosis (claudication signs with walking). Subjective numbness may occur with various trigger-point referrals.

## Examination

Given the context of patient presentation, the evaluation of the patient on physical exam extends from very brief to extended. For example, if the patient is unable to bear weight or comfortably move the hip, it would seem prudent to begin the examination with localization of the complaint with palpation. This should be followed immediately by radiographic examination.

Direct palpation of the hip joint is not possible, causing the examiner to rely on indirect, provocative maneuvers. Orthopaedic testing for the hip is rather limited. Many tests are used as a means of differentiating the hip from other causes through a localizing response by the patient. For example, the Patrick test or FABER test is accomplished by placing the ankle of the tested leg over the well-side knee and abducting and externally rotating the hip (**Figure 11-3**). This test may produce pain at the hip or the sacroiliac (SI) joint. Although the FABER test is a good test for intra-articular pathology with a sensitivity of 88%, it is nonspecific.<sup>7</sup> A more specific test involves applying an axial

compression force through the femur into the hip joint with the knee flexed to 90° or more. This can be retested with the hip flexed and internally rotated. This is sometimes referred to as Laguerre's test. The quadrant test involves placing the hip in the same Laguerre's position while the patient is asked to resist the examiner's attempt at abduction. Most other testing is based on an effort to distinguish between hip pain of low back or SI origin (see [Chapter 6](#)).

**Figure 11-3** FABER test. The patient's hip is placed into flexion, abduction, and external rotation.

There are a number of femoroacetabular impingement (FAI) tests. The general test position involves passive hip flexion, internal rotation, and adduction (see [Figure 11-4](#)). The intention is to compress the anterior superior labrum and acetabular rim. Two variations include the Fitzgerald<sup>8</sup> provocative maneuver and the McCarthy<sup>9</sup> sign. The Fitzgerald provocative maneuver's positive finding for impingement is a sharp, catching pain, with or without a click, with the hip passively brought into full flexion, external rotation, and full abduction, then extending with internal

rotation and adduction. Fitzgerald suggests that this maneuver is more sensitive for anterior tear detection, while switching the initial external rotation to internal rotation and extending with external rotation is specific for posterior tears. The McCarthy sign has the examiner first flex the opposite hip while the affected hip is extended with internal rotation, then with external rotation in an attempt to reproduce a painful click. Some studies indicate a high degree of sensitivity when compared to surgical identification.<sup>10,11</sup> One study indicated a sensitivity of 75% and a specificity of 45% in detecting FAI compared to MRA.<sup>12</sup>

**Figure 11-4** Acetabular impingement test. Hip flexion, internal rotation, and adduction.

Instability is sometimes assessed clinically using longaxis traction. With the supine patient's hip placed in 30° flexion, 30° abduction, and 10° to 15° of external rotation, the examiner leans back using his body weight.<sup>13</sup> Patients with instability may feel movement or a sense of apprehension.

Various stretch maneuvers can be applied to the hip joint. The Thomas test requires the supine patient to draw one leg toward the chest while the examiner observes the position of the opposite leg. If the hip or knee flexes, tightness in the hip flexors is likely. A focus on the rectus femoris can be accomplished by having the patient repeat

the test with the knee hanging over the edge of the examination table (see **Figure 11-5**). If the knee extends while the patient flexes the opposite hip to his or her chest, the rectus femoris is tight. A prone test for hip flexor tightness can be accomplished by passively extending the hip with the knee extended. If the hip is extended with the knee flexed, the rectus femoris is tested. This same test may stretch the femoral nerve and cause radiation of pain or other sensory complaints into the anterior thigh. Stretch testing of the abductors and adductors should also be performed. If the abductors are shortened due to contracture, a functional long leg with lowering of the ipsilateral pelvis will be created, associated with adduction of the opposite hip with a raised pelvis.<sup>13</sup> If the adductors are shortened, the ipsilateral leg is functionally shortened with a raised pelvis. On the opposite side, the hip abducts, lowering the pelvis.

**Figure 11-5** Modified Thomas test indicating tightness of left rectus femoris.

Ober's test is often performed on patients complaining of lateral knee pain (**Figure 12-11**). For the hip, this test is less a provocative test and more a test of abductor flexibility. With the patient lying on his or her side and the bottom leg flexed to 90°, the examiner slowly lowers the top extended

leg off the edge of the table while stabilizing at the iliac crest to avoid abdominal stretching. If the patella does not pass below the top edge of the table, tightness of the gluteus medius or the iliotibial band or its attachments (the gluteus maximus and the tensor fascia lata) is likely.

Another biomechanical factor that should be assessed is anteversion or retroversion of the femur. This refers to the angle the femoral neck forms with the femoral condyles. The degree of anteversion is based on the forward projection of the femoral neck into the acetabulum. With abnormal anteversion the femoral condyles are internally rotated with respect to the femoral neck; the reverse occurs with retroversion. Anteversion and retroversion are measured by using the Craig test. This test can be coupled with a measure of internal and external rotation of the hip. With the patient prone, the knee is bent to 90° and both active and passive internal and external rotation are measured. For the Craig test, palpation of the greater trochanter is necessary. As the patient's hip is passively internally and externally rotated, the examiner finds a point at which the greater trochanter feels parallel to the exam table (**Figure 11-6**). The angle formed by the lower leg and vertical is considered the angle of anteversion (if internally rotated) and retroversion (if externally rotated). See **Figure 11-7**. The average angle is considered to be between 12° and 25° of anteversion in the adult.<sup>15</sup> Excessive anteversion leads to internal rotation of the femur with potential valgus forces to the knee and possible hyperpronation.

Leg length measurement should be considered a gross but potentially valuable data source. The standard approach is to measure the supine patient from the ASIS to the medial malleolus on the same side (true or anatomic leg length) and then to measure the opposite side and compare the measurements. The same approach is repeated, but this time using the umbilicus and the medial malleolus (apparent or functional leg length). If there is a difference in

the “true” leg length, an anatomic short leg (often due to a previous fracture or deforming process at the hip) is present. If the leg length deficiency is in the apparent measurement, a variety of soft tissue factors are likely involved. The interexaminer agreement is only about 40% when examiners had to be within 6 mm of each other to be considered in agreement.<sup>16</sup> When this was extended to 12.5 mm, the agreement increased to 86%. Also, Beattie<sup>17</sup> found that the reliability was high when the mean of two measurements was used. The large literature review published by Manello<sup>18</sup> demonstrates the continuing controversy regarding the contribution of leg length discrepancy to an increase in or predisposition to low back, pelvic, or hip pain. Generally, however, to be clinically significant, the leg length discrepancy needs to be equal to or greater than 0.5 in. This means that discrepancies beyond this range have been shown to predispose individuals to conditions such as subtrochanteric bursitis or SI dysfunction.<sup>19</sup> With a functionally short or long leg, recheck findings with regard to abductor, adductor, or hip flexor/extensor tightness or weakness. If the leg length appears only on weight-bearing, check for unilateral pronation or supination as potential causes.

**Figure 11-6** Craig test for anteversion/retroversion of the hip. While palpating the greater trochanter the patient's leg is internally or externally rotated until the greater trochanter is pointing parallel to the table. The angle formed by internal rotation with a vertical line indicates the degree of anteversion; the external rotation angle indicates retroversion.

**Figure 11-7** Torsion angles of the hip. (A) Positions of femoral neck. (B) Different foot positions with anteversion and retroversion at the hip (coronal views).

There is a new interest in determining hip pain in athletes given it is a common cause of disability in high-level performers, in particular in soccer.<sup>20</sup> This has led to

sophisticated approaches to analysis of hip and pelvis loading for running, jumping, and landing. There is an emphasis now on correcting these faults prior to a surgical solution. Some elements that have been evaluated include:

- The 3G approach (groin, gluteal, and greater trochanter triangles) is a systematic approach to looking at the muscular/fascial triangle as integrated and supplementary to one another.<sup>21</sup>
- An increased alpha angle on radiographs to predict groin injury.<sup>22</sup>
- Hernias are being re-evaluated as a “groin disruption injury,” the result of functional instability of the pelvis.<sup>23</sup> The approach to management can be focused rehabilitation based on high-speed analysis of movement or, if unsuccessful, surgical stabilization.

Radiographs may include the standard AP lumbopelvic film or localize for better quality with an AP hip view complemented by a lateral (frog-leg) view. Most osseous and some soft tissue abnormalities may be evident. If avulsion fractures are suspected, the AP view may require some internal or external rotation in order to view the fragment clearly. Following are some radiographic findings associated with some selected disorders:<sup>24</sup>

- OA—The superior acetabular joint space shows narrowing with osteophyte formation at the head/neck junction; there is subchondral sclerosis.
- RA—Early phase changes are uniform, symmetric loss of joint space with associated periarticular osteoporosis. Later changes may include subchondral cyst formation and destruction of the femoral head or acetabular roof even to the point of protrusio acetabuli (protrusion of the femoral head axially through the acetabulum into the pelvis).

- Paget's disease—The bone is thickened, with more apparent trabeculae (cross-hatching) with eventual distortion of the femoral neck or shaft shape.
- Legg-Calvé-Perthes disease (ages 4 to 8 years)—Initial changes include fissuring, flattening, and sclerosis of the epiphysis with a secondary phase of remodeling leading to the classic mushroom deformity; a varus deformity usually results.
- Slipped capital epiphysis (ages 8 to 17 years)—This is a Salter-Harris type I injury characterized by posterior-inferior displacement of the epiphysis best seen on the lateral view.
- Acetabular dysplasia—The center wedge angle of Wiberg is measured.
- Femoral acetabular impingement—Anterior asphericity of the femoral head, lack of femoral head-neck offset, and retroversion of the acetabulum.<sup>25</sup>
- Fractures may be due to osteoporosis, Paget's disease, metastasis, and other pathologic processes, or trauma. Femoral neck fractures are intracapsular (subcapital and transcervical regions) or extra-capsular (trochanteric, subtrochanteric, and basicervical); intracapsular fractures are more serious and twice as common.<sup>26</sup>

Magnetic resonance imaging (MRI) is valuable for a host of intra-articular disorders, specifically the early phase of avascular necrosis. Magnetic resonance arthrography (MRA) is particularly valuable for identifying acetabular labrum tears with a reported sensitivity range of between 66% to 95% and a specificity range of 71% to 88%.<sup>27</sup>

## Groin

- With trauma or pain following a sudden forceful maneuver of the hip, palpate for sites of tenderness (e.g., adductor origin); if the history indicates a blow to the region, radiograph for possible fracture.
- If pain was insidious or due to overuse, palpate for adductor tenderness and local lymphadenopathy.
- If pain followed a lifting injury or increases with bearing down, perform a hernia evaluation.
- When a gynecologic or genital source is suspected, perform or refer for a thorough examination.

When groin pain is traumatic or due to a sudden forceful movement, palpate for tenderness at the pubic bone and adductor origin. Have the patient attempt adduction, flexion, and extension against resistance to isolate specific muscle/tendon involvement. Pain with resisted hip flexion suggests iliopsoas or possibly rectus femoris strain. Pain with resisted adduction suggests adductor tendinitis. If tenderness is severe, consider radiographs to determine possible fracture. For patients with a history of pain following lifting or those who experience pain with bearing down, perform a hernia examination. This includes palpation for direct, indirect, and femoral hernias.

Reproduction of the pain with SI or hip testing indicates referral to the groin from these areas. If pain originates in the thoracolumbar area, perform a kidney punch test. A search for skin lesions or discharge may suggest a venereal cause.

## Thigh

Trauma to the thigh requires a search for contusions. In the anterior thigh, a quadriceps contusion is likely. Palpation is important with injuries that are a few weeks old to determine the development of myositis ossificans. Posterior

involvement indicates hamstring contusion. When pain follows sudden or forceful contraction of the legs such as with running, palpation for sites of tenderness is important. If the pain is posterior at the middle to distal thigh, a hamstring sprain has occurred. Occasionally a defect in the muscle can be palpated. The degree of tearing is often reflected in the patient's ability to flex the knee against resistance. The same principles apply to a quadriceps strain, with the severity based on the patient's ability to extend the knee against resistance or perform a quadriceps isometric contraction.

When thigh complaints include numbness or paresthesia, it is important to determine whether the symptoms are subjective or objective. Objective numbness in the anterolateral thigh implicates the lateral femoral cutaneous nerve, suggesting meralgia paresthetica. If numbness is objectifiable in the anterior thigh, femoral nerve involvement is likely, especially if associated with weakness of knee extension.

## Management

For more detail on management of individual disorders see the later section, "Selected Disorders of the Hip, Groin, and Thigh."

Medical referral is necessary when fracture, dislocation, avascular necrosis, infection, tumor, or visceral pathology is suspected or found. Acute pain is managed with physical therapy and support. With muscle strains, a compressive bandage or taping or a substituting type of elastic wrap may help decrease continued strain to the muscle. These include neoprene sleeves for hamstring and quadriceps strains and hip spica wraps for adductor or iliopsoas strains.

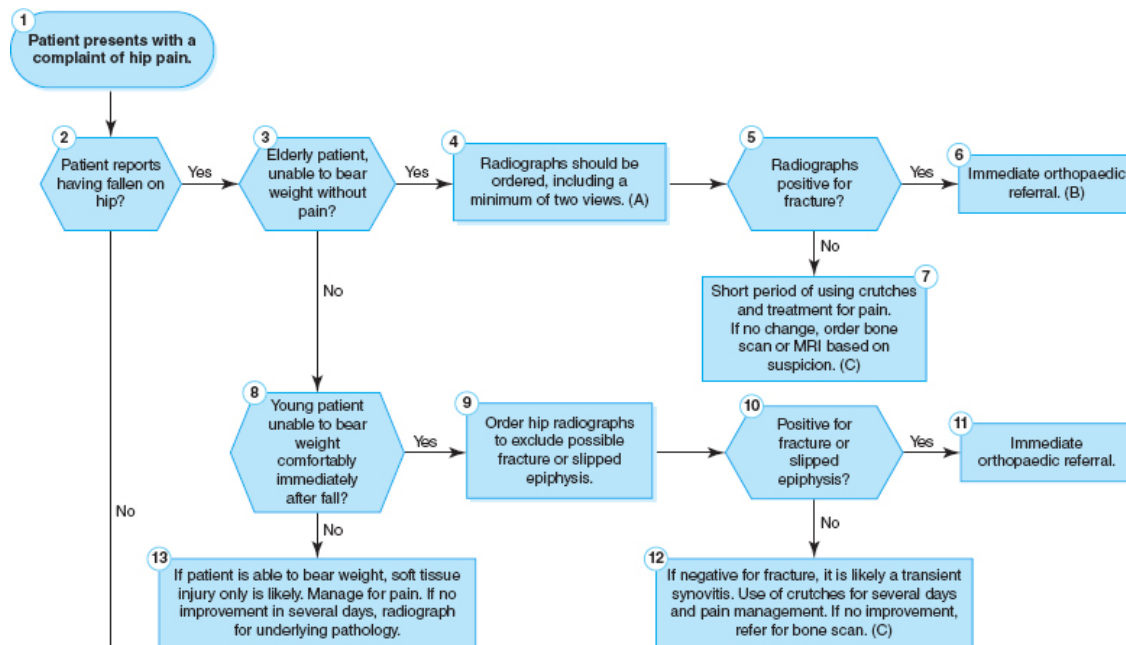

Management of most other complaints focuses on restoring normal mobility to the hip joint and pelvis, from

both a gross ROM perspective (voluntary muscular component) and an accessory motion perspective (involuntary component). OA often results in hip joint contractures. A combination of stretching and general hip stabilization exercises coupled with hip manipulation is often effective.

Prevention of further soft tissue injury at the hip and thigh involves a routine of stretching and warming up prior to activity. For patients who have had or are at potential risk for hip fracture, evaluation of common environmental obstacles should be performed with recommendations for avoidance of falls. This would include taping down of rugs, placing nonslip strips on steps or stairs, ensuring proper lighting at night, and strategically placing balance points for use of a walker or cane.

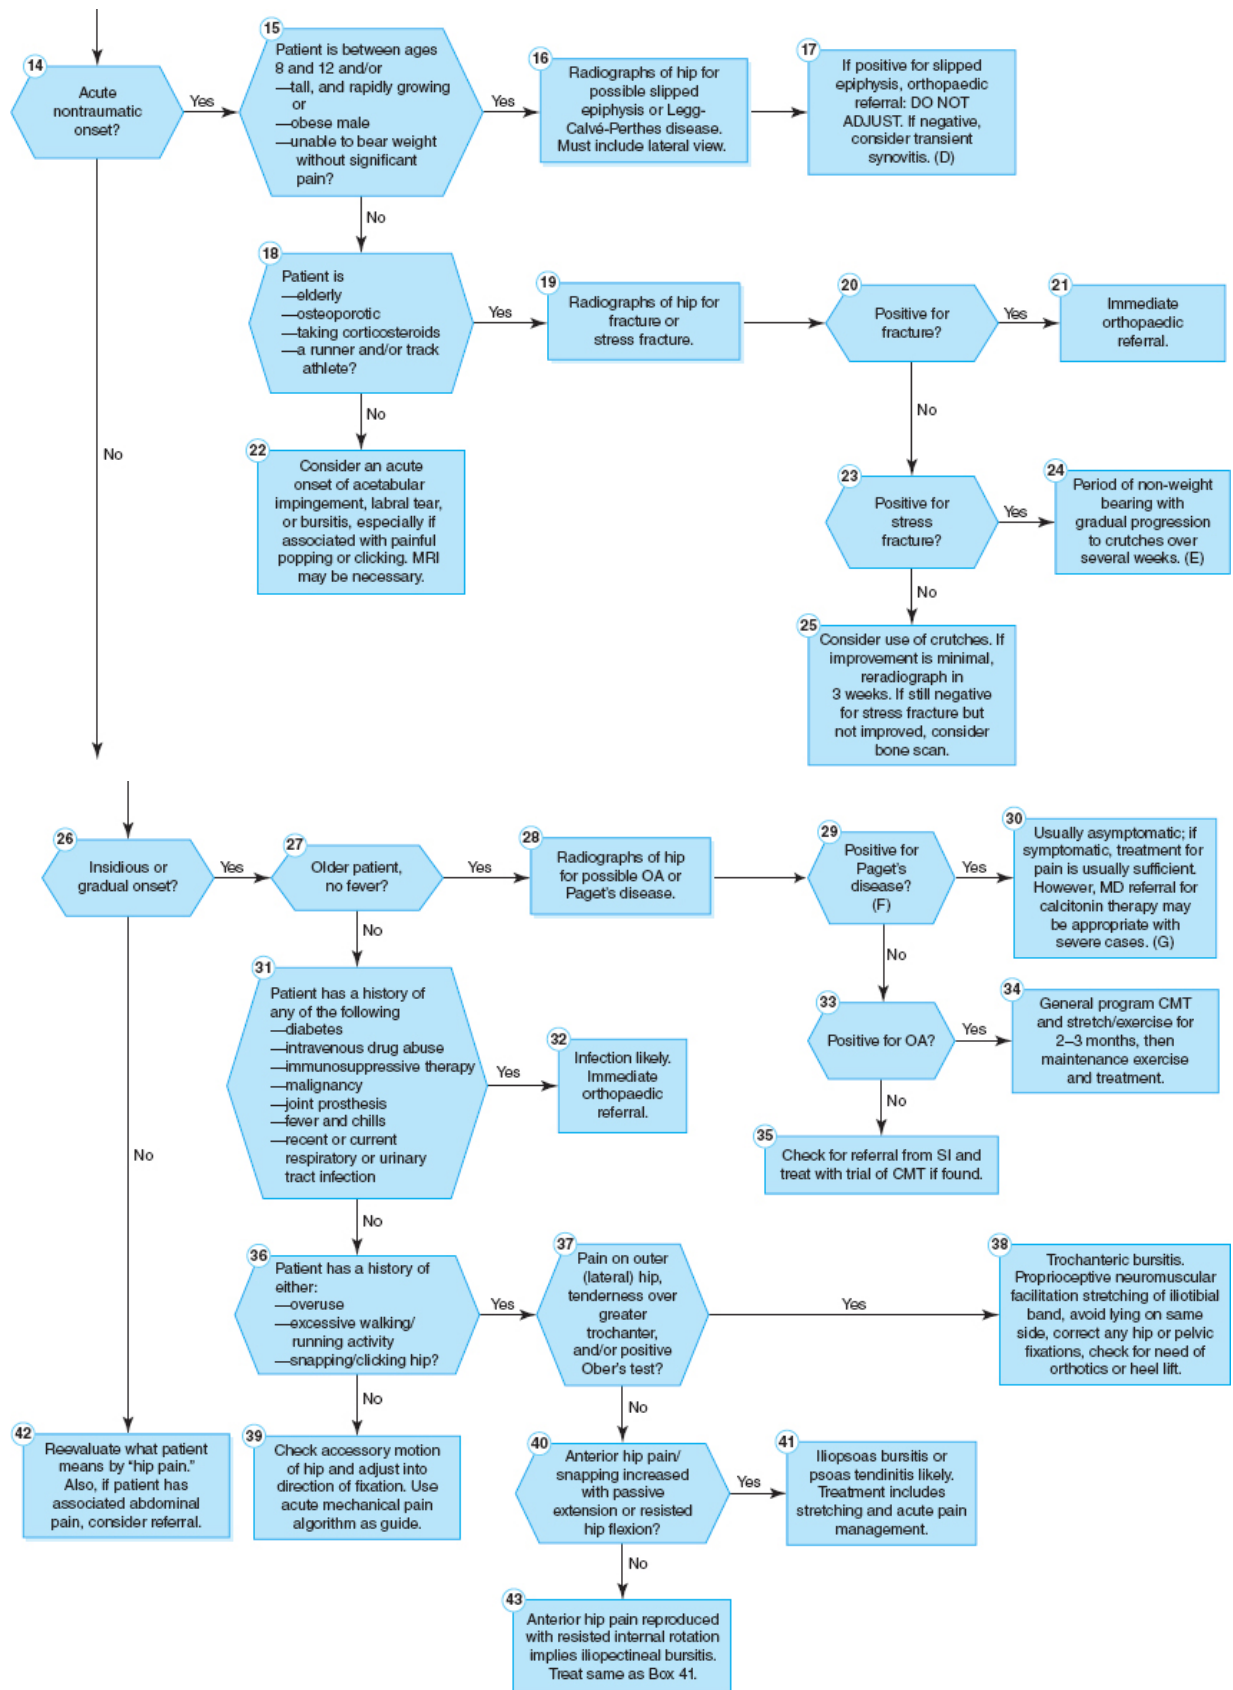

## Algorithm

An algorithm for evaluation and management of hip pain is presented in **Figure 11-8**.

#### Annotations

- A. Radiographs for hip often supplement the standard AP and lateral (frog-leg) projections with an AP pelvis projection including both hips. Lateral views must be taken if fracture or slipped epiphysis is suspected.
- B. There are two general categories of hip fractures: intracapsular and extracapsular. Intracapsular fractures are twice as common and more likely to lead to complications such as nonunion, thromboembolic disease, osteomyelitis, and necrosis (septic or aseptic).
- C. Bone scan may be necessary to detect metastasis or necrosis if suspected. MRI is better suited for soft tissue or medullary changes.
- D. Legg-Calvé-Perthes disease is twice as common in boys. It is characterized by flattening and distortion of the epiphysis due to an aseptic necrosis. Transient synovitis usually is the result of trauma. Intraarticular swelling makes weight bearing difficult; it is self-resolving. However, if persistent and no radiographic evidence, send for an MRI.
- E. Stress fractures occur in normal bone exposed to repetitive stress; therefore, any person involved in repetitive activities such as running, gymnastics, dancing, or marching should be evaluated with a bone scan.
- F. Radiographic signs of Paget's disease include cross-hatching of the femoral head, cortical thickening, and remodeling leading to a diffuse radiopaque appearance.
- G. Ninety percent of patients with Paget's disease are asymptomatic. If symptomatic, treatment is often with nonsteroidal anti-inflammatory drugs. Those with rapidly progressive disease may be given calcitonin or etidronate to slow the process.

**Figure 11-8** Hip Pain—Algorithm

# Selected Disorders of the Hip, Groin, and Thigh

## HIP

### Hip Fractures

## Classic Presentation

An elderly patient presents with hip pain, unable to bear weight, and a history of a fall onto the hip.

## Causes

In the elderly, the most common cause or predisposition of hip fracture is osteoporosis and therefore it is seen more frequently in women. One study suggests that the fracture is due to a combination of bone fatigue and axial muscular compressive forces, which then leads to falling.<sup>28</sup> Obviously, falls can result in fracture also. Other considerations are Paget's disease, endocrinopathies, multiple myeloma, and renal osteodystrophy.<sup>29</sup> In the young patient, other than a major traumatic event, pathologic fracture may be due to benign and malignant tumors. Benign tumors include a unicameral bone cyst and fibrous dysplasia. Malignant causes include osteogenic sarcoma and Ewing's sarcoma.<sup>30</sup>

## Evaluation

In the event of trauma, beyond palpation, the next step is radiographic evaluation. A search for fractures must include both an AP view and a lateral view. Fractures are divided into intracapsular (subcapital and transcervical) and extracapsular (basicervical, trochanteric, and subtrochanteric). Intracapsular fractures are twice as common as extracapsular fractures and, unfortunately, are more likely to result in serious complications such as osteonecrosis, nonunion, thromboembolic disease, and osteomyelitis.<sup>31</sup>

## Management

Advances in orthopaedic stabilization techniques and new advances in bone healing have helped increase the success rate of surgery. Unfortunately, the death rate following hip fracture is still approximately 15% (due to the above - mentioned complications).

## **Stress Fractures**

### **Classic Presentation**

The patient is young and active, often participating in activities such as long-distance running, gymnastics and, less often, dancing or marching. The pain is insidious and is worse with weight-bearing. The pain is often anterior and deep.

### **Mechanism**

With repetitive stress to the femoral neck, microfractures appear. Cellular damage leads to increased remodeling. When osteoclastic activity exceeds osteoblastic activity, the bone is weakened.

### **Evaluation**

Little is found on the examination except for perhaps end-range restriction and pain with flexion and internal rotation. Radiographs often are unrevealing. When the index of suspicion is high, a bone scan is highly sensitive.<sup>32</sup> If a tumor is included in the differential, MRI is valuable.

### **Management**

There are two different types of femoral neck stress fractures. Management is different for each.

1. Transverse—Begins in the superior cortex and continues across the neck. These fractures are potentially unstable and may lead to serious complications. Therefore, percutaneous pinning is the recommended treatment.
2. Compression—Begins along the inferior cortex and may progress to sclerosis; however, it is stable. Rest and elastic support are necessary for two weeks, followed by non-weight-bearing exercises such as bicycling or swimming. It takes on average four to six weeks for a stress fracture to heal.

# **Congenital Hip Dislocation and Hip Dysplasia**

## **Classic Presentation**

Congenital hip dislocation is usually diagnosed on physical exam of the neonate; if undetected, the child would, upon weight-bearing, have a limp and diminished active abduction.

### **Causes**

Dislocation is due to acetabular deformities. Inversion of the limbus combined with capsular tightness causes dislocation and prevents a stable relocation.<sup>33</sup>

## **Evaluation**

The classic tests used for early detection are Ortolani's click test and Barlow's maneuver. Radiographs may appear normal until the infant is four to six weeks of age. Radiographic identification of dysplasia is based on a triad of an underdeveloped proximal femoral epiphysis, lateral displacement of the femur, and an increased inclination of the acetabular roof (Putti's triad).<sup>34</sup> Severe degenerative changes are visible in chronic dislocators. MRI and diagnostic ultrasound are used to detect early dysplastic changes.<sup>35</sup>

## **Management**

Management is dependent on age. In infants up to six months, a harness (e.g., Pavlik) is used to hold the hip in flexion and prevent adduction. From ages 6 to 15 months (before walking), two to three months in a spica cast is recommended. In toddlers or in children who have not responded to closed reduction, open reduction is necessary.

### **Traumatic Hip Dislocations**

## **Classic Presentation**

Based on whether anterior or posterior; posterior dislocations account for 90% of sports-related hip dislocations.

- Posterior—An acute injury is reported with a major force applied to a flexed, adducted hip. After the injury, the hip is held in flexion, adduction, and internal rotation. The pain is severe. Pain down the back of the leg may indicate sciatic nerve damage.

- Anterior—Patient reports a force/blow to an extended, externally rotated leg. Immediately after injury, the leg is held in flexion, abduction, and internal rotation.

## Evaluation

Visual observation and history are usually enough to raise the suspicion. Radiographs to determine the extent of damage are needed. However, these would be performed in an emergency department setting.

## Management

Relocation is not possible without anesthesia. This is followed by rest and a period of non-weight-bearing with gradual return to supported walking with crutches.

### Slipped Capital Epiphysis (Adolescent Coxa Vara)

## Classic Presentation

An overweight child or a young, rapidly growing adolescent (age 8 to 17 years) presents with a traumatic (50% of the time) history, although sometimes relatively minor. Acute slippage may occur. Chronic slippage presents as a gradual hip pain with antalgia. Children may have only knee pain. This is the most common hip condition in adolescents, affecting between 0.7 and 3.4/100,000.<sup>36</sup>

## Causes

Although trauma is reported in 50% of cases, half of cases have no obvious traumatic history. An acute slippage is a Salter-Harris type I epiphyseal fracture. Hormonal influences may play a role in obese individuals<sup>37</sup> (Fröhlich syndrome-like appearance) or in tall, fast-growing adolescents.

## Evaluation

The physical examination may be generally unremarkable; however, sometimes when the hip is taken passively into flexion, it rotates externally.<sup>38</sup> The definitive diagnosis is with hip radiographs. It is essential to understand

that the slippage may not be visible on the anterior view. The lateral view gives a clearer picture of the typical posterior/inferior slippage of the femoral epiphysis.<sup>39</sup> Bilateral views should be taken because of occurrence in the opposite hip in 10% to 20% of cases.

## Management

Surgical pinning is often used. Acute slipped capital femoral epiphysis is managed with a short period of traction, followed by internal rotation to accomplish reduction, followed by pinning or screw fixation. It is imperative that there is no attempt to reduce the slippage with manipulation. The consequences can be disastrous, including avascular necrosis.

## Avascular Necrosis

### Classic Presentation

Legg-Calvé-Perthes disease is a form of avascular necrosis. The patient is usually male (four or five times more commonly) between the ages of 4 and 9 years (80%) presenting with a complaint of mild hip pain and an associated limp of insidious onset. Symptoms are bilateral 10% of the time;<sup>40</sup> 17% of patients have a traumatic history.<sup>41</sup> Fifteen percent of patients present with knee pain only. Avascular necrosis may be due to a multitude of other factors. The patient is more likely though, to present with a history of past trauma or metabolic disease.

## Causes

Legg-Calvé-Perthes disease is believed to be due to an undetermined disruption of the vascular supply to the femoral head.<sup>42</sup> Other than Legg-Calvé-Perthes disease, avascular necrosis is secondary to subcapital fractures (20%), posterior hip dislocations (8%), longterm steroid use, hyperlipidemia, alcoholism, pancreatitis, and hemoglobinopathies.<sup>43</sup>

## Evaluation

Usually there is limitation of hip abduction and internal rotation (secondary to muscle spasm). The Trendelenburg test is often positive. Over time, atrophy and limb length inequality may be evident. The definitive diagnosis is radiographic. In progression the changes begin with a small radiopaque

femoral nucleus, followed by a crescent sign, fragmentation, reossification with remodeling, and deformity of the femoral head.

## Management

Management is often conservative. It is generally agreed that children younger than 4 years of age or those with minor involvement (less than half of the femoral head) usually require no treatment. Children older than 4 to 5 years old who have good motion (abduction greater than 30°) may not require bracing or surgery.<sup>44</sup> Referral for medical consultation is required. There is no apparent evidence to support the use of crutches or non-weight-bearing in most cases. When subluxation occurs due to femoral head deformation, use of a Petrie cast or ambulatory brace may help maintain needed abduction. Surgical options are rarely required but include osteotomy. Healing takes about 18 months.

## Femoroacetabular Impingement

### Classic Presentation

A patient complains of sharp, deep hip pain with squatting. Running, stopping and starting or changing direction may also cause pain. The pain is felt anteriorly.

### Cause

Femoroacetabular impingement (FAI) is a relatively recently recognized condition resulting from a number of hip abnormalities that limit motion, in particular, flexion and internal rotation. There are two types. The cam type is due to abnormalities of the femur with a decreased offset between the femoral head and neck. The pincer type is due to acetabular abnormalities that lead to excessive coverage by the anterior acetabular rim. There is also a mixed type.

### Evaluation

There is a significant decrease in flexion and internal rotation. External rotation may also be affected.<sup>45</sup> For the more common anterior impingement, the anterior impingement test is performed. With the hip passively flexed to 90°, forced internal rotation causes anterior pain. For the less common posterior impingement, the posterior impingement test is performed with the

patient supine and the hip flexed. By extending the hip and externally rotating the posterior hip, pain is elicited with a positive test. The FABER test may cause lateral hip pain in patients with FAI. Radiographic evaluation focuses on the standard AP and frog-leg with a measurement and search for:

### ***Pincer lesions***

- Acetabular retroversion—acetabular wall is more lateral than the posterior wall; “posterior wall sign” is when the AP view shows that the wall is more medial than the center of the femoral head.
- Coax profunda—when the floor of the acetabular fossa contacts or overlaps the ilioischial line on the AP view.
- Protrusio acetabuli—femoral heads protrude through the acetabulum.

### ***Cam lesions***

- Pistol grip deformity.
- The alpha angle—measured on a cross-table view to determine asphericity and cam impingement on the anterior aspect of the femoral head-neck junction.

MRI is also used and can determine associated pathologies.

## **Management**

There are no reports of conservative management of FAI. Surgical approaches include dislocation of the hip and femoroacetabular osteoplasty.<sup>10, 46</sup> Arthroscopic treatment with either rim trimming, labral refixation, or debridement, dependent on the degree of damage has also demonstrated good short-term results.<sup>47</sup>

## **Acetabular Labrum Tears**

## **Classic Presentation**

A patient presents with moderate to severe pain with groin pain predominant. The patient has night pain. The pain is worse with activity and causes the patient to limp. Clicking and occasional giving-way of the hip occur. (*Note:* There is a wide variation in report of onset from no trauma to severe trauma.)

## **Causes**

There are many suggested causes including macro- to micro- (repetitive) trauma. Predispositions could include FAI, capsular laxity, or hip dysplasia.

Labral damage may cause chondral lesions (in 73% of patients with labrum tears)<sup>5</sup> and early degeneration.<sup>48</sup> A lesion that can mimic labrum tears is a ligamentum teres (LT) tear; the connecting ligament between the top of the humeral head to the acetabulum.

## Evaluation

The history clues most often reported, in addition to those in the classic presentation above, include hip locking or catching. It should be noted that groin pain is a common referral area for intra-articular hip pathology (visceral pathology [genitourinary] generally radiates from the flank to the groin). The report of clicking and giving way has a relatively high likelihood ratio (6.67). The cluster of these complaints would help identify the likely labrum tear cause. However, it appears that the diagnosis is elusive; one study indicates a time from the onset of symptoms to diagnosis of 21 months and a mean of 3.3 healthcare providers prior to receiving the correct diagnosis.<sup>49</sup> There are different classifications of labrum tears. One classification identifies four types: radial, radial fibrillated, longitudinal peripheral, and abnormally mobile.<sup>51</sup> Radial are the most common and usually occur in the anterosuperior location. Other classifications define the type of tear by a clock face descriptor (e.g., 6 o'clock position) or ranked based on the size of any associated articular cartilage damage.

Physical examination, although sensitive to labrum tears, is not very specific. A number of tests can be used to indirectly assess labrum tears including FABER, FAI tests, long-axis distraction, and ROM findings. The impingement test (see [Figure 11-4](#)) has the highest sensitivity (as high as 95%).<sup>49</sup> Radiographs are not helpful in making the diagnosis; however, they may provide indirect evidence of cause or effect from a labrum tear. The findings may include hip dysplasia, osteoarthritis, a lack of femoral head/neck offset or other congenital, developmental, or acquired structural abnormalities. MRI may be valuable in the diagnosis of labrum tears, but MRA has been demonstrated to be far superior, although both have limitations. Anterior labrum tears (the most common) are visualized well with MRI and MRA, whereas posterior tears are not. Studies indicate a sensitivity range of 75% to 90%, an accuracy of about the same, and a specificity of about 83% for anterior tears, whereas the detection of posterior tears was as low as 20% and lateral tears as low as 11%. Arthroscopy is, by default, the “gold standard” for diagnosis and treatment. Evaluation should also include a check for a ligamentum teres (LT) tear. There is a new test for this previously underappreciated cause of hip pain and disability.<sup>50</sup> Tears of the LT are a common cause of chronic groin and thigh pain found in 8% to 51% of patients undergoing hip arthroscopy. These tears are not easily seen on MRI, with only about 2% being visible. A new clinical test makes an attempt at increasing the clinical suspicion of an underlying tear of the LT with arthroscopy being the gold standard with direct visualization ([Figure 11-9](#)). The test is performed

with the patient supine and the knee flexed 90°. The hip is fully passively flexed and then backed-off by 20° to 30° leaving the hip at about 70° flexion. The hip is then abducted fully and again backed-off into adduction by about 30° leaving the hip at around 30° hip abduction. At the knee, the leg is rotated internally and externally noting if either produces pain. This would indicate a positive test for a torn LT.

## Management

Generally, the literature is sparse on conservative management with no data on manipulative management of acetabular labrum tears. Two small studies indicate that the use of NSAIDs and partial weight-bearing for two to four weeks may help some patients.<sup>8,52</sup> The standard medical approach is labral debridement using arthroscopy. Short-term success is quite high, especially for minor labral lesions, and in those without other hip pathology such as osteoarthritis or other involvement of the cartilage.<sup>53-55</sup> If surgery is to be performed, the data indicate early intervention may prevent further damage.

**Figure 11-9** Ligamentum teres test.

## Trochanteric Pain Syndrome

### Classic Presentation

Several bursae are capable of producing symptoms. The two major bursae are the subgluteus medius and subgluteus maximus. A smaller bursa with the gluteus minimus is less often involved. The patient presents with well-localized lateral hip pain usually with only a minor degree of limp. The patient is often between 40 and 60 years of age. Less commonly subtrochanteric

bursitis may cause pain radiating to the low back, the lateral thigh, and the knee.<sup>56-58</sup> The patient often will not be able to sleep on the involved side.

## Cause

Any condition that leads to altered hip mechanics, including low back pain, leg length discrepancy, arthritic conditions, surgery, and neurologic conditions with paresis, may cause subtrochanteric bursitis. The result is some loss of internal rotation. The degree of discomfort is often proportional to the degree of activity. Repetitive activity can be a major cause in the younger population because the friction over the bursa causes it to be inflamed.

## Evaluation

Tenderness and sometimes swelling are found over the greater trochanter. Palpation may cause a “jump” sign when localized to the lower portion of the trochanter with the knee and hip flexed. Pain may be increased with hip motion and maneuvers such as the Patrick test or Ober’s test. The distinction between trochanteric pain syndrome and osteoarthritis has not been fully differentiated; however, a 2013 study attempts to find the unique features.<sup>59</sup> Patients with lateral hip pain with tenderness on palpation of the greater trochanter and with a FABER test are likely to have trochanteric pain syndrome if there is an absence of difficulty with putting on their shoes and socks.

## Management

Management includes correction of abnormal biomechanics such as leg length discrepancies combined with indicated adjustment of the pelvis or hip. Additionally, stretching of the hip abductors using proprioceptive neuromuscular facilitation (PNF) techniques should be prescribed and performed in office. Ultrasound has little applicability unless a chronic bursitis is suspected or perhaps in assisting stretching of any tight contributing muscles. Side-posture adjusting may aggravate and in rare cases cause a trochanteric bursitis. Therefore, side-posture adjusting is contraindicated for one to two weeks during acute-care treatment. Alternative techniques should be employed during this time. In runners, pay particular attention to running technique and surface. They should be advised to avoid both banked surfaces and allowing the feet to cross the midline when running. A randomized controlled trial<sup>60</sup> comparing a corticosteroid injection, home training, and shockwave therapy found that although there was clear superiority with corticosteroid injection, this was lost at one month, with radial shockwave

therapy performing the best at one month and four months. A review<sup>61</sup> published in 2011 concluded that most conservative approaches work with a special mention to shockwave therapy. For recalcitrant cases, a corticosteroid injection is suggested and then, if ineffective, surgery is recommended.

## **Iliopectineal and Iliopsoas Bursitis**

### **Classic Presentation**

The patient often presents with a severe, acute anterior hip pain with an antalgic gait. He or she may also report pain radiating down the anterior aspect of the leg. This is due to pressure on the neighboring femoral nerve. The patient often will assume a position of flexion and external rotation of the hip to relieve the pain.

### **Cause**

These anterior bursitis are possibly due to hip flexor tightness coupled with repetitive activity.

### **Evaluation**

There is often deep anterior tenderness at the hip. Specifically, the bursa is located about 1 to 2 cm below the middle third of the inguinal ligament. The iliopsoas bursa may be palpated with the supine patient's hip flexed to 90° while palpating over the lesser trochanter. Resisted hip flexion or more specific iliopsoas testing will reproduce the pain.<sup>62</sup>

### **Management**

Rest and stretching of the hip flexors often will resolve the problem. Myofascial release of the iliopsoas must be performed cautiously.

## **Ischial Bursitis**

### **Classic Presentation**

Often the patient reports sitting for long periods of time on hard surfaces (benchwarmer's bursitis) or during horseback riding.

She or he may have referral down the back of the leg mimicking sciatica. The patient may notice that pressing the foot down on the brake pedal (or gas pedal) of a car may relieve the pain. This is due to accompanying extension of the knee, which rotates the ischial tuberosity away from the sitting surface. In the younger athletic patient, speed work (sprinting) may cause a bursitis due to excessive hamstring contraction. This must be differentiated from an apophysitis.

## **Cause**

Ischial bursitis is caused by a direct blow to the bursa, acute or chronic trauma (as in horseback riding), or prolonged irritation from hard-surface sitting. Chronic hamstring strains and occasionally prolonged standing may also cause irritation.<sup>63</sup>

## **Evaluation**

The patient may list toward the affected side with an accompanying shortened stride length. Toe standing may be painful. There is well-localized tenderness over the ischial tuberosity. Straight leg raising and Patrick's test may also reproduce pain.

## **Management**

Padding such as a small inflatable pillow may help in the acute phase. Avoidance of the inciting activity is necessary for long-term management.

## **Snapping Hip Syndrome**

### **Classic Presentation**

Other than snapping, many patients do not have pain. The location of the snapping is a good indicator of the offending structure. If traumatic, consider an acetabular labrum tear.

## **Cause**

Snapping at the hip is often due to tendons that snap over bony prominences or bursae. Occasionally, abduction may cause a suction effect similar to joint

gapping with manipulation. Even more rarely, a loose body may be found in the joint. However, with loose bodies, there are accompanying signs of mechanical blockage of movement.

## Evaluation

The location and movement pattern are often helpful. Lateral hip snapping usually occurring on hip flexion with the hip in adduction is most often due to the iliotibial band's snapping at the greater trochanter. Anterior snapping or popping occurring with active extension of the flexed, abducted, and externally rotated hip often indicates iliopsoas tendon involvement or occasionally snapping of the iliofemoral ligaments over the anterior joint capsule. Posterior snapping in the buttocks region is probably due to the biceps femoris tendon's snapping over the ischial tuberosity.

## Management

Usually these are benign and position-dependent. If painful or irritating to the patient, strengthening rather than stretching the involved muscle is often helpful. Stabilization seems to reduce occurrence. If unsuccessful, stretching may be employed as a second treatment option. For recalcitrant cases of a snapping iliopsoas tendon, arthroscopic surgery with tendon release may be of benefit.<sup>64</sup> In these cases, it has been found that intra-articular pathology often exists.

## Transient Synovitis

## Classic Presentation

A child less than 10 years of age complains of an acute or gradual onset of pain in the inguinal area with difficulty bearing weight. The child will often hold the hip in external rotation, abduction, and flexion. Trauma is not often part of the history; however, a prior viral infection is often elicited.

## Cause

The cause is unknown in many cases; however, it may be a portent of either rheumatoid disease or ensuing Legg-Calvé-Perthes disease (1.5% to 10% of cases).<sup>65</sup>

## Evaluation

Findings of a decrease in internal rotation and some restriction of other movements with some general tenderness to palpation are commonly found; however, they are nonspecific. Radiographs are not revealing. A bone scan is often diagnostic, but the specificity is low. Ultrasound may demonstrate fluid in the joint. The primary differential is a septic hip. However, the initial history is similar, with a preceding respiratory infection. Aspiration may be needed to make the diagnosis. Septic arthritis is a medical emergency. MRI may help differentiate.

## Management

In the idiopathic benign form, resolution over several weeks occurs with a non-weight-bearing period followed by crutch use over several weeks. One review<sup>66</sup> indicated that resolution should occur in two weeks on average with recurrence rates anywhere from 0% to 26%. The caution is to recheck all cases over six months to avoid missing the start of Legg-Calvé-Perthes disease.

## Osteoarthritis

### Classic Presentation

In primary OA a middle-aged or elderly patient presents with hip and possibly buttock, groin, or knee pain that was insidious in onset. Additionally, the patient notes a slow stiffening (specifically internal rotation). This often results in the patient's walking with the hip held in external rotation. The patient may complain of low back pain due to excessive extension with weight-bearing to compensate for limited hip extension.

In secondary OA, the presentation may be similar; however, there may be a history of trauma to the hip, or the patient may have other joint involvement if crystal deposition (i.e., gout) is a factor.

## Cause

Primary OA is due to progressive degeneration of femoral and acetabular articular cartilage. This is presumably caused by the accumulation of microtrauma. However, primary OA of the hip is not common. It is considered when there are preexisting abnormalities of the acetabulum or femoral head (congenital or acquired).<sup>67</sup> Secondary OA may be due to calcium pyrophosphate dihydrate crystal deposition disease, acromegaly, hemochromatosis, neuroarthropathy, and other articular problems.

# Evaluation

There is restriction to passive internal rotation and extension of the hip. Eventually, abductor or adductor contracture may develop. Pain may be produced by axially compressing the femur into the acetabulum. Nonuniform loss of joint space is found radiographically. Superior joint space narrowing with associated findings of subchondral cysts and osteophytes is the hallmark of OA. It is important to note that many patients receive the diagnosis of OA when in fact there are no radiographic findings to support this diagnosis.

Although more common in the shoulder, there are reports of adhesive capsulitis of the hip.<sup>68, 69</sup> It appears from the few reports in the literature that there is always a precipitating traumatic event. There is little to suggest how to approach this entity diagnostically given that the literature speaks only to radiographic and arthroscopic evaluation. It would appear that in patients with severely restricted hip rotation following trauma with no evidence of fracture, adhesive capsulitis should be considered.

# Management

If appropriate, reduction of weight will be of benefit. Non-weight-bearing exercise is often quite beneficial, including pool exercises and bicycle riding. Strengthening of the joint often will relieve constant pain. Stretching of hip contractures may be accomplished with gentle PNF stretching or deeper myofascial release techniques. Use of a cane should be limited to those with severe pain. A recent review of the literature by Brantingham et al. concluded that there is good evidence for short- and long-term success using manipulation for patients with OA of the hip.<sup>70</sup>

## Rheumatoid Arthritis

# Classic Presentation

A woman between ages 25 and 55 years presents with hip pain and associated periarticular soft tissue swelling, stiffness, and ROM restriction. At some point in the presentation the pain is bilateral.

# Cause

The cause is a synovial inflammatory process that creates a destructive pannus.

## Evaluation

Radiographically there is uniform, symmetric joint space diminution superiorly. Eventually this is bilateral. Associated findings are periarticular osteoporosis, subchondral cysts, and osseous destruction. In later stages, ankylosis and protrusio acetabuli (femoral head protrudes through the acetabulum) may occur. Similar findings are seen in other joints such as the hands, knees, ankles, and cervical spine. Positive laboratory findings include an elevated erythrocyte sedimentation rate (ESR) and a positive rheumatoid factor.

## Management

Comanagement is often necessary. For acute periods, the use of nonsteroid anti-inflammatory drugs is often helpful. Mild, passive movements may be helped by maintaining hip motion and help reduce swelling. The RA hip should not be aggressively manipulated.

## Tumors

### Classic Presentation

A patient aged 50 years or older presents with a complaint of deep bone pain (66% to 80% of cases).<sup>71</sup> There was an insidious onset and the pain is not relieved by rest; it is worse at night. Past history may include a previous diagnosis of lung, breast, kidney, prostate, or thyroid cancer (if metastatic).<sup>72</sup>

### Causes

The causes are metastasis and multiple myeloma.

### Evaluation

Laboratory may reveal an increase in ESR, serum calcium, alkaline phosphatase, and, if from a prostate tumor, prostate-specific antigen. Multiple myeloma has characteristic findings of Bence-Jones proteinuria, increased ESR, monoclonal spiking on electrophoresis, and an M spike on immunoelectrophoresis. Radiographic changes may be lytic or blastic, depending on the type of tumor. Breast and kidney tumors tend to be lytic, whereas a prostate tumor tends to be blastic. Multiple myeloma has a lytic presentation.

# Management

Referral for oncologic consultation is needed.

## Paget's Disease

### Classic Presentation

Ninety percent of patients are asymptomatic. They may notice an increase in hat size or develop an insidious onset of low back and/or hip pain if symptomatic. Usually Paget's disease is found inadvertently on radiographs of middle-aged or elderly patients.

### Cause

The cause is unknown; however, a viral etiology is suspected. In less than 2% of cases sarcomatous degeneration is a complication.<sup>73</sup>

### Evaluation

Radiographic evaluation will demonstrate a cross-hatched appearance of the femoral head trabeculae. Later changes include remodeling, with increased opacity and deformation, and later bowing.

## Management

There is no medical treatment that prevents or cures Paget's disease. Asymptomatic patients are not treated. Those who are symptomatic are treated with a choice of various drugs. The most common drug used with pagetic pain is calcitonin, now available in a nasal spray. Other drugs include the diphosphonates, which inhibit osteoclast activity.

## GROIN Osteitis Pubis

### Classic Presentation

The patient often will report either a sudden, forced adduction injury or a repetitive minor trauma seen with kicking or running.

Pregnant women may be prone to irritation also.

## **Cause**

Direct compressive or distractive injury may cause pain at the pubic joint.

### **Evaluation**

There is tenderness at the pubic joint with compression and sometimes with compression of the two ASISs toward each other. Resisted adduction is also provocative in many cases. Occasionally a bone scan is necessary to diagnose because of the lack of sensitivity on radiographs.

## **Management**

Management includes rest with a slow return to activity and gradual increase in flexibility; avoidance of the inciting activity, especially side-foot kicking or bilateral adduction maneuvers. Gross instability at the joint may require surgical stabilization.

### **Adductor Sprain**

## **Classic Presentation**

The patient is usually an athlete who is involved in kicking, sprinting, water skiing, or jumping (high jumps or hurdles). He or she reports a sudden pulling sensation in the groin that was incapacitating.

## **Cause**

The cause of an adductor sprain is sudden contraction of the adductors from a stretched position of hip abduction or flexion. The most common site is at the myofascial junction of the adductor magnus.

## **Evaluation**

The patient has a discrete site of tenderness in the adductor muscle group or at the pubic attachment. Resisted adduction sharply increases the pain or discomfort.

# Management

Elastic figure-of-eight strapping is applied with the hip in slight extension and internal rotation. This will assist the adductor in normal walking for a week or so. Gentle stretching and a slow return to activity are suggested.

## THIGH

### Hamstring Strain

## Classic Presentation

The patient is often an athlete or “weekend warrior” who feels a sudden pull or pop at the back of the thigh following a forceful knee extension maneuver.

## Cause

The mechanism is an overcontraction of the hamstrings while in a position of stretch. Tearing occurs most often at the junction of the muscle and aponeurosis. Avulsion of the ischial apophysis is possible in younger athletes.

## Evaluation

Palpation of a site of tenderness at the distal muscle belly associated with increased pain on resisted knee flexion is diagnostic. Pain is correlated to the degree of injury. Full ruptures are quite painful.

## Management

Treatment includes rest, ice, use of crutches for several days, gentle stretching when tolerable, and a long-term goal of restrengthening beginning when 75% of the normal ROM is available. For first-degree strains, return to normal activity is often within a couple of weeks; for second-degree, four to six weeks; for full ruptures, it often takes three to four months to return to a normal level of activity. A focus on prevention includes pre-event stretching, maintaining a proper strength ratio between the hamstrings and quadriceps (0.6:1), and proper strength balance between hamstrings.

### Quadriceps Strain

# **Classic Presentation**

The patient reports feeling a sudden pulling pain in the anterior thigh after attempting to sprint, “missing” a kick, or suddenly stopping.

## **Cause**

Sudden contraction of the quadriceps may result in a simple pull or a full rupture. Some predispositions include tight quadriceps (or not stretching prior to a sport activity), imbalance between the quadriceps of the opposite leg, or a short leg.

### **Evaluation**

Actively extending the knee causes pain. Inability to perform a simple quadriceps isometric contraction with the leg extended indicates moderate to severe damage. A palpable defect or muscle mass on resisted extension indicates possible rupture.

## **Management**

Management includes ice coupled with a neoprene or elastic support wrap. Crutches may be needed for several days, depending on the degree of injury. Stretching should be initiated as early as possible but with caution. Complete ruptures require surgical repair.

## **Contusions and Myositis Ossificans**

# **Classic Presentation**

The most common area is the quadriceps. The patient will report a direct blow to the knee followed by swelling and decreased ability to flex the knee.

## **Cause**

A direct blow causes damage to the underlying muscle with subsequent hematoma formation. When the hematoma is encouraged to remain, myositis ossificans may occur. The contributing factors for myositis ossificans are forcefully stretching after injury, deep massage to the area of injury, and the use of deep heat such as ultrasound.

# Evaluation

There is an obvious area of swelling and often discoloration. The patient's active and passive ability to flex the knee is limited. If the injury occurred several weeks before, a painful lump may be palpable, indicating possible myositis ossificans. Radiographs often will demonstrate the degree of maturation of this calcification response.

# Management

Application of a tensor bandage with an ice pack in a flexed knee position for several hours (alternating icing for 20 minutes, no ice for 10 to 20 minutes) is helpful in preventing accumulation of blood into the area. With moderate to severe contusions, use of crutches for two to three days may be helpful. Mild stretching may begin after two to three days. Treatment decisions regarding myositis ossificans development are made after several weeks, based on the deformity and degree of knee flexion restriction. Surgical excision may then be performed if deemed desirable.

## Meralgia Paresthetica

# Classic Presentation

The patient complains of numbness or tingling in the lateral thigh.

# Cause

Compression of the lateral femoral cutaneous nerve may occur at the inguinal ligament, or slightly below, due to prolonged sitting. The patient is often either overweight or carries keys or other objects in the front pockets.

# Evaluation

The symptoms may be made worse with direct pressure on the nerve where it is most superficial, about 1 inch inferior to the ASIS. Maneuvers that increase symptoms include passive hip extension or forced hip flexion causing traction and compression, respectively. An area of sensory deficit or hyperesthesia may be found at a lateral patch of skin on the anterolateral thigh.

# Management

Treatment and prevention include avoiding prolonged sitting, losing weight if necessary, and avoidance of carrying objects in the pockets. In the acute phase, physical therapy modalities such as interferential techniques may be helpful.

---

## The Evidence

### Translation Into Practice Summary (TIPS)

The literature on history and examination of the hip is focused on identifying osteoarthritis, instability, labrum tears/impingement, and fracture. The age of the patient and the relationship to trauma or no trauma is a useful indication of specific problems. For many conditions, the diagnosis is primarily radiographic (i.e., x-ray or special imaging) with no specific tests designed or tested for the physical examination. For example, for hip joint infection, Legg-Calvé-Perthes, slipped-epiphysis, avascular necrosis, stress fracture, and tumor, there are no helpful physical examination indicators.

### The Literature-Based Clinical Core

- Age gives a helpful starting point in determining the risk of specific disorders.
- For most age-related conditions other than osteoarthritis, there are no specific literature-based tests and diagnosis is reliant on radiography/special imaging.
- The combination of findings on history and examination are useful in ruling-in or out osteoarthritis. Four or five of the following: squatting-aggravates symptoms, lateral pain with active hip flexion, scour test with adduction causing lateral hip or groin pain, pain with

active hip extension, and passive internal rotation of less than or equal to 25°. Limitation in the planes of movement is helpful in identifying osteoarthritis.

- The patellar-pubic percussion test is good at ruling-in or out hip fractures but is of questionable practical value except on-field.
- Clicking of the hip associated with pain is suggestive of labrum pathology.
- Hip dysplasia or instability in infants may be indicated by limited hip abduction.
- Flexion-abduction, external rotation (FABER) testing and flexion-internal rotation-adduction (FAIR) are sensitive for hip pathology but entirely nonspecific.
- Trendelenburg's test is moderately good at detecting lateral tendon pathologies and gluteus medius tears.
- Although hip ROM testing is reliable, pain with resistance is more valuable in detecting lateral tendon pathologies such as gluteus minimus or medius problems.
- The tests for labrum tears and impingement have not been evaluated in the literature.

### **The Expert Opinion-Based Clinical Core**

- A history of recent infection and the insidious onset of hip pain warrant investigation of hip joint infection, especially if the pain prevents weight bearing.
- The sudden insidious onset of hip pain and inability to bear weight in a young patient warrant the investigation for slipped epiphysis.
- A limp and/or knee pain in a child warrants the investigation of Legg-Calvé-Perthes.
- Persistent hip or groin pain in an athlete, in particular a female athlete, is highly suspicious for stress fracture.
- Lateral hip pain, worse when lying on that side with greater trochanter tenderness, is likely trochanteric

bursitis. However, the newest general designation when the bursa is not found to be involved is trochanteric pain syndrome.

## **APPENDIX 11-2**

# Hip Pain Diagnosis Table

Hip Pain Diagnosis Table					
Diagnosis	Comments	History Findings	Positive Examination Findings	Radiography/Special Studies	Treatment Options
Hip Subluxation/ Fixation	<ul style="list-style-type: none"> <li>Can be primary Dx if patient is asymptomatic or mildly symptomatic (e.g., mild stiffness or pain level &lt; 2/10).</li> <li>Must indicate chiropractic exam findings to support Dx.</li> </ul>	<i>Nonspecific</i>	<i>Palpation</i> —Local tenderness or other signs of subluxation <i>Ortho</i> —None <i>Neuro</i> —None <i>Active ROM</i> —Variable restriction <i>Passive ROM</i> —End-range restriction <i>Motion palpation</i> —Specific articular restriction or symptoms produced on end-range	<ul style="list-style-type: none"> <li>Radiography not required for the diagnosis of subluxation.</li> <li>Radiographic biomechanical analysis may assist in treatment decisions.</li> </ul>	<ul style="list-style-type: none"> <li>Chiropractic adjustive technique.</li> <li>Decisions regarding specifically which technique(s) is/are applied and modifications to the given approach will be directed by the primary Dx and patient's ability to tolerate pre-adjustment stresses.</li> </ul>
Hip/Thigh Sprain/Strain <i>Note: Sprain/strain is not synonymous with spasm or hypertonicity.</i>		<i>Mechanism</i> —Overstretch or overcontraction Hx as acute event <i>Worse with Specific ROM</i> —Contraction of muscle or stretch of muscle or joint	<i>Ortho</i> —Specific tests for each muscle including tenderness at muscle/ tendon <i>Neuro</i> —None <i>Active ROM</i> —Pain on active ROM that contracts involved muscles <i>Passive ROM</i> —Pain on end-range stretch of involved muscle or ligament	<ul style="list-style-type: none"> <li>Radiography not required for diagnosis unless significant trauma implies fracture or epiphyseal injury.</li> </ul>	<ul style="list-style-type: none"> <li>Myofascial therapy.</li> <li>Limited orthotic support (taping or brace).</li> <li>Ergonomic advice.</li> <li>Strengthening and preventive exercises.</li> </ul>
Diagnosis	Comments	History Findings	Positive Examination Findings	Radiography/Special Studies	Treatment Options
Meralgia Paresthetica	<ul style="list-style-type: none"> <li>Must be differentiated from nerve root source.</li> </ul>	<i>Mechanism</i> —Entrapment of the lateral femoral cutaneous nerve is often due to pressure from obesity/ pregnancy or external objects such as keys, etc. pressing on nerve distal to the inguinal ligament <i>Symptoms</i> —Complaint is mainly hypersensitivity and/or numbness and tingling; no weakness reported	<i>Palpation</i> —Direct pressure one-inch distal to ASIS may reproduce complaint <i>Ortho</i> —Forced passive, full flexion of hip or passive extension may reproduce complaint <i>Neuro</i> —Hyperesthesia over lateral anterior thigh; no motor deficits	<ul style="list-style-type: none"> <li>Radiographs not required.</li> <li>Electrodiagnostic studies rarely needed unless to differentiate from nerve root.</li> </ul>	<ul style="list-style-type: none"> <li>Eliminate any pressure causes, including recommendations to loosen belt, lose weight, and avoid wearing objects that press on nerve.</li> <li>Physiotherapy may be beneficial in acute stages.</li> </ul>
Gluteal or Iliopsoas Tendinitis, Trochanteric or Ischial Bursitis	<ul style="list-style-type: none"> <li>Patient may complain of snapping in addition to specific areas of pain.</li> <li>Snapping may be painless and not represent an active acute condition.</li> </ul>	<i>Mechanism</i> —Often no Hx of overt trauma; however, overuse may cause a friction effect resulting in a chronic bursitis	<i>Palpation</i> —Tenderness at specific bursal or tendon insertion site <i>Ortho</i> —Stretch or stretch/ contraction of involved muscle/tendon may increase pain for tendinitis	<ul style="list-style-type: none"> <li>Radiography not usually necessary initially except to rule out fracture with acute trauma.</li> </ul>	<ul style="list-style-type: none"> <li>Myofascial therapy for muscle/ tendon problems.</li> <li>Physiotherapy for pain and swelling control for bursitis.</li> <li>Padded protection for superficial bursa.</li> <li>Stretching and strengthening of involved muscle/tendon.</li> <li>Ergonomic advice to avoid irritation of involved bursa.</li> </ul>

Myofasciitis	<ul style="list-style-type: none"> <li>Used when specific trigger points are identified on physical examination.</li> <li>Also may be used if a strain is not evident from the history but there are indicators of muscle tenderness, stiffness, or pain.</li> </ul>	<p><i>Onset:</i> Nonspecific regarding onset</p> <p><i>Symptoms:</i> Patient usually complains of pain, aching, and/or tenderness in specific muscle or tendon areas that may radiate pain in non-dermatomal pattern</p>	Trigger points are evident as localized tenderness in a muscle that corresponds to traditional (Travell/Simons) trigger point charts. These points may be local or refer pain when compressed	<ul style="list-style-type: none"> <li>Not required or recommended.</li> </ul>	<ul style="list-style-type: none"> <li>Myofascial approaches such as myofascial stripping, trigger point massage, or spray and stretch approaches are the standard.</li> <li>Home stretching and modification of activity suggestions.</li> </ul>
Laxity Hypermobility	<ul style="list-style-type: none"> <li>The hip is an inherently stable joint and if laxity is present it is difficult to demonstrate clinically.</li> </ul>	A history of a single-event traumatic injury to the joint is not found; however, either overuse (micro-trauma) or generalized inherent looseness is/are evident	Capsular or ligament testing reveals "looseness" that falls within the physiologic range of normal	<ul style="list-style-type: none"> <li>Not usually recommended unless when differentiating pathological laxity from congenital or overuse acquisition.</li> </ul>	<ul style="list-style-type: none"> <li>Strengthening program.</li> <li>Bracing or functional taping during rehabilitation or during strenuous activities.</li> </ul>

# CHAPTER 12

## Knee Complaints

### Context

Knee complaints are common in an orthopaedic setting.<sup>1</sup> In a general community setting, 10% to 15% of adults report knee symptoms.<sup>2</sup> Knee pain accounts for approximately 3% to 5% of all visits to medical physicians.<sup>3</sup> Statistics for chiropractic visits are less clear. Generally, the Job Analysis of Chiropractic<sup>4</sup> reports that 9.4% of patients who seek chiropractic care have lower-extremity complaints. It is unclear which percentage is attributable to knee complaints. Although there are no available statistics on the frequency of presentation in chiropractic offices, chiropractors often serve a role as a conservative management alternative to orthopaedic consultation. In this context, the chiropractor's approach includes an evaluation of possible spinal or pelvic contributions in addition to local knee dysfunction or pathologic conditions. The distinction between referred or radiating pain and local knee problems may be as obvious as a direct radiation of pain from the low back, pelvis, or hip to the knee; however, the biomechanical contribution may not be quite as evident. Inherent in the evaluation process is the need to determine any neurologic connection between a knee complaint that is associated with a low back or pelvic complaint. When knee pain is due to an obvious direct trauma, the evaluation process focuses on a regional evaluation. If, however, the knee pain is local and either insidious or due to an overuse phenomenon, biomechanical evaluation of the lower extremity and lumbopelvic region must be included to determine contributing factors.

The knee may be the site of pain originating from or caused by a variety of sources, including the following:

- Referred pain from pain-sensitive structures in the low back, pelvis, and lower extremity (including facet joints, the sacroiliac and hip joints, and trigger points)
- Radiating pain from nerve root compression
- Peripheral nerve root entrapment (sciatic, peroneal, saphenous, etc.)
- Generalized dysfunction of the lower extremity (femoral anteversion/retroversion, genu varum/valgus/recurvatum, tibial torsion, pronation/supination, etc.)
- Local causes of pain
  1. Trauma

2. Overuse
3. Other (tumor, aneurysm, infection, etc.)

The knee is frequently injured based in part on its position of exposure to outside trauma. Virtually unprotected from outside forces, the knee is vulnerable to any number of impact injuries, including blows from the outside (valgus forces), dashboard injuries, and direct impact falls. Superficial damage may be readily accessible via palpation and stress testing. Internal damage is more often disguised, yielding only indirect and often delayed clues to the degree of injury. When intra-articular swelling is present, orthopaedic assessment is often delayed or the results of testing minimized because of the positional restrictions imposed on testing and reactive muscle spasm. The stability provided by joint effusion may delay the appreciation of an unstable knee. The true residual integrity of the knee may take several weeks to become apparent following the resolution of swelling.

Soft tissue injuries are usually the result of either overuse or disuse. Overuse is usually detected through careful questioning regarding activities that require repetitive movement or prolonged or awkward positioning. This may also require an evaluation of the patient performing or acquiring the suspected inciting activity. A suspicion of disuse requires an evaluation of any biomechanical predispositions such as pronation/supination, lower extremity torsion, or patellar tracking abnormalities. If a patient presents with an insidious onset of pain with accompanying swelling, a radiographic and possibly a laboratory search for arthritides, neoplasm, or infection should be instituted. With children it is particularly important to include an evaluation of the hip. The knee is often a site of pain referral with intrinsic hip abnormalities in children.

Some common clinical presentations are as follows:

- The athlete with anterior knee pain (patellofemoral arthralgia and/or patellar tracking disorders)
- The elderly patient with a complaint of knee pain and stiffness (osteoarthritis)
- The younger athlete with a complaint of tibial tuberosity pain (Osgood-Schlatter disease)
- The patient with the complaint of instability (chronic anterior cruciate ligament [ACL] damage)
- The patient with a complaint of painful locking (meniscus tear)

## General Strategy

### History

## Clarify the Chief Complaint

- Determine whether the complaint is one of pain, stiffness, locking, swelling, instability, crepitus, or numbness and tingling.
- Localize the complaint to anterior, posterior, lateral, or medial.

## **Clarify the Mechanism If Traumatic**

- Hyperextension: consider an isolated ACL tear or patellar dislocation.
- Hyperflexion: consider a posterior cruciate ligament (PCL) tear (if associated with major trauma, an associated ACL tear).
- Sudden deceleration (stopping or cutting): consider an isolated ACL tear.
- Valgus force (no rotation): consider medial collateral ligament (MCL) tear.
- Valgus force with rotation (foot fixed on the ground): consider multiple tissue damage including ACL, MCL, and menisci.
- Blow to a flexed knee (local damage can include contusion, fat pad irritation, or patellar fracture): consider a PCL tear if significant force is applied.
- Determine the timing, location (intra-articular or extra-articular) and degree of any accompanying swelling.
- Determine whether there was or is locking, instability, or weakness associated with the injury or postinjury.

---

## **Determine Whether the Mechanism Might Be One of Overuse or Misuse**

- Repetitive flexion and extension in midrange (e.g., running): consider iliotibial band (ITB) syndrome or popliteus tendinitis with lateral knee pain.
- Repetitive jumping or sprinting: consider patellar tendinitis (jumper's knee); in adolescents consider apophyseal injury such as Osgood-Schlatter disease with anterior knee pain.
- Constant valgus stress applied directly or indirectly: consider chronic MCL strain or pes anserinus tendinitis with medial knee pain.
- Constant squatting: consider meniscus injury.

If insidious, determine the following:

- Are there associated systemic signs of fever, malaise/fatigue, lymphadenopathy, multiple affected areas, etc.?
- Are there local signs of inflammation, including swelling, heat, or redness?
- Is there local deformity?
- Is there associated weakness, numbness, tingling, or other associated neurologic dysfunction?

---

## **Determine Whether the Patient Has a Current or Past History/Diagnosis of the Knee Complaint or Other Related**

## Disorders

- Determine whether there are any past traumas, surgeries, or diagnoses.
- Determine whether there have been any studies such as radiography or magnetic resonance imaging (MRI) performed on the patient.
- Determine whether there are any associated low back, hip, or lower leg/foot/ankle complaints.

## Evaluation

- Based on the history and presentation, perform either a region-specific or a condition-specific examination (e.g., examine the medial knee region versus perform meniscus tests).
- Determine whether radiographic views should be obtained; based on condition, determine whether specific views should be ordered.
- Avoid the initial use of MRI unless severe damage is suspected or a delayed diagnosis will affect future function; if the patient is unresponsive to conservative care, MRI may play a valuable role in determining the degree of damage and the need for surgery.

## Management

- Infection, tumor, and fracture require medical referral.
- Nonisolated ACL tears require a surgical consultation.
- Isolated ACL and MCL tears may respond to conservative management, including a period of bracing and cautious rehabilitation; the decision to manage conservatively is based on age, activity level, and functional requirements of the individual and the experience of the doctor.
- Meniscus tears that are the source of unresolving signs and symptoms or are demonstrated as large tears on MRI are best managed with minimal surgical intervention.
- Most other conditions can be managed with a combination of manipulation/mobilization, rehabilitation, and activity modification.

## Relevant Anatomy and Biomechanics

There are three “articulations” at the knee: (1) tibiofemoral, (2) tibiofibular, and (3) patellofemoral. The first two are synovial articulations. The patellofemoral articulation is a functional joint in which many of the same pathologic conditions found in true joints must be considered. The knee is statically supported by a peripheral system made up of the capsule, its thickenings, and the collateral ligamentous system (**Figure 12-1**). Internally, stability, and control of rotation are provided by the meniscal cruciate system. The cruciates, capsule, and collateral ligaments connect the femur to the tibia. The unique orientation of the cruciates allows tension to develop through most

ranges of motion. The cruciates are named according to their tibial attachment. The ACL is smaller (about the size of the little finger) and more vulnerable than the PCL (about the size of the thumb). The middle genicular artery runs along the length of the ACL and is often torn with midsubstance tears of the ACL. The ACL acts as the primary restraint to forward movement of the tibia on the femur non-weight-bearing and posterior movement of the femur on the tibia with weight-bearing. The PCL serves a synergistic role in providing restraint to backward movement of the tibia on the femur non-weight-bearing and resisting forward movement of the femur on the tibia with weight-bearing. The MCL is longer than the lateral collateral ligament (LCL) and has a more direct connection to the capsule. The LCL connects the distal femur to the fibular head and is separated from the joint by the tendon of the popliteus muscle. The popliteus acts as the primary lateral protection to valgus forces. It also acts as a secondary support for the PCL. The MCL acts as the primary protection to varus forces and acts as a secondary support for the ACL.

**Figure 12-1** Major ligaments of the knee joint.

The menisci act to deepen the joint, adding static stability. They aid in shock absorption and help govern rotational movement at the knee. Neural reflexes are activated by stimulation or stretching of the knee ligaments.<sup>5</sup> These are important protective reflexes that cause contraction of muscles in response to a perceived stress. One study incorporated nine patients who volunteered to have their ACLs electrically stimulated using an arthroscopic technique.<sup>6</sup> Surface EMG was used to record hamstring activity. The activity was measured first with no local anesthesia and then with local anesthesia. A marked increase in hamstring activity occurred without anesthesia, but there was no increased activity with anesthesia, indicating a reflex arc between the ACL and hamstrings.

The patella is the largest sesamoid bone in the body. It functionally extends the lever arm for the quadriceps muscle, making extension of the knee much more effective. Stabilization of the patella is provided by the quadriceps

muscles, their fascial extensions (retinacula), and the distal attachment to the tibial tuberosity via the patellar tendon (**Figure 12-2**). The spaces between the femur and the patella and the tibia and the patella are cushioned by the suprapatellar pouch and the infrapatellar fat pad, respectively. When the patella is not stable because of a high-riding position (patella alta) or underdevelopment of the lateral femoral condyle or posterior surface of the patella, abnormal motion occurs that may damage or irritate ligaments, muscles, and cartilage.

**Figure 12-2** Commonly irritated bursae of the knee.

It has been assumed that certain knee structures are more sensitive than others if sensitivity is defined as conscious perception of pain. Yet, most of the research has focused on mapping responses with sensory evoked potential in anesthetized patients or summarizing neurosensory output from the entire joint with respect to perception of knee position (i.e., proprioception). A recent study<sup>7</sup> focuses on the conscious perception of pain in an unanesthetized patient. A list of pain-sensitive structures based on this study follows.

- Probing/palpation of the central ridge and medial and lateral facets of the patella resulted in no pain.
- Probing/palpation of the odd facet of the patella resulted in a nonpainful awareness that was poorly localized by the patient.
- Probing/palpation of the suprapatellar pouch, the joint capsule, and the medial and lateral retinaculum resulted in a moderate to severe pain that was well localized.
- Probing/palpation of the femoral insertions of the ACL and PCL resulted in a nonpainful awareness that was poorly localized.
- Probing/palpation of the tibial insertion and femoral origin of the ACL/PCL resulted in a moderate to severe, poorly localized pain.
- Probing/palpation of the menisci resulted in nonpainful awareness that was poorly localized for the inner rim and slight to moderate, poorly localized pain at the capsular margins and anterior and posterior horns.

- Probing/palpation of the articular surfaces of the femoral condyles, trochlea, and tibial plateaus produced a nonpainful awareness or slight pain that was poorly localized.

These findings support some of the commonly held beliefs that follow:

- Damage to the points of origin of the cruciates and peripheral attachment points for the menisci is painful; however, internal derangements (midsubstance tears of the cruciates and deeper meniscal tears) are not in and of themselves extremely painful (subsequent to injury). The pain is probably more due to the associated effusion (bloody or synovial).
- Damage to articular cartilage and hyaline cartilage on the posterior patellae is virtually painless.
- Irritation or damage to the suprapatellar pouch, retinaculi, and joint capsule causes moderate to severe pain and is often the source of pain when deeper structures are torn (e.g., capsular tearing or distension with internal derangement).

The primary movements of flexion and extension predominate in most functional activities. The other four movement patterns of internal/external rotation and abduction/adduction are less often voluntarily (actively) acquired or needed. Rotation and abduction/adduction at the knee are more often the consequence of voluntary hip movement. Passive abduction/adduction at the knee is not possible with the knee in full extension. As the knee flexes, these movements increase; however, they are still passively acquired. Rotation range of motion increases as the knee flexes because of the increasing mechanical advantage of the hamstrings and other secondary rotators. Flexion is primarily due to the hamstring muscles. Assistance is given by the ITB when the knee is flexed beyond 30° to 40°. Extension of the knee is performed by the quadriceps muscles with some assistance by the ITB through the last 30° to 40°. Extension is a stronger movement pattern than flexion. In the non-weight-bearing knee, internal rotation is due to the popliteus, semimembranosus, and semitendinosus muscles with some minor assistance from the sartorius and gracilis muscles. External rotation is mainly accomplished by the biceps femoris with assistance from the ITB.

Starting with the knee in extension, the bony and soft tissue components involved in stability and movement are sequenced. The knee is locked into external rotation when in full extension due in part to the lateral femoral condyle being shorter than the medial condyle. In full extension, this externally rotated position uncrosses the cruciates to some degree and places slightly more stress on the peripherally placed collateral ligaments. The tendons of the pes anserinus muscles, hamstrings, and ITB act as static stabilizers when the knee is in full extension. As the knee flexes, it rotates internally. This rotation crosses the cruciates and takes some tension off the collaterals. Through the first 20° to 30° a rolling motion occurs between the tibia and the femur. Past 30° a sliding (gliding) motion occurs.

Restriction to extension is provided by tension in the posterior capsule and by the cruciates and the bony “lock” of the screw-home mechanism. Flexion is limited by approximation with the calf to the hamstring muscle group. Additional restriction may be provided by tension in the anterior capsule or tightness in the quadriceps. Rotation is limited (and governed) by the cruciates and menisci.

## Evaluation

### History

Careful questioning of the patient during the history taking can point to the diagnosis ([Table 12-1](#)).

### Pain Localization

Possible causes of pain based on localization ([Figure 12-3](#), A through D, and [Table 12-2](#)) follow:

- Anterior
  1. Traumatic—patellar fracture, fat pad irritation, contusion of other soft tissue structures, meniscus tear, pes anserinus bursitis (anteromedial)
  2. Nontraumatic—extensor disorders (patellar tendinitis or Osgood-Schlatter disease), patellofemoral disorders (patellofemoral arthralgia or chondromalacia)
- Posterior
  1. Traumatic—PCL tears, meniscus tears, gastrocnemius soleus tears (tennis leg), semimembranosus bursitis
  2. Nontraumatic—strain of gastrocnemius or soleus, semimembranosus insertion tendinitis, bursitis, Baker’s cyst, popliteal thrombus, referral from other disorders
- Lateral
  1. Traumatic—LCL tear, ACL tear with associated fracture, meniscus tear, fibular head subluxation
  2. Nontraumatic—ITB syndrome, popliteus tendinitis
- Medial
  1. Traumatic—MCL tear or rupture, medial meniscus tear
  2. Nontraumatic—MCL sprain, pes anserinus tendinitis, bursitis

### Traumatic and Overuse Injuries

When the patient reports trauma, several clues taken together may indicate a specific damaged structure. The mechanism of injury, coupled with the

associated signs or symptoms at the time of injury, may be suggestive of a characteristic pattern for a specific problem. There are four helpful questions:

- 1.** Was there any swelling following the injury? Swelling that occurs immediately or within the first few hours is suggestive of hemarthrosis. Blood in the joint causes irritation and is usually more painful and tense than with synovial swelling. There are two strong possibilities with hemarthrosis: an ACL tear and a fracture. If swelling is delayed, taking more than several hours, and is not especially painful (unless the patient moves the knee), synovial swelling is likely. Anything that acts to irritate the synovium can cause increased synovial fluid production. Common causes include meniscus tears, ACL flaps, and loose bodies.

**Table 12-1** History Questions for Knee Pain

Primary Question	What Are You Thinking?	Secondary Question	What Are You Thinking?
Was there trauma? (Did you hurt your knee in an accident or sports injury?)	Fracture, meniscal, cruciate, or collateral ligament tear	Hyperextended knee?	ACL injury
		Knee hit from outside?	MCL, ACL, or meniscus
		Weight on knee, twisted it (with or without contact)?	Meniscus
		With bent knee, fell on or hit front of knee?	PCL
		Pop at time of injury?	ACL, meniscus, or fracture
		Immediate joint swelling?	ACL or fracture
		Delayed swelling?	Meniscus or other joint irritation
		Knee painfully locks in one position?	Meniscus or flap of ACL
		Knee is held at 20° to 30° flexion to avoid pain?	General indicator of fluid in the joint
Did the pain begin after a repetitive activity?	Overuse syndromes; patellofemoral, patellar or popliteal tendinitis, ITB syndrome, mild sprain or strain	Knee painfully gives way?	Nonspecific; pain inhibits quadriceps
		Is the pain in the front of your knee and worse with jumping?	Patellar tendinitis or Osgood-Schlatter disease
		Is the pain on the outside of your knee and worse with downhill walking?	Popliteus tendinitis or ITB syndrome
		Is the pain on the inside of your knee and worse with breast-stroke kick, bicycling, or skiing?	MCL sprain; possible pes anserinus strain
Is the complaint more of stiffness?	Osteoarthritis, posttraumatic adhesions, subluxation	Do you have a past history of trauma or surgery?	Post-meniscectomy likely; trauma, adhesions from poor rehabilitation
		Age and weight of patient?	Osteoarthritis (confirm with weight-bearing films)
Is there a sense of weakness or instability?	Capsular instability, neurologic weakness	Past injury of painful swelling resolving with increasing instability?	ACL insufficiency due to past tear
		Past/current history of low back pain?	Neurologic weakness, especially if low back pain improved
Are there other problems that seemed to occur at or slightly before the beginning of your knee pain?	Arthritides, connective tissue disease, visceral referred pain	Other joints that hurt?	Check for arthritides (gout, rheumatoid arthritis, osteoarthritis, pseudogout, etc.)
		Sore throat several weeks before?	Rheumatic fever (check for murmurs)
		Abdominal pain or chronic diarrhea?	Inflammatory bowel disease arthropathy

**Figure 12-3** (A) Anterior knee; (B) medial anterior knee; (C) lateral knee; (D) posterior knee.

**Table 12-2** Knee Pain Localization

#	Structures	Overt Trauma	Insidious or Overuse
1	Quadriceps (rectus femoris)	Strain or rupture, contusion	Strain
2	Quadriceps tendon, suprapatellar pouch (deep)	Avulsion of quadriceps tendon, suprapatellar bursitis	Tendinitis, apophysitis in younger individuals
3	Vastus medialis obliquus (VMO) insertion, medial retinaculum	Sprain of medial retinaculum or strain of VMO due to patellar dislocation	Patellar tracking disorder with chronic sprain/strain of medial retinaculum or VMO
4	Patella, patellar bursa	Fracture, dislocation, bursitis	Bipartite patella, chondromalacia patella
5	Medial tibiofemoral joint, meniscus, coronary ligament, medial patellofemoral ligament, medial plica	Fracture, medial meniscus tear, traumatic plica irritation	Sprain of either coronary ligament or patellofemoral ligament, or medial plica syndrome
6	Infrapatellar fat pad	Fat pad irritation	Fat pad irritation
7	Patellar tendon, infrapatellar bursa	Bursitis	Patellar tendinitis
8	Medial proximal tibia, pes anserinus insertion	Fracture, pes anserinus bursitis	Pes anserinus bursitis
9	Tibial tuberosity, patellar tendon insertion	Fracture, avulsion fracture	Osgood-Schlatter disease in youngsters; patellar insertional tendinitis in adults
10	Tibialis anterior, extensor tendons	Contusion	Anterior shin splints, extensor strain
11	Tibia	Fracture	Stress fracture
12	MCL, medial meniscus	Medial collateral sprain or rupture, medial meniscus tear	Mild MCL sprain, osteoarthritis
13	ITB	Contusion	ITB syndrome
14	Vastus lateralis, lateral retinaculum	Contusion	Vastus lateralis strain, lateral retinaculum sprain or fibrosis
15	Lateral tibiofemoral joint, lateral meniscus	Meniscus tear, fracture	Meniscus tear, capsular sprain
16	Fibular head, LCL insertion	Subluxation, dislocation, LCL sprain	Subluxation
17	Insertion of biceps femoris onto fibular head, peroneal nerve	Direct trauma to peroneal nerve	Biceps femoris insertional tendinitis, peroneal nerve entrapment
18	Lateral meniscus, popliteus tendon, lateral gastrocnemius	Lateral meniscus tear	Popliteus tendinitis, lateral gastrocnemius strain, lateral meniscus tear
19	Semimembranosus insertion, medial meniscus, semimembranosus bursa	Medial meniscus tear	Bursitis, insertional tendinitis, medial meniscus tear
20	Medial head of gastrocnemius	Tennis leg	Strain of medial gastrocnemius

Note: See [Figure 12-3](#) for localization of numbered areas.

2. Did the knee give way at the time of injury? Giving way is a potentially helpful clue when not painful. Painful giving way often represents a reflex inhibition of the quadriceps that occurs with many painful knee conditions. However, if there was no pain at the time of giving way, instability (often ACL related) is likely the cause.
3. Was there a pop at the time of injury? A pop at the time of injury is indicative of an ACL tear, especially if the pop was accompanied by immediate pain and swelling. Other causes include a dislocated patella and, more rarely, a meniscus tear.
4. Does the knee lock? Locking of the knee can be divided into pseudolocking and true locking. Pseudolocking occurs when the knee is held at approximately 30° of flexion in an attempt to accommodate joint

effusion. The knee joint has the largest volume capacity at 30°. Therefore, when intra-articular swelling is present, less tension is developed with the knee in this position. Although it may be painful to move the knee, it is usually possible to move a few degrees into flexion or extension. True locking occurs with mechanical blockage. The knee is often in flexion and is rigidly, painfully locked in one position. No movement is possible until the knee is unlocked (often with a forced extension attempt). True locking is indicative of a meniscus tear or, less often, osteochondritis dissecans.

The mechanism of injury may be helpful when a contact injury is reported. Outside blows to the knee in a valgus direction are likely to damage medial structures. With the knee flexed, the MCL is most vulnerable. When the knee is in extension, the pes anserinus group is also vulnerable. Rotational injuries with a fixed foot often result in a sequence of damage beginning with a meniscus tear. If combined with an outside valgus force, the MCL, ACL, and meniscus may be damaged (terrible triad/O'Donoghue triad). Hyperextension injuries are often noncontact, but they may damage the ACL as a result of simultaneous contraction of the quadriceps. ACL damage also may occur with sudden deceleration or cutting maneuvers. One study<sup>8</sup> seems to indicate that perhaps there is another explanation (in particular with skiing injuries) because it appears that the quadriceps contraction actually acts to stabilize the knee. When performing open-chain exercises (e.g., seated knee extensions), the quadriceps may in fact provide some stability in the range of 70° to 80° of flexion or more. The authors feel that ACL injury with skiing is probably due more to rotations and translations that are imposed by a large moment arm created by the ski-boot complex.

Overuse injuries are most often sports related. Running may predispose the individual to ITB syndrome. If the patient is running or walking downhill, popliteus and ITB syndrome are possible if the patient presents with lateral pain. Pronation is believed to predispose the individual to several conditions, including chronic first-degree MCL tears, patellofemoral tracking problems, ITB syndrome, and popliteus tendinitis. Jumping and sprinting activities will predispose the patient to one of several extensor disorders, including patellar tendinitis and several age-related apophyseal problems including Osgood-Schlatter disease and Sinding-Larsen disease. Pain is felt more at the tibial tuberosity with Osgood-Schlatter disease, more at the patellar tendon with patellar tendinitis, and more at the inferior pole of the patella with Sinding-Larsen disease. If pain is felt going up or down steps, patellofemoral problems such as patellofemoral arthralgia or chondromalacia should be suspected.

## **Weakness**

The complaint of weakness must always be clarified. It is important to determine whether the patient has pain associated with the sense of

weakness, or stiffness that might be misinterpreted as weakness. True motor weakness at the knee is unusual unless found bilaterally with central nervous system/spinal cord disorders. Unilateral weakness may occur in diabetics with amyotrophy. Most lumbar disc lesions occur at the lower lumbar segments affecting more distal movement patterns; however, with L5 nerve root lesions, some patients have weakness of the hamstrings. When the knee is stiff from osteoarthritis (OA) or the patient is very inflexible, the patient must work against this restriction. This may be perceived as weakness. When pain accompanies weakness, testing should focus on contractile structures about the knee. Researchers evaluating the selective tension approach developed by Cyriax found that although intraexaminer reliability was acceptable after a training session, interexaminer reliability was not acceptable.<sup>9</sup> The study may have had limits due to the limited number of examiners and type of patient.

## **Instability**

Instability is most often due to ACL injury. Meniscus injuries may also cause a giving way. The degree of instability may be a helpful guide. ACL instability is often nonpainful and felt with rotational movement patterns. Patients often report having to walk a particular way to lock the knee prior to placing weight on it. Instability with meniscus tears is more often painful due to mechanical interference with normal movement. Instability may also be felt with a proximal tibiofibular subluxation. This occurs at approximately 30° of flexion.

## **Restricted Motion**

Restricted motion may be indicative of intra-articular swelling, joint mice, joint contracture, or tight musculature. Contractile causes of restricted motion are often uniplanar (i.e., flexion/extension). Joint effusion causes a restricted pattern whereby full extension is not possible and flexion beyond 90° is often difficult. The historical distinction is often the difference between acute traumatic onset, acute nontraumatic onset, and insidious onset. Acute traumatic internal damage will almost always cause joint effusion. Acute nontraumatic onset is also likely to be joint effusion but due to different causes, such as inflammatory arthritides or infection. Chronic or insidious onset is more likely due to soft tissue contracture, especially when associated with a history of immobilization or lack of activity. If the patient reports stiffness after sitting for long periods of time that resolves with 15 to 30 minutes of activity, two common possibilities are patellofemoral problems and OA. Patellofemoral disorders are more common in the younger patient; OA is more common in the older patient (unless there is a previous history of trauma).

## **Superficial Complaints**

Superficial complaints include numbness and tingling and localized swellings. Numbness and tingling local to the medial knee are often due to saphenous nerve irritation. If extending into a longer area of numbness, a nerve root lesion is possible. Localized swellings are caused by inflamed bursae, ganglions, meniscal cysts, lipomas, or, on rare occasions, villonodular synovitis (visible as calcified masses on x-ray). When deformity is present at the joint line, especially in an older patient, OA is the likely cause. Localized swelling at the tibial tuberosity in an adolescent is highly indicative of Osgood-Schlatter disease.

## Examination

The physical examination may be restricted, and findings may be obscured by swelling or decreased range of motion. This may result in frustration on the part of the chiropractor or the patient and lead to a desire for more expedient evaluation tools. The important contribution of the clinical examination is often undermined by the premature use of more expensive technologies such as magnetic resonance imaging (MRI) and arthrography. A recent study<sup>10</sup> indicated that with traumatic knee pain, the correct diagnosis was arrived at 83% of the time when the history, clinical examination, and routine radiographs were used to make the diagnosis. The diagnoses were later confirmed by arthroscopy (see **Table 12-3**). A small study<sup>11</sup> of children and adolescents confirmed a similar finding. The results indicated that the positive correlation between clinical examination and arthroscopic findings was 78.5%. When judging the positive predictive value for ACL or meniscal injuries, the clinical examination values were 96.2% and the negative predictive value was 93.3%. Compare this to the MRI values, which had a positive predictive value of 71.4% and a negative predictive value of 72.4%. Although a small study, it supports previous studies that suggest a premature referral for MRI may result in no added diagnostic value above the clinical examination, yet increase healthcare costs. Therefore, focus should be on a thorough history and examination, even if delayed, prior to resorting to or relying on the “definitive” answer of MRI. Exceptions are made when the clinical examination is not clear or there is an immediate need to determine the extent of damage.

**Table 12-3** Some Neoplasms of the Knee

Type	Summary Information
Osteosarcoma	<ul style="list-style-type: none"><li>• The most common malignancy of the knee</li><li>• Second most common primary bone tumor; most common, though, in ages 10-25 years; male/female ratio is 2:1</li><li>• 60% of all osteosarcomas are found in the knee; 40% in the distal femur</li><li>• Usually &gt;5 cm, metaphyseal location, sclerotic, disruption of cortex with Codman’s triangle, hair-on-end or onion-skin periosteal response</li></ul>

Chondrosarcoma	<ul style="list-style-type: none"> <li>• Third most common primary bone tumor</li> <li>• Only 7% involve the knee</li> <li>• May be secondary to osteochondroma, enchondroma, Paget's, fibrous dysplasia, or irradiation</li> <li>• May be asymptomatic with little swelling; found in ages 40–60 years; male/female ratio is 2:1</li> <li>• Central or peripheral location</li> <li>• Central are osteolytic with endosteal scalloping, and popcorn sign</li> </ul>
Synovial sarcoma (synovioma)	<ul style="list-style-type: none"> <li>• Rare malignant tumor arising from synovium of joint capsules, bursae, or tendon sheaths</li> <li>• 50% occur in the knee; usually found in ages 20–40 years</li> <li>• May be rapidly fatal</li> <li>• A painful tender lump may be palpable</li> <li>• A spherical soft tissue mass &gt;7 cm is commonly found</li> </ul>
Ewing's sarcoma	<ul style="list-style-type: none"> <li>• Rare malignant bone tumor found usually in the first two decades of life</li> <li>• Usually in long bone diaphysis; about half around the knee</li> <li>• Gradually increasing pain, soft tissue mass, possible fever, anemia and leukocytosis</li> <li>• Great variation, however, diaphyseal moth-eaten appearance (cracked-ice) and a laminated periosteal response are often seen</li> </ul>
Metastatic carcinoma	<p>Knee accounts for &lt;1.5% of skeletal metastasis sites</p> <ul style="list-style-type: none"> <li>• Most commonly from the lungs</li> <li>• Other sites may be thyroid, breast, prostate, and melanoma</li> <li>• Most are osteolytic</li> <li>• Blown-out, soap-bubble appearance is associated with renal and thyroid tumors</li> </ul>
Osteochondroma (exostosis)	<ul style="list-style-type: none"> <li>• A benign developmental defect following lateral herniation of an epiphyseal plate</li> <li>• Most common tumor of the entire skeleton; 50% around the knee</li> <li>• Growth stops with skeletal maturity; 1% may undergo malignant transformation</li> <li>• May be either pedunculated or sessile</li> <li>• Hereditary multiple exostosis is male dominant with a 10% chance of malignant transformation</li> </ul>
Nonossifying fibroma (fibrous cortical defect)	<ul style="list-style-type: none"> <li>• Very common in the first two decades, with 40% of children having one or more: 95% found in those &lt;20 years of age</li> <li>• 75% occur at the knee; mainly distal femur</li> <li>• Flame-shaped lesion, eccentrically placed in the long-bone metaphysis</li> <li>• Usually active on bone scan</li> </ul>
Aneurysmal bone cyst	<ul style="list-style-type: none"> <li>• Metaphyseal, expansile lesion, usually with a calcified eggshell rim</li> <li>• Usually occurs in the first three decades</li> <li>• Trauma may be initiating factor</li> <li>• Active on bone scan; it may be necessary to differentiate from a malignant expansile tumor</li> </ul>
Giant cell tumor (osteoclastoma)	<ul style="list-style-type: none"> <li>• 60% occur at the knee, with 80% benign and 20% malignant; malignant transformation usually occurring within the first 5 years</li> <li>• Involves both the metaphysis and epiphysis to the subarticular plate</li> <li>• Scalloping and thinning of cortex; eccentric location often at distal femur</li> </ul>
Pigmented villonodular synovitis (benign synovioma)	<ul style="list-style-type: none"> <li>• Benign disorder with synovial hyperplasia and hemosiderin deposition</li> <li>• Most common site is the knee</li> <li>• Usually young adults with swelling; however, little pain</li> <li>• Plain films may demonstrate a soft tissue swelling</li> <li>• MRI demonstrates lesion</li> </ul>

The acute injury evaluation on the field follows a sequential approach. The first step is a search for neurologic and vascular integrity through palpation, observation, and active movement testing distal to the knee. If neurovascular

function is intact and no obvious fracture is evident, the next step in the evaluation is testing for collateral ligament damage. This is performed, if possible, in full extension first, then at 30° flexion if negative for laxity. If the integrity of the collaterals is intact, the cruciates are next challenged using the Lachman's test (or an anterior drawer test if the patient cannot extend the knee to 10° to 20° of flexion). Further evaluation includes meniscus testing and testing of the integrity of the patellar restraint system. If the athlete can bear weight, he or she should be tested sequentially through two-legged balance and squatting movements to single-legged balance with an attempt at 20° to 30° of squat. If the patient passes this evaluation, more complex skills, such as running, then stopping, are evaluated.

The in-office evaluation of the knee is first begun with palpation for specific sites of tenderness in an attempt to localize, primarily, superficial tissue. This is directed by whether the history is one of trauma or overuse. With traumatic injury, palpation of the collateral ligaments at the joint line often will indicate tenderness with sprains. Palpation of the joint line anteriorly, medially, and posteromedially may reveal tenderness with meniscus tears. In addition, anterior joint line tenderness at the medial joint line may indicate damage to the coronary ligament (capsular ligament at the joint). Tenderness on either side of the patella may indicate retinacular tearing. Tenderness on either side of the patellar tendon with the knee flexed is a strong indicator of fat pad irritation. Palpation is aided by placing the patient's knee in the Hardy or figure-four position with the involved side ankle resting on the well leg in a seated position. This position opens up the joint space and places tension on the collateral ligaments, making them more accessible.

When the history indicates no obvious trauma, palpation may focus on the insertion sites for various muscle/tendon possibilities.

- Tenderness at the lateral epicondyle of the femur or anterolateral tibia is found with ITB syndrome.
- Tenderness behind the LCL or in front of the femoral insertion of the LCL is indicative of popliteus tendinitis.
- Tenderness at the insertion of the vastus medialis oblique (VMO) indicates a tracking abnormality; this may also be evident at the adductor tubercle.
- Tenderness at the posterior knee superior to the joint line with the knee bent may be found with gastrocnemius strain; below the joint line, with soleus strain.

The strategy for evaluation of superficial soft tissue damage (in addition to palpation) is to compress, stretch, or contract the tissue. Testing for less accessible, deep intra-articular damage requires indirect tests such as compression testing for the menisci and stability testing for the cruciates. Although there are numerous variations of standardized testing, the primary tests are addressed here.

# Anterior Cruciate

ACL testing is based on challenging the posterior-to-anterior stability of the tibia. The position of testing varies. If an anterior pull on the tibia is applied at 10° to 20° of knee flexion, it is called the Lachman test (**Figure 12-4**); at 90° it is called the anterior drawer test (**Figure 12-5**). The difference is in the sensitivity. For acute injuries, Lachman's test is more sensitive.<sup>12</sup> This is primarily due to the position of slight flexion that places the hamstrings at a disadvantage. If the hamstrings are in spasm, the direct line of pull with the knee at 90° is an additional force to pull against with the anterior drawer test. Rotational testing refers to testing for damage to the ACL and other structures. When medial or lateral stabilizing structures are damaged along with the ACL, a rotational instability is created. The first evaluation for this is a modification of the anterior drawer test. By pulling forward with the knee in internal and then external rotation, the lateral and medial supporting structures, respectively, are tested (Slocum's test).

The prototype rotational test is referred to as the pivot shift test (**Figure 12-6**). This test takes advantage of the passive tension of the ITB.<sup>13</sup> This tension will pull the tibia forward into medial subluxation when an ACL tear is present along with medial or lateral damage. As the knee approaches 30° to 40° of flexion, the ITB crosses the axis of rotation (the lateral epicondyle) and now acts as a flexor. This will passively pull the tibia back into neutral. Although there are many variations of this test, this is the basic mechanism by which most of these tests function.

**Figure 12-4** Lachman's test. To test for anterior stability, the knee is flexed about 10° to 20°. The femur is stabilized while the examiner pulls forward on the tibia.

**Figure 12-5** Anterior drawer test. The patient's hip is flexed to 45° and the knee is flexed to 90°. The examiner stabilizes the foot while pulling forward on the tibia. The posterior drawer test uses the same position but pushes the tibia back.

**Figure 12-6** The pivot shift test for rotary instability. The patient's knee is held in 10° of flexion. While applying a valgus force at the fibular head with the knee internally rotated, the knee is passively flexed.

A meta-analysis by Benjaminse et al.<sup>14</sup> agrees with past reviews that indicate that:

- The Lachman test has a pooled sensitivity of 85% and a pooled specificity of 94%.
- The pivot-shift test is very specific with a pooled specificity of 98% but only 24% sensitivity.
- The anterior drawer test is poor in acute settings, but in chronic ACL conditions it has very good pooled sensitivity (92%) and specificity (91%).

## Meniscus

Testing for the meniscus is essentially a compressive challenge. The two most widely used tests (other than joint line tenderness) are McMurray's and Thessaly's.<sup>15</sup> McMurray's test applies compression to the posterior and middle third of the meniscus (**Figure 12-7**, A and B). The first part of the test is a full-compression maneuver accomplished by passively flexing the patient's heel to the buttock. While in this end-range position, the tibia is internally and externally rotated while the examiner palpates the joint line for clicking or popping. A positive test is signaled by clicking and popping with accompanying pain. Soft positives may include clicking, popping, or pain only. The next portion of the test is to apply a combination of valgus/varus and internal/external rotation while extending the leg passively to 90°. Although it is often suggested that a specific combination of forces tests a specific meniscus (medial versus lateral), this is not borne out by studies.<sup>16</sup> When a positive McMurray's test is found, it more often represents a medial meniscus tear.

The Thessaly test involves the patient bearing weight on the involved side (with the examiner's support) and bending the knee into partial flexion of 20°. <sup>17</sup> The patient then rotates in each direction several times to determine if this elicits pain, joint line discomfort, or locking/catching (**Figure 12-8**).

Apley's is a compression and distraction test combination.<sup>18</sup> The advantage of Apley's test is that the anterior meniscus can be compressed because of the direct axial compression directed through the tibia. With the patient prone, the tibia is internally and externally rotated as the examiner continues to apply a compressive force while passively extending the leg. A positive test is the production of joint line or deep pain. A confirmation of this finding may be evident with a relief of pain with distraction of the tibia in this same position.

**Figure 12-7** McMurray's test for the meniscus. (A) The first position is full flexion. While the examiner internally and externally rotates the knee, the joint line is palpated for clicking or popping. (B) If the first position is unrevealing, the knee is extended while applying combinations of varus, valgus, internal rotation, and external rotation.

A relatively new test has been proposed for evaluating the lateral meniscus.<sup>19</sup> The authors call it the dynamic test. The patient is positioned with the hip in 60° abduction, flexed and rotated externally about 45°. The knee is flexed 90°. The examiner palpates the lateral joint line and keeps pressure at

the outer rim while adducting the hip, keeping the knee flexed. The test is considered positive if (1) pain is felt and increased at the point of finger pressure during the maneuver, or (2) a sharp pain is felt in the final position (**Figure 12-9**, A and B). The reported sensitivity was 85%, specificity 90.3%, positive predictive value 73.2%, and negative predictive value 95%.

**Figure 12-8** Thessaly test.

Shellbourne et al.<sup>20</sup> attempted to find the correlation of joint line tenderness to meniscal lesions in patients with acute ACL tears determined by surgery. Of the patients involved, 51% had medial joint line tenderness (JLT); of those patients, 45% had a medial meniscus tear, 49% had no medial JLT, and 35% of these had a medial meniscus tear. Furthermore, 34% had lateral JLT and 58% had a lateral meniscus tear; 66% had no lateral JLT, but 49% had a lateral meniscus tear. Medial JLT was 45% sensitive, 35% specific for a medial meniscus injury. Lateral JLT was 58% sensitive and 49% specific for a lateral meniscus injury. This study suggests that joint line tenderness is often not likely a predictor of an associated meniscal tear with an acute ACL tear.

McMurray's test is very specific but has a very low sensitivity for meniscal tears. Palpation for JLT has fairly good sensitivity but lacks good specificity. There do not appear any well-designed tests that determine the stability of the collateral ligaments that are scientifically validated for specificity and sensitivity. **Exhibit 12-1** is a graphical representation of determining the likelihood of a meniscus tear. The use of MRI in detecting meniscal tears is moderately reliable. In 106 patients (115 menisci) who were subjected to MRI and arthroscopy for evaluation of meniscal tear, reparability showed only a fair success rate (67%) in correctly identifying the tear type, side of the tear, and type of tear.<sup>21</sup> The averages for predicting meniscectomy were accuracy (69%), sensitivity (68%), specificity (75%), positive predictive value (90%), and

negative predictive value (43%). The following criteria were used to judge whether a meniscal tear would possibly heal, and whether it was surgically reparable:

**Figure 12-9** The Dynamic test for lateral meniscus tears. (A) The patient is positioned with the hip in 60° abduction, flexed and rotated externally about 45°. The knee is flexed 90°. (B) The examiner palpates the lateral joint line and keeps pressure at the outer rim while adducting the hip, keeping the knee flexed.

- At least 1 cm in length
- Displaceable with a probe
- Located within 3 mm of the meniscosynovial junction
- Seen to extend through at least 51% of the meniscal thickness
- Associated with minimal damage to the inner meniscal fragment or meniscal peripheral body

## Collateral Ligaments

The MCL is by far the most frequently injured collateral ligament. The principles used to test the MCL can easily be applied to the LCL when damage is suspected. Testing begins with the knee in full extension. A valgus force is applied through leverage against the lower leg. If the knee is unstable, there will be a palpable and visible increase in opening on the medial side of the knee. In children, opening in this position more often represents epiphyseal damage and indicates the need for a stress radiograph. If no opening occurs in full extension, the examiner proceeds and positions the knee at 30° of flexion and reapplies the same valgus force. At 30°, if the knee opens medially and feels as though no end-point was reached, a third-degree rupture of the MCL has occurred. If there is opening with an end-point reached, a second-degree tear is present. If there is no opening but pain is produced, it is likely that there is a first-degree sprain. Cross-checking with contraction of the medial musculature will differentiate ligament pain from muscle pain in most cases. Only one study<sup>22</sup> has tested the reliability of collateral ligament stability testing, and it does not appear to have a high interexaminer reliability.

# Patellofemoral Disorders

There are basically three approaches to patellofemoral testing: (1) compression, (2) stability, and (3) tracking. Compression testing involves direct compression of the patella with the knee flexed 5° to 10°. If pain is produced, chondromalacia patellae is suspected. The extension of this test is to ask the patient to contract the quadriceps while the examiner holds the patella down with a superior-to-inferior force (patellar inhibition test).

Stability testing for the patella is the reverse order of positions used for collateral ligament testing. The patient's knee is placed in 30° of flexion first while the examiner cautiously applies a lateral force to the medial patella. If this does not produce pain or apprehension, the test is cautiously repeated in full extension.

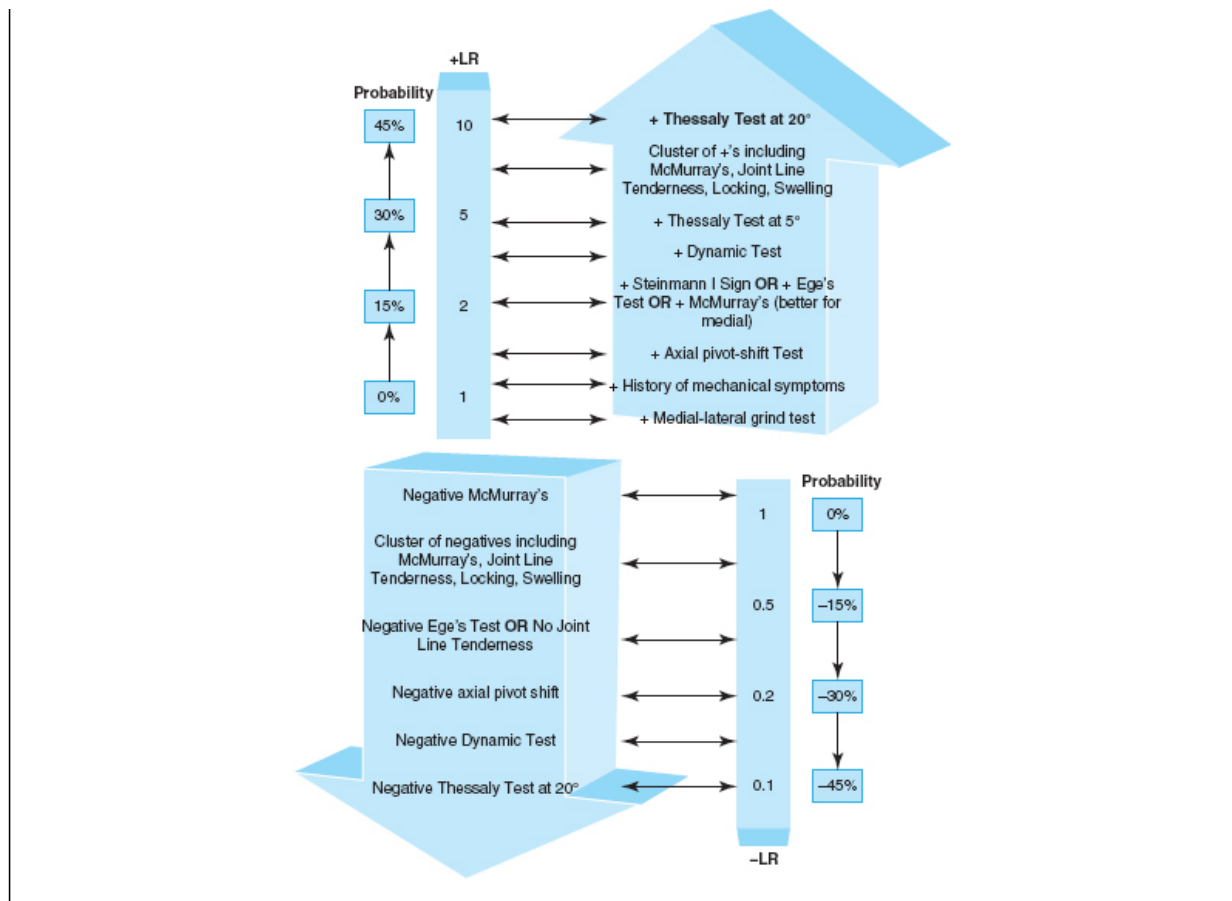

Tracking is tested by having the patient go through a full squat. The patella is palpated throughout the movement, and the patient is asked to identify any specific range where pain is felt. In general, if the pain is felt only at the bottom of the squat, patellar problems are less likely; meniscus problems are more likely. Tracking can also be evaluated indirectly by examining postural abnormalities that may contribute to tracking predisposition. For example, the combination of anteversion of the hip combined with external tibial torsion causes an increase in the Q (quadriceps) angle, leading to strain at the patella and medial knee. Version of the hip is discussed in [Chapter 11](#).

Internal or external tibial torsion is often determined by simple observation. With the patient seated, the examiner can obtain an axial view of the knee and foot ([Figure 12-10](#)). If the foot is turned out more than 20°, external tibial torsion is likely; if internally rotated more than 15°, internal tibial torsion is likely. Although the Q angle is often given significant weight in the diagnosis and management of patellofemoral disorders, a recent review<sup>23</sup> challenges these assumptions. This review of the literature on Q angle measurements indicates the following:

## **Exhibit 12-1 Likelihood Patient Has a Meniscus Tear Approximating Probability**

The likelihood ratios (LRs) in this graphical representation represent estimates of probability based on the aggregate of multiple reviews of each test finding. They are only approximations and only reliable indicators of a change in the context of a patient having an intermediate pre-test probability of between 20% to 80%. If the pre-test probability is very high or very low, the LR has little effect on changing the probability.

**Figure 12-10** Skyline view of external torsion of the tibia.

- There is very little evidence to suggest that a Q angle greater than 15° to 20° will, as a single factor, predispose the knee to tracking problems.
- Although women display a larger mean Q angle than men, the underlying reasons are not apparent at this time; the assumption that women have wider hips than men is not supported by the literature.

One final strategy in evaluating for patellofemoral tracking causes is to palpate and test for the presence of a plica, which might contribute to tracking abnormalities. There are various approaches, but the basic idea is to press the

patella from lateral to medial while the leg is either actively or passively extended. Stuttering or snapping at the medial, inferior patella suggests the presence of plica.

The functional portion of the knee examination focuses on tightness of lateral structures with emphasis on the ITB and weakness of medial structures with focus on the VMO. The primary ITB test is the modified Ober's test, which is designed to evaluate ITB or hip abductor tightness. VMO testing is nonspecific, but an evaluation of tracking through the last 20° may identify a functionally "weak" VMO. This is an indirect finding indicated by stuttering of extension or inability to extend while keeping the knee in the same position (without pressing down or lifting up at the knee).

## Extensor Disorders

Extensor disorders refer to damage or irritation to the quadriceps muscle and its attachment points at the patella and the patellar tendon and its attachment into the tibial tuberosity. By simply having the patient extend the knee from a flexed position against the examiner's resistance, pain is often produced at the site of the pathologic process. Pain at the tibial tuberosity in an adolescent indicates Osgood-Schlatter disease, whereas in an adult pain suggests patellar tendinitis. Pain at the patellar tendon is strong evidence for patellar tendinitis; on occasion, however, a deep infrapatellar bursitis or fat pad syndrome may cause pain. Pain at the inferior pole of the patella in an adolescent is suggestive of a process similar to Osgood-Schlatter disease called Sinding-Larsen disease.

### Specific Soft Tissue or Muscle/Tendon Tests

- **ITB:** The ITB is tested in two ways: direct pressure over the lateral epicondyle and stretching of the ITB in an attempt to determine predisposition. Direct pressure over the lateral epicondyle is performed with the knee flexed to 30° to 40° and is referred to as Noble's test. Stretching of the ITB is accomplished through passive adduction of the hip. This is referred to as Ober's test (**Figure 12-11**). A modification of this test is to stretch the hip with the knee extended over the side of the table. Although this maneuver may not reproduce the pain, it often indicates tightness when the patella fails to lower below the level of the top of the examination table. It is important to stabilize the iliac crest to prevent stretch above this point.
- **Popliteus:** The popliteus is evaluated through resisted internal rotation. This may increase the lateral knee pain found with popliteus tendinitis. Palpation points of tenderness are found in front of the LCL on the distal femur or directly behind the LCL. Another approach is to have the patient bear all the body weight onto the affected side and bend the knee to 30°.

If the femur is internally rotated, pain may increase with popliteus tendinitis.

**Figure 12-11** Modified Ober's test. The modified Ober's test involves extending the leg off the back of the table while stabilizing the ilium in an attempt to stretch the ITB and hip abductors.

- Semimembranosus: The semimembranosus may be involved in an insertional tendinitis. There is tenderness at the posterior attachment of the muscle or resisted knee flexion may increase pain at the posterior medial knee.
- Biceps femoris: Pain at the posterior fibular head may be increased with resisted knee flexion.

## Evaluation for Stiffness

When there is restricted range of motion (ROM) at the knee, an attempt at distinguishing between soft tissue involvement and an internal pathologic process is necessary. When there is tightness in the capsule, gentle stretching of the knee in the direction of restriction will usually increase the range without a significant increase in pain. Mild contraction of an antagonist muscle followed by passive movement into the restricted movement pattern will usually increase ROM when that muscle is the cause.

When neither approach helps or when the attempts at increased movement are met with pain, an intra-articular process is most likely.

## Radiographs/Special Studies

Diagnostic imaging guidelines were recently released in 2008.<sup>24</sup> These practice guidelines for musculoskeletal complaints in adults are an evidence-based approach developed through a rigorous process involving an international team of chiropractic experts. These provide an excellent source for determining the need for imaging, the types of imaging recommended, and physical examination and history indicators that will help direct decision making. Standard radiographs of the knee include an anterior-to-posterior (AP) non-weight-bearing view and a lateral non-weight-bearing view with the knee flexed to 30°. Based on the Ottawa rules,<sup>25</sup> radiographs should be ordered after acute knee injury if any of the following are true:

- The patient is over the age of 55 years.
- There is isolated tenderness at the patella.
- There is isolated tenderness at the fibular head.
- The patient is unable to flex the knee 90°.
- The patient is unable to bear weight immediately after the injury or take four steps in the emergency department.

In this landmark study, patients who were not initially radiographed were told to return if the pain did not improve or progressively worsened. Approximately 4,000 patients were followed for two 12-month periods (one year before and one year after the intervention). There was a reduction of 26% in the referral rate for knee radiographs compared to a reduction of only 1% in the control group. On average, the time spent in the ED was reduced by about 30 minutes and the cost was reduced to less than half (\$80 versus \$118). No significant fractures were missed. With suspected ACL damage, indirect indicators include the lateral capsular sign (Segond's fracture) indicated by a lateral tibial plateau fracture seen on the AP view, a tibial spine fracture seen on the tunnel view, and the lateral notch sign (depression fracture of the lateral femoral condyle) best seen on the lateral view.<sup>26</sup> Evaluation of the osteoarthritic knee is via a posterior-to-anterior (PA) view that is taken bearing weight with the knees bent to 45° and a 10° caudal tube tilt. When osteochondritis dissecans is suspected, a tunnel view is required. Osteochondritis is indicated most often by a divot of bone on the distal, lateral portion of the medial femoral condyle. Patellofemoral evaluation may be performed via several tangential views. The standard sunrise view provides little information unless OA of the patella or fracture is being evaluated. Other views such as the Merchant and Lauren view are variations on this theme that are used to evaluate tracking abnormalities. Two measurements, the congruence angle and the patellar tilt, are respective lines of mensuration used with these views. For patients with suspected past subluxation or dislocation of the patella, a combined approach using an axial (i.e., tangential) view coupled with a flexed and extended lateral view is sensitive for detecting malalignment and indicators of trochlear insufficiency.<sup>27</sup> For an accurate interpretation, the lateral view must line up the femoral condyles without any rotation effects causing misinterpretation of patellar tilting. MRI of the knee should be reserved for suspicion of major ACL or meniscal pathology or when the patient is unresponsive to conservative care. Magnetic resonance imaging (MRI) can be used to detect a number of knee lesions including the following:

- 1. Meniscus tears**
- 2. Cruciate tears**
- 3. Collateral ligament tears**
- 4. Infection**
- 5. Bone infarct**
- 6. Bone marrow infiltration**
- 7. Patellar tendinosis**
- 8. Soft tissue tumors**

The patient is supine with the leg externally rotated between 10° and 15°. A surface quadrature coil is necessary to increase the signal-to-noise ratio. Both sagittal and coronal images are considered routine with thickness slices between 3 and 5 mm. Slice thicknesses as small as 1.5 mm are obtainable with two new techniques: fast low angle shot (FLASH) and gradient recalled acquisition in the steady state (GRASS).

For meniscus tears a sagittal, spin-echo, T1-weighted image is commonly used. Coronal views are also used and may identify common tears such as the bucket handle, parrot-beak, and the variant, discoid meniscus. The meniscus usually has a low-intensity (dark) image on MRI. It appears as a bowtie-like structure on sagittal images. Tears usually have a higher signal intensity (lighter), probably due to fluid content. Care must be taken to avoid misinterpreting several normal structures as pathology, including the transverse ligament, popliteus tendon, lateral inferior geniculate artery, and concavity of the outer portion of the meniscus.

The cruciate ligaments are also low-signal diagonal images. If, upon viewing several sagittal, 3 mm sliced images, the ACL is not seen, it is assumed that it is torn. The posterior cruciate is assumed to be torn when its diagonal, low-intensity image is interrupted. If the image is widened, or the intensity is increased, swelling is likely indicating damage. On coronal images, the ACL appears as a diagonal low-signal structure, while the PCL appears as a vertical low-signal structure.

Researchers in one study<sup>28</sup> evaluated the relevance of abnormal findings on MRI of the anterior horn of the meniscus and existence of actual pathology. There was a 74% false-positive rate (26% true-positive rate). The authors recommend clinical correlation with MRI findings because some of the false-positive patients were asymptomatic and some had other pathologies.

An interesting study by LaPrade et al.<sup>29</sup> examined the prevalence of abnormal MRI findings in asymptomatic knees. This study indicates that there is a 5.6% prevalence of meniscal tears in an asymptomatic population. There was also an unexplained prevalence of 24.1% of Grade II signal changes of the posterior horn of the medial meniscus. There was approximately a 15% overall prevalence of other abnormal findings. They conclude that magnetic resonance findings are significant only when correlated with clinical findings.

## Management

- Patients with fracture, tumor, or infection should be referred for medical management.
- Patients with isolated ACL tears with resolved swelling may be managed conservatively if they are not serious amateur or professional athletes. This includes hamstring training, proprioceptive neuromuscular facilitation (PNF) training, and bracing.
- Patients with small, peripheral meniscus tears or those that are demonstrated via MRI to be vertical, stable tears may initially be

managed conservatively. If nonresponsive, it is important to recommend repair; when possible, it should be without meniscectomy.

- All soft tissue disorders, such as tracking disorders, first- and second-degree muscle/tendon problems, and first- and second-degree ligament disorders, can be managed conservatively. Isolated rupture of the MCL may be managed conservatively with casting and rehabilitation by experienced doctors; for those with less experience, comanagement or referral for surgery is recommended.
- When restrictions to accessory movement are found, short-arc, quick-impulse adjusting should be attempted with the knee in a distracted position. If not distracted, the knee should not be adjusted into flexion or in full extension. Recent evidence<sup>30</sup> supports the need to evaluate the low back and sacroiliac (SI) joint for subluxation. Manipulation of the SI joint was found to reduce inhibition of knee extensors.

There is a new focus on hip exercises as preventive for patellofemoral and other knee problems. The EMG evidence suggests that minimizing TFL activation is important and can be accomplished using the following: the clam, sidestep, unilateral bridge, and both quadruped hip extension exercises.<sup>31</sup>

## Manipulation

An interesting descriptive study evaluated the effect of sacroiliac manipulation (adjusting) on knee muscle inhibition in patients with anterior knee pain.<sup>32</sup> The results of this pilot study indicated that using Cybex muscle testing, SI manipulation may benefit patients with anterior knee pain by decreasing muscle inhibition. A follow-up randomized controlled trial<sup>33</sup> also confirmed an immediate effect on reducing knee extensor muscle inhibition. Certainly, larger controlled studies are needed.

As indicated in a review of chiropractic treatment of lower extremity problems,<sup>34, 35</sup> there are few large studies, but the preponderance of studies indicate benefit for those with osteoarthritis and patellofemoral arthralgia when manipulation is incorporated. Primarily, there are single case reports of chiropractic manipulation being effective for patients with knee pain.<sup>36, 37</sup> Knee joint mobilization does have some literature support. The results of a study by Moss et al.<sup>38</sup> indicate that using accessory motion mobilization on osteoarthritic knees produces some immediate decrease in pain and a reduction in the “up and go” test of knee function.

A separate review by Crossley et al.<sup>39</sup> on management of patellofemoral pain seemed to indicate that there was some improvement with corrective foot orthosis and a progressive resistance brace. There is no literature for or against the use of patellofemoral orthoses, acupuncture, low-level laser, chiropractic patellar mobilization, or patellar taping. A possible value for manipulation under anesthesia is for patients with total knee arthroplasty. Some studies<sup>40, 41</sup> indicate improvement in range of motion following MUA.

# Rehabilitation

In early electromyographic (EMG) studies conducted in the 1980s, Soderberg et al.,<sup>42, 43</sup> using surface electrodes, determined that more muscle activity was detected in the vastus medialis, biceps femoris, and gluteus medius using quadriceps isometric “setting” exercises than with a straight leg raise (SLR). The rectus femoris, on the other hand, was more active during the SLR. Skurja et al.<sup>44</sup> also found similar types of activity when comparing isometric knee extension with the SLR. These findings went unchallenged for more than a decade. Another assumption, partially based on these studies, was that the vastus medialis oblique was isolated in its increased activity through the last 10° to 15° of knee extension.

More recently, researchers have attempted to test some of these old concepts and to go beyond testing only the SLR or isometric exercise. Newer motivations are the need to find low-tech approaches to exercising patients with specific problems such as patellofemoral disorders and anterior cruciate deficiency. Each presents unique problems to prescribing the type of exercise, and more importantly the range of motion least harmful to each group. The “paradox” has been that patients with ACL deficiency might do better with closed-chain (i.e., foot in contact with a surface) exercise in moderate degrees of flexion whereas patients with patellofemoral problems would suffer from the increases in joint reaction and compression forces. Patients with patellofemoral problems do better with exercises close to full extension, but this is a range considered functionally dangerous for patients with ACL injury or deficiency (especially if performed as an open-chain exercise) due to the imbalance of quadriceps contraction pulling the tibia forward without concomitant hamstring protection.

In 1994 Cryzlo et al.<sup>45</sup> measured the EMG activity about the knee using indwelling wire electrodes during the performance of a number of exercises. These exercises included the following:

- The SLR—subject supine, raises leg with knee straight until 75° of hip flexion is reached
- Short-arc knee extension (SAEX)—subject seated with knee flexed to 45° off the end of the table; subject extended from 45° to full extension using a 12.5-lb weight
- Short-arc knee extension with hamstring co-contraction (SAEHS)—same as the SAEX; however, subjects asked to press back against thigh roll (to elicit hamstring contraction) as they extended through 45° to full extension
- The squat—subjects were asked to perform a two-legged squat to 90° of knee flexion, hold for three seconds, and return to original position
- Isometric knee co-contraction (ICO)—“setting” exercises were performed at 15°, 30°, and 45° of knee flexion with the subject contracting isometrically both the hamstrings and quadriceps

A summary of the results follows:

- Although during the SLR there was more rectus femoris activity than with the vasti muscles, it was not statistically significant. Also, activity of the VMO and vastus lateralis oblique (VLO) was essentially equal; there was no predominance of VMO activity. Activity of both the VMO and VLO was highest during the first 15° of the SLR. Basically the same was found for the SAEX and SAEHS exercises with significant increases in activity through the last 15° of knee extension. Although the SAEHS was designed to increase hamstring contraction, the activity level was quite low (highest activity between 30° and 45°).
- With the squat, the VMO/VLO and rectus activity was generally higher than the hamstring activity. The VMO/VLO activity was more than the rectus femoris during the ascend phase and highest during the hold phase. For the rectus femoris, the highest activity was also during the hold phase. Hamstring activity was highest during the ascend phase (although extremely low activity in general).
- Isometric knee co-contraction was the only exercise to provide a balanced activity between flexors and extensors. It was the only exercise tested that demonstrated any significant activity for the hamstrings.

Clinically, the usefulness of these data is interpreted as follows:

- Although the squat exercise may be a valuable alternative to knee extension in the patient with ACL deficiency, it does little to activate (strengthen) the hamstrings. The hamstrings are necessary for a stable joint with patients with ACL deficiency. A balanced exercise might be SAEHS or the ICO in all ranges except 15° of flexion to full extension. In this terminal range of knee extension there is an overbalance of quadriceps activity over hamstring activity.
- The final arc of 15° of extension is suggested for strengthening the quadriceps; however, there is very little to suggest selected contraction of any of the quadriceps group (i.e., VMO over VLO or rectus).

## Elastic Tubing Exercise

A recent study by Hintermeister et al.<sup>46</sup> evaluated EMG activity (surface electrodes) of five exercises that utilized elastic tubing. These exercises included the following:

- Single knee dip—subject stood on elastic tubing with involved side only; holding end of tubing in hand (on involved side), other end attached to chair (which the subject used to stabilize with); the subject performed partial squats on the involved side only at a rate of 30 knee dips/minute while balancing with the chair.

- Double knee dip—subject stood on tubing and grasped end of tubing with hands (held at waist level) and performed squats.
- Leg press—subject was seated with tubing around heel and other end attached behind the subject; with the hip in maximum flexion there was some tautness in the tubing; the subject then pressed the leg into extension against the resistance of the tubing.
- Hamstring pull—subject was seated with the tubing anchored around the ankle with the other end anchored in front; with the knee flexed to approximately 20° there was some tautness in the tubing; subject was instructed to drag the foot across the floor as far as possible and lift slightly while returning to the initial position.
- Side-to-side jump—subject had the tubing secured around her or his waist and anchored away from her or him to the side; subject then jumped laterally (to her or his side) in the opposite direction of the tubing attachment.

The results suggested a progression of demand on the knee musculature. A summary of the EMG findings and the sequence of demand on knee musculature follows:

- Double knee dip—demand on the vasti muscles was over 50% of a maximum voluntary contraction (MVC). There was more activity of the VMO over the VLO; however, this may not be clinically significant.
- The leg press—not a very powerful exercise; however, there seemed to be preferential recruitment of the rectus femoris over the vasti muscles and some activation of the tibialis anterior muscle.
- Hamstring pull—it was no surprise that the hamstring activity was significant (more for the medial hamstrings) and, in addition, there was significant adductor firing that occurred with the hamstring activity.
- Single knee dip—similar results to the double knee dip; however, significant increases in activity of the vasti muscles and rectus femoris with some preferential recruitment of the VMO (VMO, 103%; VLO, 83%; rectus femoris, 73% MVC).
- Side-to-side jump—as might be guessed, the most demanding exercise was the jump with approximately 10% increases in all quad muscle activity over the single knee dip. Also the medial gastrocnemius demonstrated significant activity.

Recommendations by the authors suggest using the less stressful exercises first based on the needs of a specific rehabilitation program (e.g., ACL problem versus patellofemoral problem). For example, for patients with an ACL deficiency, a hamstring pull and leg press might be good starting exercises. Progression to more challenging exercises should be based on the ability to perform the less stressful exercises first. It should be noted that most of the exercises demonstrated a slight increase in VMO activity compared with VLO activity; however, most researchers do not believe that this is clinically significant.

# VMO Recruitment

It is generally accepted that the VMO is important for patellar stabilization, in particular through the last 15° or so of extension. As a result, many studies have attempted to determine if any particular exercise was significantly better at isolating the VMO. It has been almost unanimously agreed based on numerous EMG studies that most exercises do not show a clinically significant increase in VMO activity over VLO activity. A study by Laprade et al.<sup>29</sup> reemphasizes this point and in addition calls into question a commonly reported claim that adding adduction to knee extension increases VMO activity over extension alone. In the past it was assumed that because the VMO originates primarily from the adductor longus and magnus tendons and the medial intramuscular septum adding adduction would increase or preferentially stimulate the VMO. This is a logical assumption not borne out by this study. Although one study (upon which most of this connection between adduction and VMO activity was based) indicated significant increases, it is clear that the study's EMG values were not normalized, and therefore the conclusions must be questioned. It also has been suggested that the VMO might have some medial (internal) rotation effect on the tibia. This is based on the observation that the lowermost fibers of the VMO attach to the anteromedial aspect of the tibia. The study by Laprade et al. tests this hypothesis. This study also addresses whether there are any significant differences in VMO or VLO recruitment between patients with and without patellofemoral pain syndrome.

In this current study by Laprade et al.<sup>47</sup> subjects were asked to perform four isometric exercises while surface EMG readings were taken:

1. Adduction—subjects adducted their thighs against two rubber cups with their knees flexed to 50° and hips flexed to 80°.
2. Adduction with knee extension—subjects performed simultaneous adduction and knee extension; subjects were instructed to squeeze their knees together and lift against an ankle strap.
3. Medial tibial rotation—the subject's knee was at 70° flexion/30° lateral rotation and hip at 80° flexion; a footplate that was padded provided resistance to medial rotation.
4. Medial tibial rotation with knee extension—similar to the positioning for medial rotation; the subjects were asked to simultaneously medially rotate and extend the knee.

The results did not demonstrate any difference in the activity of VMO or VLO muscles or ratio of activity between the VMO/VLO between the symptomatic and asymptomatic groups. The results also indicated no preferential recruitment of the VMO over the VLO for most exercises including adduction with extension. There was some increase in VMO over VLO contraction using medial rotation with extension. Still, the difference between VMO and VLO activity would in no way isolate the VMO over the VLO. This

exercise would, however, guarantee a good strengthening effect for both muscles with some degree of VMO focus.

## **Graded Treadmill Walking**

Treadmill walking is often prescribed during the early phases of rehabilitation after significant injury or surgery. One study<sup>48</sup> measured the EMG activity of leg muscles at 0% to 24% grade (incline). As the grade increased, there were significant increases in VMO, vastus lateralis, and biceps femoris activity. The increases in the vasti muscles were about double those of the biceps femoris. Interestingly, there was no such increase in the peak amplitude of the medial hamstrings. Although there were increases for the quads and biceps femoris, it is not known whether this amount of increase contributes to a strengthening effect. The average amplitude was less than 25% of a maximum voluntary contraction for all the muscles regardless of grade.

As the grade was increased, the ankle and hip ROM increased while the knee ROM decreased. The decrease in knee ROM was due to a specific decrease in knee extension with an increase in grade. So, although the knee flexion angles remained similar through different grades, the amount of extension achieved decreased with increasing grade. The authors suggest that a balance between the needs of an anterior cruciate-deficient patient and a patient with patellofemoral pain may be met by having the patient use a grade of just greater than 12%. They suggest that at this grade, the knee remains bent around 30° and therefore avoids extension, which is detrimental to the ACL patient. This amount of grade also avoids the middle to extreme flexion positions that may be detrimental to the patient with patellofemoral pain.

---

## **Stair-Stepping**

Stair-steppers have become quite popular as an aerobic alternative to treadmills. Little research has been performed for stair-steppers; therefore, most of the claims are anecdotal or promotional. One study<sup>49</sup> evaluated the EMG activity of muscles about the knee and hip. The researchers monitored the activity of these muscles with increasing cadence and also measured again with retrograde stepping. Their results indicated increases in muscle activation for the gluteus maximus, rectus femoris, vastus medialis, and gastrocnemius with increases in stepping cadence. There were no significant increases for the semimembranosus and semitendinosus except for the extremes of 35 to 95 steps/minute. However, with retrograde stepping at a cadence of 60 steps/minute, there was an increase in the medial hamstring activity. Interestingly, there was no increase in gluteus maximus activity as predicted by many stair-stepper enthusiasts and manufacturers.

Placed in the context of rehabilitation for an ACL-deficient knee, it was observed by the authors that the increase in hamstring activity was minimal whereas the quadriceps increase was greater with stair-stepping. To achieve a balance so that there is less strain on the ACL and more stability from the

hamstrings, it was recommended that stepping at a slower cadence was probably safest. There was no particular advantage to faster stepping given the lack of hamstring activity increases. They also felt that although there was an increase in medial hamstring activity with retrograde stepping, it was rather minimal and the awkwardness of the activity did not justify using this method as an alternative to forward stepping. It should be noted that retrograde stepping is more aerobically demanding.

## Bicycle Riding

It is generally accepted that bicycle riding is a good approach to rehabilitation of ACL injury whether surgically managed or not. The concerns, as always with ACL deficiency, are extension of the knee and quadriceps contraction pulling the tibia forward on the femur. A recent study<sup>50</sup> measured the strain behavior for the ACL with bicycle riding using different power levels and cadences (60 and 90 rpm) and found no significant differences among them. This finding suggests that there is enough muscular control to compensate for increases in either resistance or cadence. In fact, the quadriceps were most active when the knee was in flexion, which would act as a stabilizer through a posteriorly directed pull. Although this may seem contradictory to visual judgment, due to an angle of pull change at around 60° to 70° of knee flexion, the quadriceps produce a posteriorly directed force. ACL strain was greatest between about 120° to 200° (0° with pedal at top; 180° with pedal at bottom). This correlates with a high EMG activity of the gastrocnemius.

## Summary Approach to Knee Rehabilitation

A general exercise approach begins with isometric setting exercises ([Tables 12-4](#) and [12-5](#)). These are performed both in full extension (if possible) and at 20° to 30°. In this minimally flexed position, the patient pushes the heel into the ground or table to achieve a co-contraction of the hamstrings and quadriceps. When the knee is prepared with a facilitation phase of isometrics, progression to isotonic within the pain-free range is then begun, starting with a weight that allows pain-free performance of three sets of ten repetitions. Increases in weight are dictated by the progressive resistance exercise (PRE) or daily adjustable progressive resistance exercise (DAPRE) protocols ([Table 1-8](#)). When patellofemoral problems are found, terminal extension exercises through the last 20° may be helpful. If there is instability in the knee, however, open-chain knee extension exercises should be avoided and substituted with closed-chain exercises such as partial squats or leg presses.

**Table 12-4** General Knee Rehabilitation\*

Type	Muscles	Sets	Repetitions	Contractions	Rest Period
Quad setting (isometrics)	Quadriceps/hamstrings	1 or 2	10-12	8 seconds	3-5 seconds
Straight leg raises	Quadriceps/psoas	2 or 3	10-12	3-5 seconds	3-5 seconds
Supine (with setting)	Vastus medialis				
	Biceps femoris				
Vastus medialis	Vastus medialis				
Biceps femoris	Biceps femoris				
Stretching	Gastrocnemius/soleus	5	10-20	8-10 seconds	5 seconds
(use proprioceptive neuromuscular facilitation [PNF] hold-relax approach)	Hamstrings				
	Tensor fasciae latae				
	Quadriceps				
	Adductors				

\*Initial phase, performed three times daily. A rest period of 1 to 3 minutes between sets is recommended.

**Table 12-5** General Knee Exercise Program

Exercise/Stretch	Activity	Amount
<b>Beginning Phase—Begin When Patient Has 90% ROM; No Joint Irritation</b>		
<b>Stretch</b>	PNF stretch for hamstrings, ITB, and gastrocnemius	3-5 sets; 10-20 reps
<b>Isometrics</b>	Performed every 20°	1-2 sets; 10-20 reps
<b>Straight leg raise with weights</b>	Supine, prone, and side-lying (5-10 lb)	2-3 sets; 10-20 reps
<b>Functional work</b>	Shallow knee bends, lunges, and step-downs	2-3 sets; 10-12 reps
<b>Isotonic exercise (with elastic tubing)</b>	All knee motions	Base on PRE or DAPRE approach
	Well-leg bicycling and rowing,	30 minutes; three times weekly

<b>Aerobic exercise</b>	upper body work	at target heart rate
<b>Intermediate Phase—Begin When Patient Has 75% Strength and Endurance of Well Leg. Continue the stretch, functional work, and aerobic exercise and add the following:</b>		
<b>Isotonics</b>	Knee and hip work (emphasize eccentrics)	Base on PRE or DAPRE approach
<b>Sport cord training</b>	1/3 knee bends, leg presses, and forward-backward run	Average of 3 sets; 20 reps
<b>PNF diagonals</b>	D1 and D2 hip flexion/extension first; knee straight, progressing to same patterns incorporating knee flexion/extension	Several sets to fatigue
<b>Proprioceptive work</b>	Wobble or balance boards using both legs, progressing to one-legged balance if possible	Average of 5 sets; 3–5 minutes
<b>Advanced Phase—Begin When Patient Has 90% Strength and Endurance of Well Leg. Continue stretch and proprioceptive work; continue above isotonic work if isokinetic machines are not available.</b>		
<b>Isokinetics</b>	Knee flexion/extension patterns	10–20 reps at multiple speeds (emphasize faster speeds to decrease load)
<b>PNF sport or activity specific</b>	Patterns imitate patient's sport patterns	Several sets to fatigue
<b>Agility drills</b>	Figure-eights, cutting maneuvers, cariocas, rope	5–10 sets for total of 45 minutes

	jumping, side-to-side jumping sliders	
<b>Plyometrics</b>	Progress from two-legged to one-legged jumping; progress from straight-line to side-to-side jumping	Several sets to fatigue

Key: ROM, range of motion; PNF, proprioceptive neuromuscular facilitation; PRE, progressive resistance exercise; DAPRE, daily adjustable progressive resistance exercise.

When using a bicycle for rehabilitation it is important to keep the seat height at a level that prevents full knee extension if there is underlying ACL insufficiency ([Table 12-6](#)). For patellofemoral problems, avoid a low-seat position that adds compressive forces to the patella. Pool or aquatic exercise is a useful approach for patients with osteoarthritis of the knee, progressing to bicycle riding and finally full weight-bearing exercise.

**Table 12-6** Exercise Program for Specific Conditions: Specific Emphasis on Modifications to the General Program

<b>Condition</b>	<b>Emphasize</b>	<b>Avoidance/Contraindication</b>
<b>ITB syndrome</b>	ITB stretching	Initially, downhill running Initially, side-posture adjusting (same side)
<b>Patellofemoral arthralgia and chondromalacia</b>	VMO strengthening Vastus lateralis and ITB stretching Orthotics (if pronation found) Bracing or taping initially to allow pain-free exercise	Initially knee extension between 20° and 90° Low-seat position on bicycle
<b>Meniscus tears</b>	General rehabilitation	Full flexion (full squat) positions Full extension with rotation
<b>ACL tears</b>	Hamstring training Specific focus on vastus lateralis, biceps femoris, and tibialis anterior muscles Functional bracing Proprioceptive training PNF diagonal flexion patterns	Isometric (open-chain) exercise against resistance at 20° Isotonic exercise (open-chain) from 20° to 70° Leg extensions with heavy weight

<b>PCL tears</b>	Quadriceps training PNF knee extension patterns	Open-chain hamstring exercises
<b>MCL tears</b>	Strengthening of both abductors and adductors Strengthening of internal rotators Hinged-knee support for 1–3 weeks	Resisted knee extension from 45° to full extension initially
<b>Patellar tendinitis</b>	Eccentric training of quads Patellar strap or taping may have limited usefulness initially	Initially avoid jumping activities Initially avoid high-weight extensions
<b>Osgood-Schlatter disease</b>	Stretching of quadriceps, hamstrings, and gastrocnemius Bracing	Jumping and running activities should be decreased to reduce pain

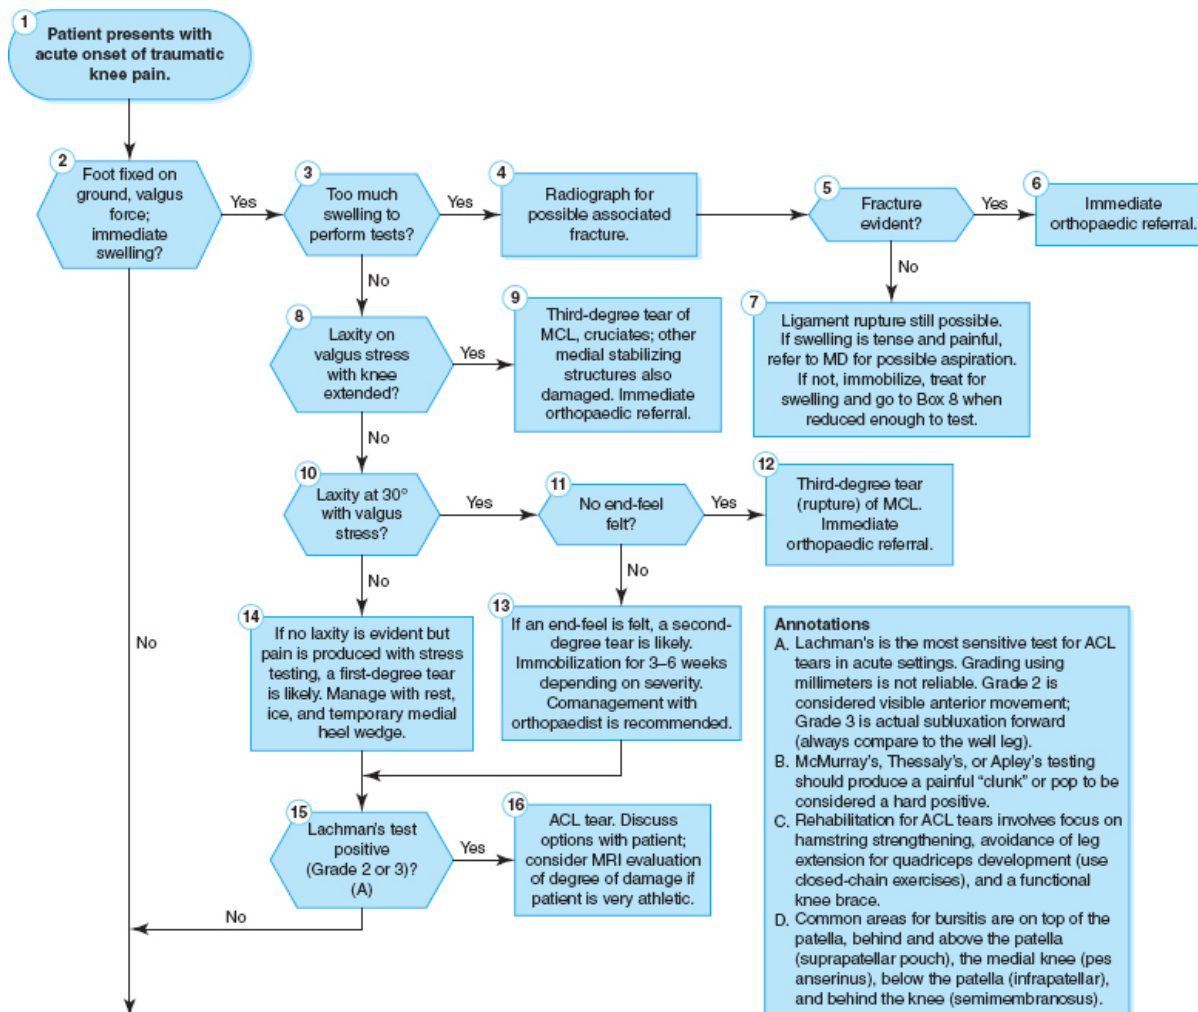

Stretching of the hamstrings, quadriceps, gastrocnemius, and ITB (and attachments) is important to maintain proper flexibility at the knee. It is particularly important for patellofemoral tracking problems.

Bracing is used for three purposes: (1) for those patients with ACL-deficient knees (functional brace), (2) for those in need of support during rehabilitative training, and (3) for prophylactic purposes to protect against further injury. Functional braces are quite expensive. They represent a variety of custom-fitted supports that provide a block to full knee extension and various hinge supports for both protection from further injury and control of rotational movement. Examples include the CTi and Townsend.<sup>51</sup> Prophylactic bracing provides metal bars to prevent valgus or varus forces from causing further damage. Examples include the Anderson Knee Stabler and McDavid Knee Guard. Used with sporting activities, these braces may help or ironically may increase the injury rate, possibly due to an early fatigue of the involved leg or prestressing of the knee due to poor fitting.<sup>52, 53</sup>

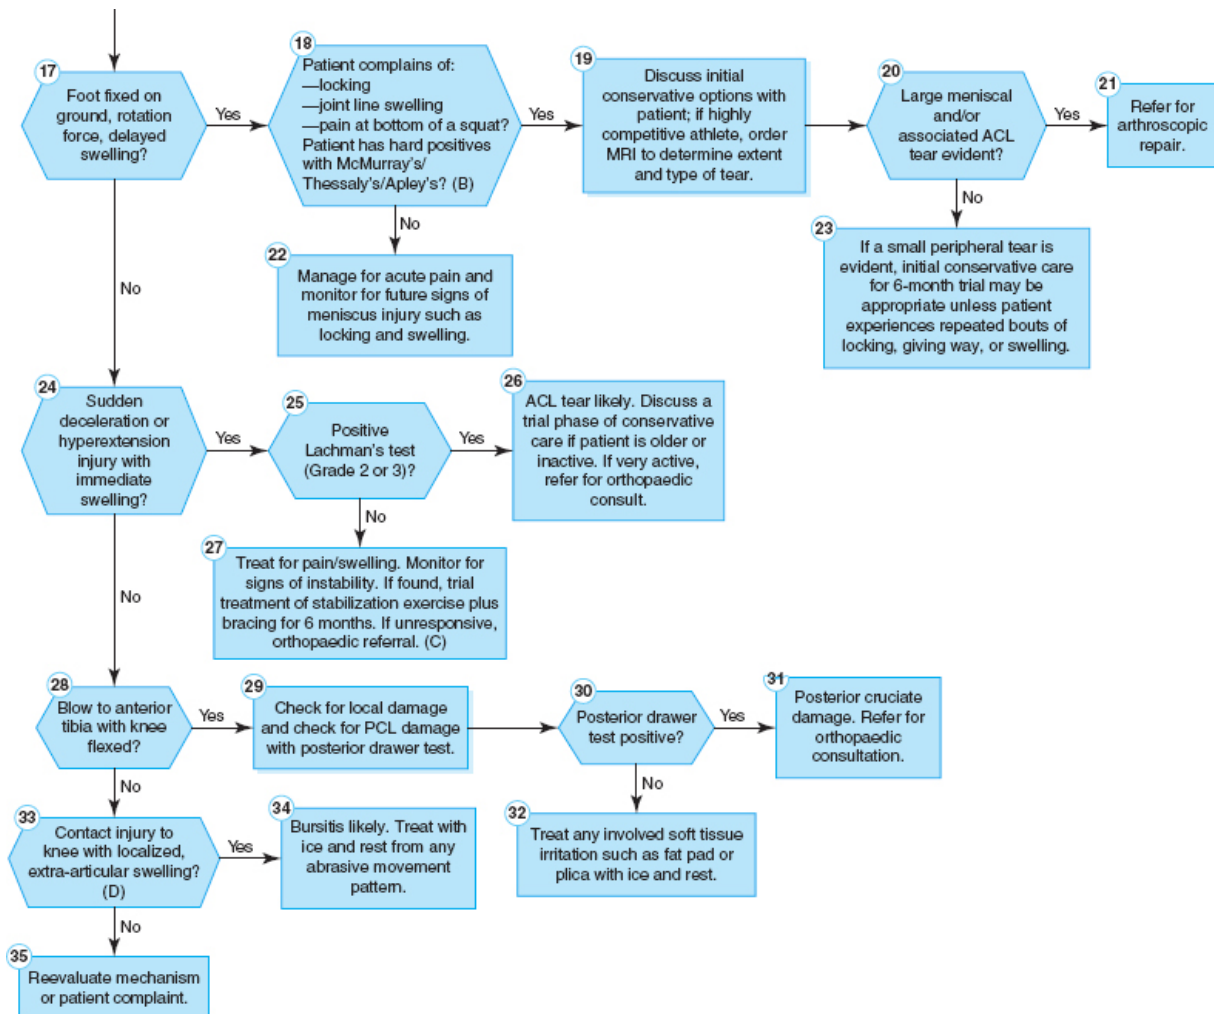

Rehabilitative support may be provided by taping or brace support. Patellofemoral tracking problems are in need of patellar stability and tracking control. Various braces with patella holes and strapping support or taping applying a strapping approach (McConnell taping) are used.<sup>54</sup> Braces for patients with Osgood-Schlatter disease incorporate a reverse horseshoe design to provide a restraint to superior pull on the tibial tuberosity. Many of these devices probably function more from a proprioceptive mechanism than from the support they are purported to provide.<sup>55</sup>

# Algorithms

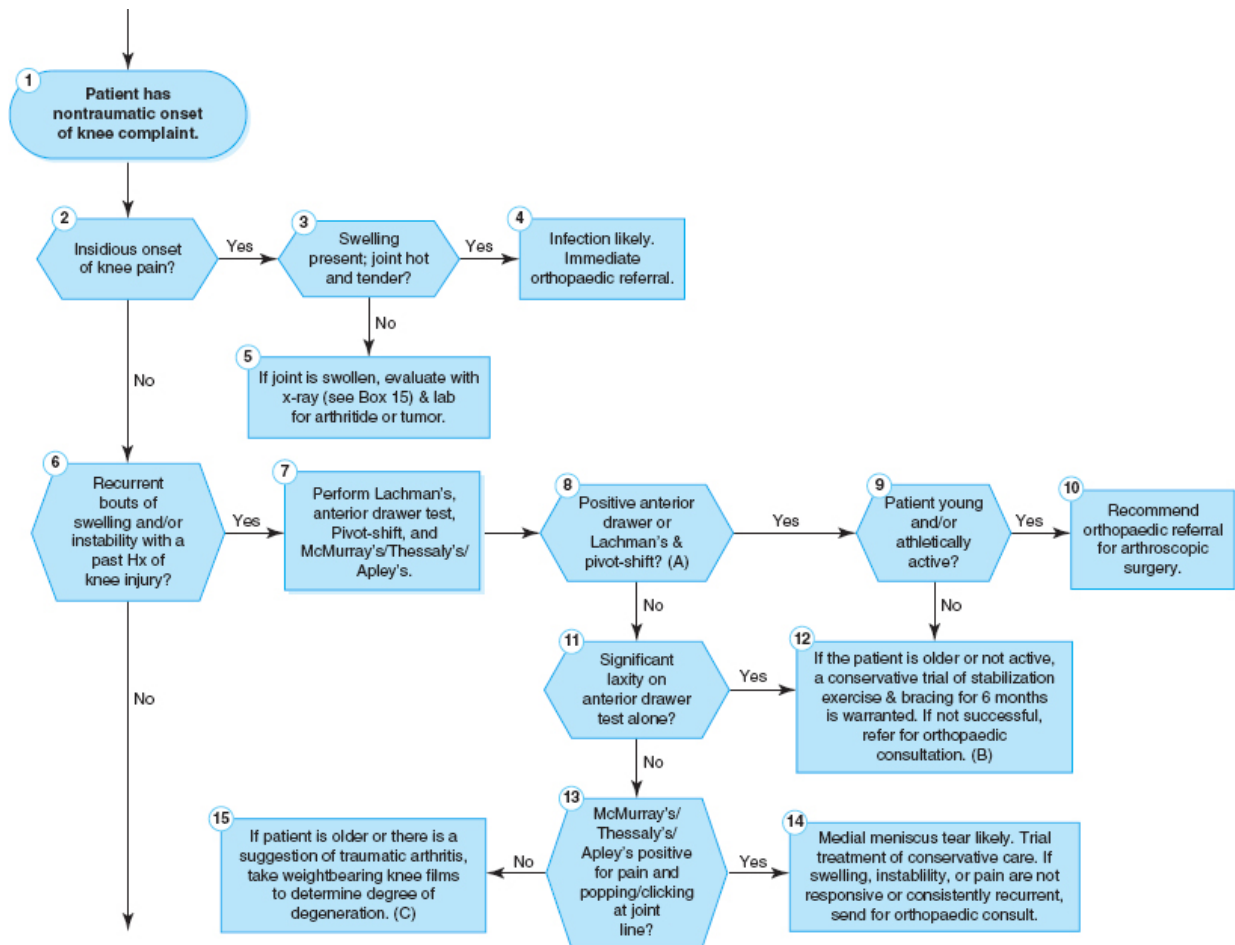

Algorithms for traumatic knee pain and nontraumatic knee complaints are presented in **Figures 12-12** and **12-13**.

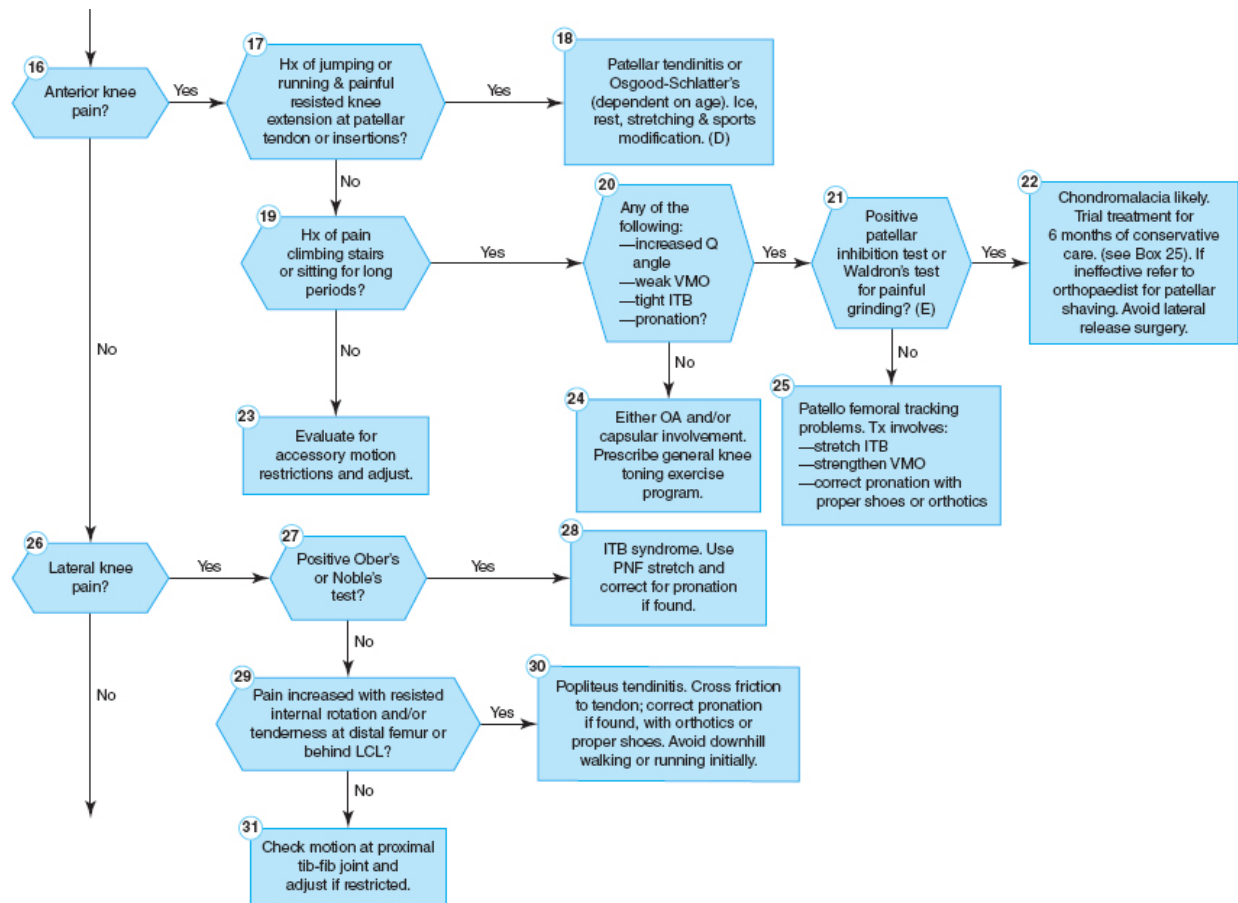

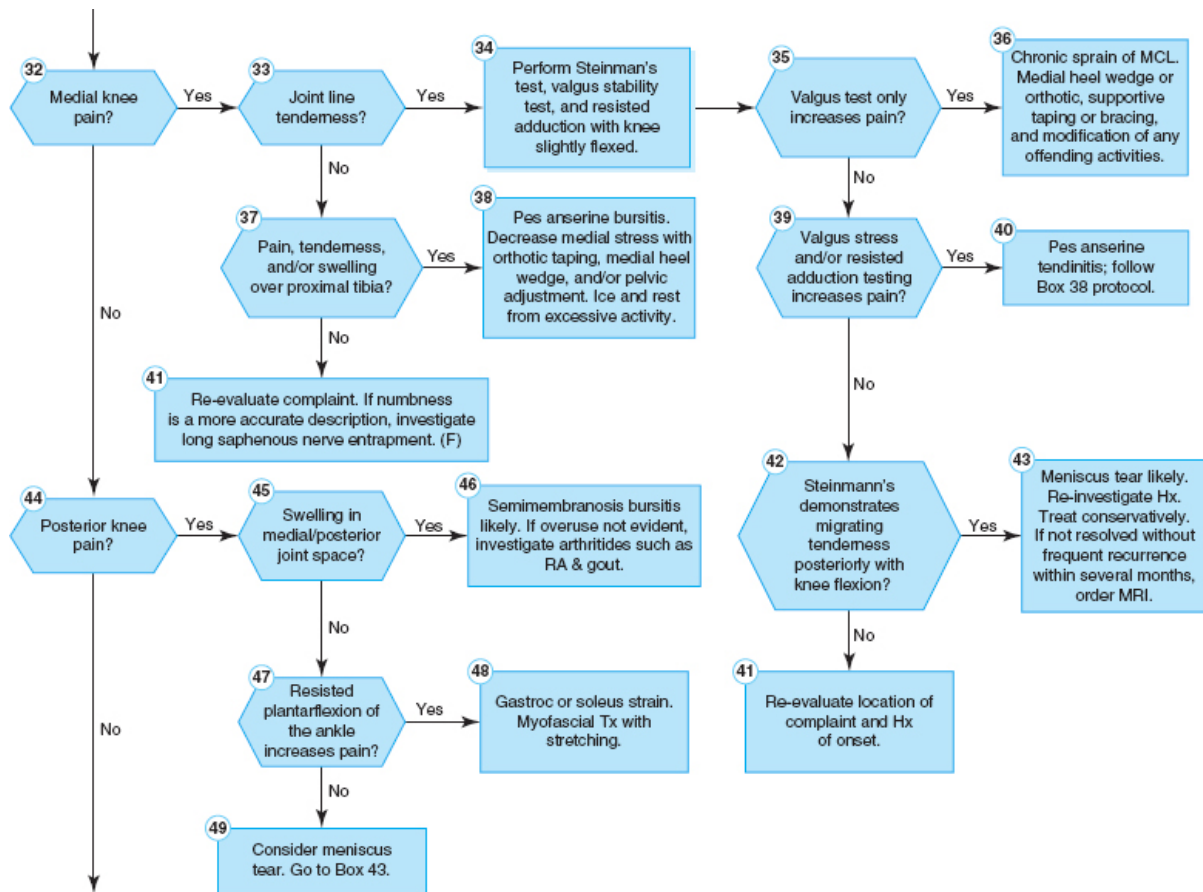

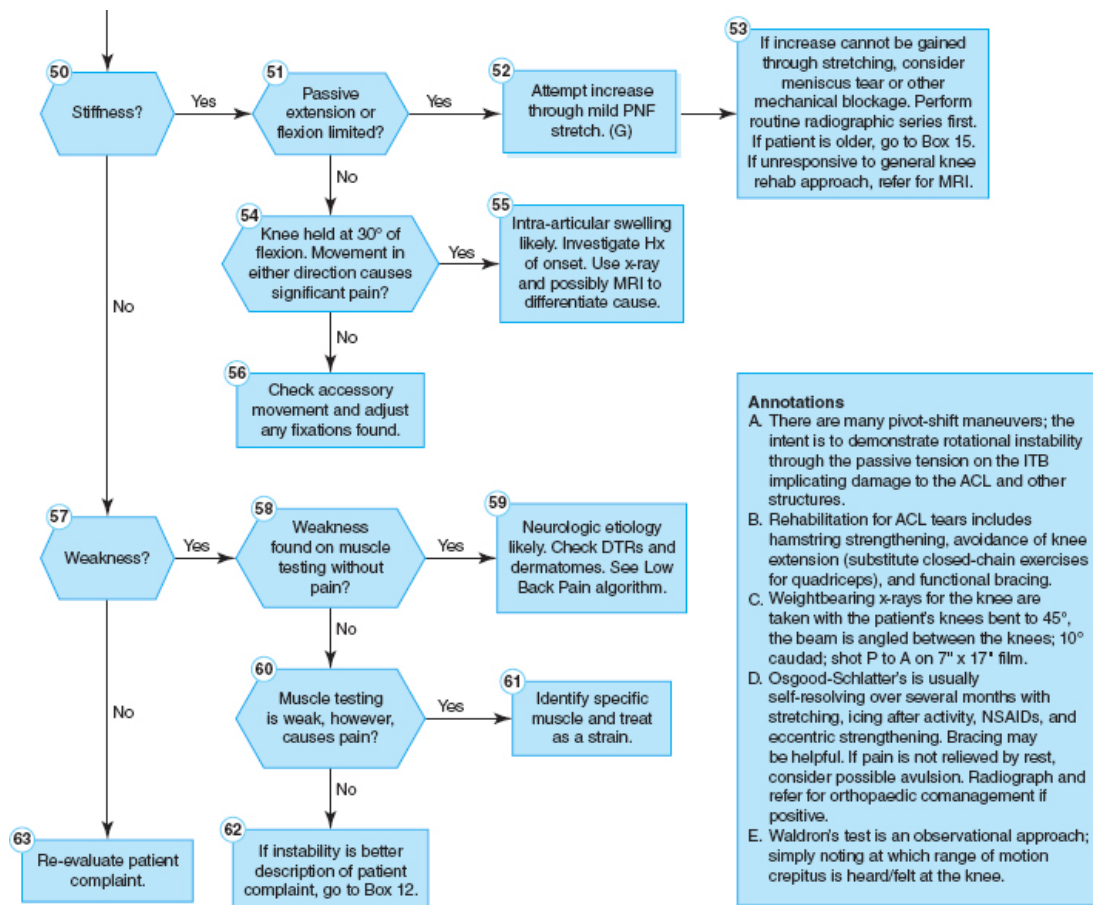

**Figure 12-12** Traumatic Knee Pain—Algorithm

**Figure 12-13** Nontraumatic Knee Pain—Algorithm

## Selected Disorders of the Knee

A summary of most of the disorders discussed on the following pages is presented in [Table 12-7](#).

**Table 12-7** Summary of Knee Disorders

Disorder	Signs and Symptoms	Positive Tests	Treatment	Avoidance
Patellofemoral arthralgia and chondromalacia patellae	Peripatellar pain Movie sign Painful crepitus	Clarke's Waldron's Retinacular test VMO Coordination test Modified Ober's	Correct pronation Strengthen VMO Stretch lateral structures (ITB) Brace/tape for stability	Flexion/extension through crepitus range Low-seat position for bicycling
ITB syndrome	Lateral knee pain at insertion or more commonly lateral epicondyle at 30° flexion	Modified Ober's Noble's	Stretch ITB Correct pronation Rotational adjustment of knee	Downhill running Side-posture adjusting on same side
Popliteus tendinitis	Lateral knee pain with tenderness behind LCL	Resisted internal rotation Pain increased by weight-bearing at 30°; internal rotation of femur	Isometric internal rotation exercises Correct pronation Cross-friction of tendon in front of or behind LCL	Downhill walking or running
Osgood-Schlatter disease	Tender and/or enlarged tibial tuberosity Tight quadriceps	Resisted extension increases pain	Stretch quadriceps Bracing Icing after activity Eccentric quadriceps training	Excessive jumping or running
Bursitis	Localized swelling/tenderness	Compressive maneuvers	Ice Pulsed ultrasound	Pressure Direct trauma Overuse
Superior tibial fibular subluxation	Lateral knee pain with instability History of ankle injury (sometimes)	Instability at 30° full weight-bearing	Fibular head adjustment (support or crutches may be needed for 1 or 2 days post-adjustment)	Excessive hamstring exercises
ACL tear	Pop at time of injury Immediate swelling Gradual instability	Lachman's Drawer Pivot shift	Strengthen hamstrings Functional bracing Proprioceptive training Surgery (often needed for active individuals)	Knee extension exercises
MCL tear	Ligament tenderness Possible sense of instability	Stability testing at 0° or 30°	General strengthening Hinged brace for several weeks	Knee extension from 60° to full extension
Meniscus tear	Joint line tenderness Swelling Locking Giving way	McMurray's Apley's MRI	Acute pain relief Adjust with distraction Refer if signs/symptoms continue	Squatting and rotation stress
Osteochondritis dissecans	Anterior knee pain Possible locking	Wilson's test Tunnel view radiograph	Surgery if loose fragment	Manipulation

## TRAUMATIC

### Anterior Cruciate Ligament Tears

## Classic Presentation

Patients present in either an acute or a chronic phase. In an acute presentation, the patient will report a sudden onset of knee pain following either a hyperextension maneuver or a contact injury with the

knee being hit from the side. He or she may remember a “pop” heard at the time of injury. Joint swelling appears quickly. The patient is unable to bear weight.

In the chronic presentation, the patient will have a past history of the above presentation with a follow-up history of gradual resolution of swelling and pain. The presenting complaint is usually more one of instability rather than pain. There may also be reported occurrences of nontraumatic joint line swelling.

## Cause

ACL damage can be isolated (often a noncontact injury) usually due to hyperextension and/or sudden contraction of the quadriceps as occurs with sudden stopping or cutting. In a recent study, electromyography and knee flexion analysis were performed for cutting, stopping, and landing.<sup>56</sup> The maximum quadriceps contraction was 161% of maximum voluntary contraction (MVC) occurring just before heel strike and peaking in mid-eccentric motion. At foot strike, the average angle of knee flexion was only 22°. Hamstring activity (protective) was very low—as low as 14%. The combination of knee angle, high quadriceps activity and low protective hamstring activity may indicate why these maneuvers are commonly involved with isolated ACL tears. Contact injury with a rotary component is more likely to damage the ACL and other structures such as the menisci or MCL. When the ACL tears, it usually occurs in the midsubstance of the ligament. Because of the paralleling vascular supply, vascular rupture often occurs, leading to a quickly developing joint swelling that is tense and painful.

## Evaluation

In an acute setting, the most helpful indicators are historical, including the mechanisms described above plus immediate swelling, and a “pop” heard at the time of injury. Evaluation in the acute setting is with Lachman’s test.<sup>57</sup> The test is applied by stabilizing the distal femur while the examiner attempts to pull the proximal tibia forward with the knee held at 10° to 20° of flexion (Figure 12-4). In more chronic settings, the anterior drawer test may be used. It is the same approach of pulling the tibia forward; however, the hip is flexed to 45°, knee at 90° (Figure 12-5). The disadvantage of this test is that contracted or spasmed hamstrings are in a biomechanically advantaged position, resisting the examiner’s attempt at forward displacement of the tibia. It is probably not possible to detect partial tears clinically with these tests.<sup>58</sup> If multiple tissue damage is suspected, the examiner uses a rotary test, “pivot shift” approach (Figure 12-6). There are many variations, but each relies on the passive tension of the ITB to pull the tibia forward when approaching extension, and to pull it back into neutral as more flexion is acquired.<sup>8</sup> In general, the examiner applies a valgus force at the fibular head with rotation at the tibia while flexing and extending the knee, attempting to detect not only anterior-to-posterior movement but also rotation of the tibia. Radiographs may demonstrate a small fracture referred to as the lateral capsular sign at the lateral tibial plateau (Segond’s fracture). Also, tibial spine fractures (seen on a tunnel view) and the lateral notch sign (lateral femoral compression fracture seen on the lateral view) are indirect indicators of ACL rupture. Articular cartilage damage is also quite common with ACL tears. MRI is useful in determining the integrity of the ACL.

## Management

Treatment of ACL tears is dependent on several factors.

1. Isolated tears are more responsive to conservative care than complicated tears.
2. Complicated tears (acute rotary instability) deserve orthopaedic consult with possible surgical consequences.
3. Age- and activity-related criteria are used to determine need and quality of stability.

Conservative treatment should be reserved for chronic ACL deficiency (in particular, in the older, less athletic individual) and acute tears with resolved swelling. Treatment is directed at substituting other structures for the laxity created by the loss of the ACL.

Attempting to develop a clinical decision approach regarding surgical management, authors in one study<sup>59</sup> reached several suggestions.

1. Measures of anterior tibiofemoral laxity, while indicative of ACL rupture, cannot be used to predict degree of dysfunction resulting from an ACL rupture.

2. Simple clinical outcome scales based on patient self-report are better indicators of the degree of dysfunction associated with ACL rupture than laxity measures, or scales such as the International Knee Documentation Committee (IKDC) that combine physical examination findings and patient self-report of function.

3. Noncopers can be accurately identified and discriminated from the small, unique subset of copers based on tests early after injury.

Copers were defined as those subjects who were able to return to function at a high level (Level I) at least weekly after injury without complaint of instability. Noncopers are defined as those who are unable to return to their premorbid level of sports play or activity because of repeated episodes of giving way.

A 10-year prospective trial<sup>60</sup> tested the outcome of using a patient management algorithm and screening examination for highly active individuals with ACL injury. A summary follows:

- As seen in many other trials, with highly active individuals the most discriminating factor for needing surgery was concomitant injury of the meniscus in particular, or a Grade II or III collateral ligament injury.
- Patients were classified as copers (good potential for nonsurgical management) or noncopers (surgical candidates) based on concomitant injury, unresolved impairments, and results from a screening examination that relied heavily on function testing (primarily a timed hop test).
- Out of 345 patients who met the study criteria, 198 were classified as noncopers (58%). The remaining 146 were classified as copers (42%).
- Sixty-three of 88 potential copers returned to preinjury activities without surgery (72% of copers and 18% of all subjects).
- At 10-year follow-up, only 25 of the original 63 who returned to full activity did not have surgery (7% of total group of ACL injured patients and 28% of copers).
- By using the strategy developed by the University of Delaware, it appears that about 18% of a group of ACL injured patients might be identified as those not initially needing surgery.
- The primary rehabilitation strategy was a perturbation training approach where a platform is used to challenge an individual by constantly shifting the stability of the platform, thus demanding accommodation by the patient.

If the patient is an athlete, surgery is often the only option.<sup>61</sup> In less active individuals, a stabilization program coupled with bracing may be sufficient (**Table 12-8**). The stabilization program focuses on hamstring strengthening, closed-chain quadriceps exercises (avoiding seated knee extensions), and proprioceptive training with balance devices.<sup>62</sup> It is generally recommended to avoid open kinetic chain (OKC) exercises to avoid displacement of the tibia and further stretching of the joint capsule and soft tissue. However, a recent study<sup>63</sup> indicated that when athletes with ACL tears were randomized into either an OKC exercise group or a closed kinetic chain (CKC) exercise group there was a greater degree of quadriceps strength development in the OKC with no indication of increased translation or laxity. Bracing is usually custom-fitted with a functional brace that should offer some degree of protection against hyperextension and rotational forces. Surgical options include stabilization with local tendons or synthetic materials. In a recent study, researchers tested the Legend brace, a functional brace for ACL deficiency or reconstruction for patients with ACL deficiency.<sup>64</sup> The individuals were tested weight-bearing and non-weight-bearing for anterior-to-posterior (AP) shear, internal/external torque, and varus/valgus moments. The brace effectively diminished AP shear and internal torque; however, it did not reduce strain from external torque or varus/valgus moments.

In another study, college football players in full gear ran a 40-yard dash and a four-cone agility drill wearing braces on both knees or no brace at all.<sup>65</sup> The braces tested were the DonJoy Legend, the Breg Tradition, the OMNI-AKS 101W, the McDavid Knee Guard, and the Air Armor Knee (models 1 and 2). The results were that with the 40-yard dash, the Air Armor 1 and Omni did not affect speed; and the Air Armor 1 and the McDavid Knee Guard showed the least amount of migration. With the four-cone drill, only the Breg caused a slower speed performance compared to the control; the Air Armor 1 and 2 showed the least amount of migration.

Prolotherapy is an alternative treatment that incorporates injection, usually of dextrose, into a joint to assist in healing and perhaps increase stability through a proposed mechanism or increasing growth of normal cells or tissue. In a recent prospective study, researchers evaluated the effect of prolotherapy that consisted of dextrose injection every two to four months over a one- to three-year period.<sup>66</sup> The results indicate that those patients with symptomatic ACL laxity had both clinically and statistically significant improvement in ACL laxity.

**Table 12-8** Conservative Management of ACL Tears

Parameter	Acute Stage	Subacute Stage	Chronic Stage
Criteria for diagnosis of staging	Positive Lachman's with associated intra-articular swelling, pain; unable to bear weight; in select patients, MRI confirmation.	Positive Lachman's with reduced intra-articular swelling; able to bear weight; ROM limited.	Positive Lachman's or drawer sign; minimal or no swelling; knee feels unstable with rotation maneuvers; full or close to full ROM.
Goals	Reduce swelling, control pain, determine patient's functional needs for future planning of management.	Continue to reduce swelling and control pain; increase ROM, and develop basic strength and proprioception.	Strengthen the hamstrings to 80% of well leg quadriceps; proprioceptively train the lower extremity to react to quick changes in ground surfaces.
Concerns	The swelling is a hemarthrosis, making it painful and potentially destructive; associated damage to meniscus, capsule, and fracture must be considered and/or evaluated.	As swelling decreases, more instability than originally suspected may become evident; if unacceptable to patient or indicators of gross laxity, order MRI or refer for orthopaedic consultation.	Patient may become overaggressive in rehabilitation phase and reinjure leg through overcontraction of quadriceps or hyperextension.
Requirements for progression to next stage	Pain and swelling reduced enough to allow 50% ROM; isometric strength evident in available range.	90% ROM available; isotonic contraction through available range if capable of achieving 3 sets of 10 repetitions with minimal weight.	Full ROM; 80% strength of well leg quadriceps; able to perform complex movements such as side stepping and cuts without pain or instability.
Manipulation/mobilization	Contraindicated in the knee at this time.	Mild mobilization may assist in reducing remaining swelling and increase ROM.	Manipulation of any associated foot/ankle, hip, pelvic, or lumbar fixations; mild mobilization to the knee.
Modalities	Ice, elevation, TENS, or high-volt galvanic (80–120 Hz/20 min 3 times daily).	Ice and high-volt galvanic (1–150 Hz/20 min/day).	None needed; however, ice after activity if mild swelling still occurs.
External brace, support, etc.	Immobilization should be kept to a minimum; a long cylindrical knee immobilization device may be helpful for up to 5 days.	Protective hinge-brace allowing ROM with an extension block.	Functional knee brace is needed when performing sports activities (includes stabilization in rotation, anteroposterior glide, protection from hyperextension and valgus forces).
ROM/flexibility	Passive ROM within available range; elevation when possible.	Gradual increase in ROM with postisometric and mild PNF techniques.	Maintain flexibility of quadriceps, hamstrings, and triceps surae groups.
Open-chain exercise	Isometrics within available range.	Isotonics within available range performed as straight-leg exercises first; bicycle riding okay if well leg is used for pedaling (bad leg along for the ride); avoid high seat position.	Progressive strengthening using DAPRE or PRE approach.
Closed-chain exercise	None.	Mild quarter squats with weight on both feet with brace worn.	Three-quarter squats with resistance from weight or elastic tubing; leg presses also good.
Proprioceptive training	Electrical stimulation at quadriceps and hamstrings with minimal contraction.	Seated wobble board training; begin mild PNF diagonal training; PNF rhythmic stabilization at 30° for hamstrings.	BAPS or wobble board training; balance jumps on minitrampoline; train with full-resistance PNF diagonal patterns.
Associated biomechanical items	Avoid hyperextension or active extension through the last 60°.	Avoid hyperextension.	Continue to avoid hyperextension on bicycle; avoid knee extension machines through the last 60°.
Lifestyle/activity modifications	No weight-bearing, bed rest for 3–5 days with gradual attempts at partial weight-bearing with crutches.	Use crutches for any stair climbing; avoid activities that cause extension of the knee, especially while standing.	Use the functional brace with sporting activities.

Key: TENS, transcutaneous electrical nerve stimulation; BAPS, biomechanical ankle platform system (Medipedic [Jackson, Michigan]).

In a recent study, researchers compared three groups of patients over a period of about one year who had received surgery for their ACL deficient knees.<sup>67</sup> These groups were: Group 1–bone-patellar tendon–bone graft, Group 2–semitendinosus and gracilis graft with iliotibial band augmentation, and Group 3–semitendinosus and gracilis only. Outcomes were based on a subjective survey and testing

with a KT-1000. Reconstruction with a semitendinosus and gracilis or a patellar graft yielded similar subjective results. The patellar autograph gave better objective results (stability measured by the KT-1000). There was no benefit to the addition of the ITB tenodesis. Previous studies have indicated that AP translation of the knee increases after 30 minutes of running. In one study, researchers evaluated and compared normal knees, ACL deficient knees, and reconstructed ACL ligament knees after exercise.<sup>68</sup> All demonstrated increased laxity using a single-examiner testing with a KT-1000. The normal knee demonstrated a mean of 0.75 mm; the ACL-deficient knee demonstrated a mean of 0.62 mm; and the reconstructed knee demonstrated a mean of only 0.25 mm.

Damage to the articular surface appears to lead to degenerative osteoarthritis and, with time, can lead to full knee replacements. ACL tears have been shown to cause chondral lesions. Pain, catching, and swelling have been noted with these lesions in those patients participating in impact loading activities. In one study,<sup>69</sup> researchers looking at 31,516 arthroscopies provided by 136 surgeons from June 1991–October 1995, 63% demonstrated chondral defects. These defects were 41% Grade III (partial thickness involvement greater than 50% of the depth of cartilage) and 19.2% Grade IV (full thickness lesions, down to the bone). The average age was 43 years. While this procedure appears to be promising, ongoing research and long-term follow-up is necessary before final conclusions can be reached.

Indications for autologous chondrocyte implantation (ACI) are focal full-thickness chondral defects of the femoral condyles, trochlea, and osteochondral defects (OCD). OCD of the patella, tibia, and multiple defects are relative indications for the procedure. Contraindications include inflammatory arthritis, moderate-to-severe degenerative joint disease, and osteoarthritis. Preventing a symptomatic cartilage defect from progressing to advanced degenerative arthritis and providing long-term relief while allowing patients to return to physical activities is the goal when considering autologous chondrocyte replacement (ACR). A recent review<sup>29</sup> concluded that there is insufficient evidence that ACR is cost effective compared with two other approaches that include microfracture or mosaicplasty.

## Posterior Cruciate Injury

### Classic Presentation

A young athlete complains of knee pain following a blow to the front of his tibia with the knee in a flexed position. Although the swelling was minimal, he noticed discoloration down the back of his lower leg after a couple of days.

### Cause

A posterior cruciate tear is less common than an ACL tear. It is usually caused by an anterior blow to the tibia with the knee in a flexed position or by forced hyperflexion. The incidence of PCL injury is between 1% to 44% of acute knee injuries.<sup>22</sup> This large variation in reported incidence is due to the setting (e.g., motor vehicle versus sports or other injury). It is likely that PCL injury occurs more commonly in contact sports.

### Evaluation

Swelling is usually less severe due to rupture of the capsule with drainage down the fascial plain of the lower leg. In many cases this will, over days, lead to discoloration of the back of the calf. Testing should begin with observation with the patient supine and the knee flexed to 90°. Depression of the tibial tubercle compared with the healthy leg is a common finding. As mentioned above, damage to the cruciates may occur in isolation, or with other structures. When there is isolated damage, straight instability may be evident on stress testing. The standard test for the PCL is the posterior drawer test. The patient set-up is the same as for the anterior drawer test with the patient supine, hips flexed to 45°, and knees flexed to 90°. The examiner first observes for a “sag” sign where the tibial tuberosity of the involved leg is posterior in relationship to the well leg. If so, grasping the calf and pulling toward neutral would be necessary to establish the “start” position. With the patient relaxed, the examiner exerts a posteriorly directed force on the tibia, observing and palpating for posterior displacement. The same standard of measure is used as for the ACL with Grade I being in the range of 5 mm, Grade

II in the range of 6–10 mm, and Grade III greater than 10 mm (1 cm). By using a combination of the drawer test coupled with internal and external rotation (such as the Slocum test used for anterior rotary instability), the examiner may detect the posterior instability that has a rotary component. With an internal rotation/posterior force, the examiner may detect excessive movement indicative of posteromedial instability. Posterolateral instability is detectable with an external rotation/posterior force coupling. This test may be performed in either the supine or seated position. Another valuable test is the dynamic posterior shift test. The patient's hip is flexed to almost 90° and maintained in this position while the examiner passively extends the knee. Gravity, plus the tightening effect of the hamstrings, will cause the tibia to subluxate posteriorly in knees with posterior laxity. Continuing to extend the knee to near full extension, the knee will suddenly jerk, or clunk, into reduction. The patient may feel a reproduction of the instability sensation during the maneuver. Finally, a simple active test is to have the patient sit with the knees off the end of the table. The examiner resists knee flexion and observes for posterior movement at the tibia.

## Management

It appears that many individuals with PCL damage are able to continue participating in sports. Rehabilitation focuses on strengthening the quadriceps with initial de-emphasis on the hamstrings. Surgical repair is usually not as successful as for ACL injury and normally has some degree of residual laxity.

Both a prospective study and a more recent study in 2002<sup>70, 71</sup> followed 133 patients from the time of injury to an average of 5.4 years follow-up. The intention was to determine the natural history of acute, isolated PCL tears over time. Sixty-eight patients returned for long-term follow-up. Evaluation included stability testing and several functional questionnaires including the Noyes knee score, Lysholm score, and Tegner activity score. A summary of their findings follows:

- Patients with greater laxity did not have the worst subjective scores.
- Half of all patients returned to the same sport at the same, or higher, level (regardless of the severity of laxity).
- One-third returned to the same sport at a lower level.
- One-sixth did not return to the same sport.
- There was no change in laxity from time of injury to follow-up.
- There was no relationship between the amount of pain and the degree of laxity.
- There was no radiographic indication of an increase in osteoarthritis.
- There were few associated meniscal tears with isolated PCL tears (probably due to the fact that the injury occurs on an unloaded knee).
- Although there were differences in the athlete's ability to perform tests of quadriceps strength, it was not felt that there was an obvious deficiency in quadriceps strength in patients with PCL injury. Patients with low subjective scores on knee questionnaires may need more focus on quadriceps training.

In the second study, there was no relationship between subjective scoring and degree of instability and no specific indicators of who will deteriorate.

## Meniscus Tears

### Classic Presentation

The patient presents with a complaint of knee pain usually following a rotational injury to the knee. Injury of the knee involving flexion and internal rotation of the tibia may cause traction, pulling the posterior horn of the medial meniscus toward the center of the joint, resulting in a peripheral tear at the attachment site and a longitudinal tear of the meniscus substance. With posterior horn tears, the meniscus will often return to its normal anatomic position with extension of the knee; however, if the tear extends beyond the MCL (creating a bucket-handle tear), a problem with locking may occur when the knee is in a flexed position. The patient noticed that swelling in the knee developed over a number of hours. Since the injury, the patient may have episodes of knee locking wherein he or she experiences significant pain and is unable to move the leg for a few seconds until the involved knee is forcefully extended. Knee swelling or giving way may be the main complaint. A study evaluating MRI findings in asymptomatic patients revealed that 16% of asymptomatic patients have meniscal tears. For patients 45 years or older, the prevalence increased to 36%.<sup>72</sup>

One study attempting to determine the relative value of adding MR to the evaluation of younger patients with suspected meniscal injury had interesting results.<sup>73</sup> The clinical exam and MRI had similar diagnostic performances, questioning the need for MRI in most cases. There was lower sensitivity for patients younger than 12 years of age. Some differences between the clinical exam and MRI were based on specific pathologies:

- Lateral discoid meniscus: CE = 89%, MRI = 39% sensitivity
- Medial meniscus tear: CE = 81%, MRI = 90% sensitivity

Researchers in one study evaluated the relevance of abnormal findings on MRI of the anterior horn of the meniscus and existence of actual pathology.<sup>74</sup> There was a 74% false-positive rate (26% true-positive rate). The authors recommend clinical correlation with MRI findings because some of the false-positive patients were asymptomatic and some had other pathologies.

## Cause

Most meniscus injuries are due to combined compression with rotation at the knee. There are many types of tears; however, they are generally divided into horizontal and vertical tears. Because of the minor blood supply, meniscus tears do not usually bleed much into the joint. The free edge of the tear, however, may cause irritation with a reactant synovial fluid production. The meniscus is often involved when the ACL is torn, in which case the predominance of signs and symptoms will come from the cruciate damage.

### Evaluation

In addition to the history, it is important to challenge the knee with compression and rotation. The two primary tests are McMurray's and Thessaly's.<sup>15, 75</sup> The combination of joint line tenderness with a positive McMurray's or Thessaly's test is a strong indicator of meniscal involvement. The McMurray test begins with forced, passive flexion of the knee coupled with rotation as the examiner palpates the joint line for popping (clunking) and pain ([Figure 12-7](#)). If negative, the knee is passively extended with combined forces of internal or external rotation coupled with varus and valgus forces. Thessaly's test involves the patient weight-bearing on the involved foot and rotating on the knee to elicit pain, joint line discomfort, or locking or catching. ([Figure 12-8](#)). Apley's compression test is performed with the patient prone. An axial force is applied through the tibia to the knee as it is passively rotated. This is performed in all degrees of flexion and extension. A lateral meniscus test called the dynamic test may also be useful ([Figure 12-9](#)). Further evaluation with MRI may be helpful in determining the type and extent of tear and assisting in the decision whether or not to treat surgically.

## Management

There are a number of tears that can be treated conservatively while others may require surgical repair. Radial type tears seem less easily reparable, although some complete tears do warrant attempts at repair. Radial tears in the inner one-third (nonvascular zone) of less than 5 mm may not heal but can be left alone. Healing of chronic bucket-handle tears requiring partial meniscectomy are unlikely to occur often, while acute bucket-handle tears seem to respond better to repair. Radial tears in the posterior horn seem to heal better than those occurring in the middle portion due to greater vascularity.

Longitudinal (vertical) tears in the periphery are most amenable to repair, and it has been stated that stable tears less than 1 cm in length can be left alone. Stable tears are defined as:

- Those in which the central portion cannot be displaced more than 3 mm.
- Longitudinal tears that are stable in the peripheral two-thirds can generally be left alone, especially if they do not exceed 5 mm.
- Tears that are partial thickness tears can be left alone if they do not exceed 5 mm in length.
- Oblique and horizontal tears show greater difficulty healing and may require surgical intervention. In patients with degenerative menisci or discoid menisci, surgical repair is ill-advised.

Studies<sup>76, 77</sup> have examined factors that affect healing for meniscal repair. The authors conclude that the ideal patient profile for meniscal repair is a patient younger than 30 years of age who has a tear within 3 mm of the meniscosynovial junction. The injury should be repaired relatively soon and in conjunction with an ACL reconstruction.

A “conservative” rehabilitation protocol demonstrated a higher rate of complete healing. This consisted of protected weight-bearing (crutches with partial touching of the ground) and protected range of motion from 20° to 90° for the first six weeks.

Given the concern of osteoarthritis in patients treated with partial meniscectomy, one review of the literature investigated the likelihood of osteoarthritic progression.<sup>78</sup> Osteoarthritis progressed more often after medial partial meniscectomy in patients older than 40 years of age. For those with medial meniscectomy the best radiographic results were in patients with valgus knees (compared to varus).

Although chiropractors do not perform surgery, we are often asked whether surgery should be considered for meniscus injury and what type of surgery is best. One study<sup>79</sup> helps define some differences between two common arthroscopic approaches to meniscus repair. It is well known that total meniscectomy leads to early degenerative changes in the knee. Unfortunately, even partial meniscectomy will often lead to advanced degenerative changes. Therefore, when possible, meniscal repair is recommended. Unfortunately, healing rates are reported between 50% and 89%. The two common approaches used are the outside-in and the inside-out techniques. The advantage of the inside-out technique is that it allows for more consistent suture placement perpendicular to the tear. However, it requires a larger incision and more risk of neurovascular damage. The outside-in technique reduces this risk and does not require a large incision; unfortunately, it can address only anterior and middle-third tears.<sup>80</sup> This is due mainly to the anterior placement of the needles. This study confirmed that posterior horn tears of the medial meniscus did not heal well, if at all, with the outside-in technique. The authors recommend the outside-in technique for all lateral meniscus tears, and for anterior and middle tears of the medial meniscus. The inside-out technique should be reserved for posterior tears of the medial meniscus. A newer technique, an “all-inside” repair device, has not demonstrated a higher success rate, with greater than one-third failure rate reported.<sup>81</sup>

Vertical, stable tears in the peripheral meniscus often will heal, especially in the younger patient.<sup>82</sup> Most other tears will usually progress to recurrent bouts of swelling and pain with decreasing asymptomatic periods. Arthroscopic repair or partial meniscectomy is the most common surgical approach with isolated meniscal damage. In the 1980s, patients were entered into a long-term study of meniscal allograft transplantation with ACL reconstruction.<sup>83</sup> Two types of allografts were used: lyophilized and deep-frozen. At almost 15 years (and previously after 3 years) patients were reevaluated with knee questionnaires (Lysholm), radiographs, MRI, and in some cases arthroscopy. The deep-frozen were far more successful and served the function of a real meniscus compared with the lyophilized. The latter carries an increased risk of early degenerative changes in the knee.<sup>84</sup> Chiropractic manipulation may be helpful in reducing meniscus symptoms. Whether it affects the long-term course of meniscus tears remains to be seen. Manual reduction of a meniscus lock is also an important management tool.

## **Medial Collateral Ligament Tear**

### **Classic Presentation**

When the tear is second- or third-degree, the patient will report a history of contact or noncontact injury that forced the knee into valgus. There is often sharp medial pain with associated swelling at the time of injury. With first-degree tears, the patient frequently will have no history of trauma; however, he or she will report a history of an overuse activity with more mild to moderate pain at the medial knee.

### **Cause**

Either traumatic outside-to-inside forces (valgus stress) will lead to partial or total disruption of the MCL fibers or chronic strain through valgus-loading biomechanical factors (e.g., pronation) will lead to chronic stress resulting in a first-degree sprain.

### **Evaluation**

With trauma, it is important to test for MCL integrity. The examiner applies a valgus force to the extended knee. If there is significant opening (compared with the opposite, well leg), a third-degree

tear (rupture) of the MCL has occurred in addition to other medial stabilizers such as the meniscus or cruciates. (*Note:* In children a positive finding likely represents epiphyseal damage and warrants stress radiography.) If the test is negative for instability in extension, the patient is evaluated in 20° to 30° of flexion (with the hip stabilized to prevent rotation). If the knee opens in this position without an end-feel, an isolated third-degree tear has occurred. If there is opening with a definite end-point (compared with the opposite side) a second-degree tear is likely. If there is no instability but the test produces medial joint pain, a first-degree sprain or pes anserinus tendinitis is possible. Adding an active contraction into knee flexion or medial rotation may cause pain with a pes anserinus strain.

## Management

Third-degree sprains with associated meniscal or cruciate involvement should be referred for orthopaedic surgical management. Isolated third-degree tears are occasionally managed with two to three weeks of restricted bracing followed by gradual weight-bearing and rehabilitation.<sup>85</sup> Second-degree tears are managed with two weeks of hinge-cast immobilization followed by rehabilitation. First-degree tears involve correcting any biomechanical predispositions such as orthotics for pronation, modification of sporting or recreational activity, and strengthening of the medial and lateral stabilizers. In an animal study by Warden et al.<sup>86</sup> standard low-intensity pulsed ultrasound was compared to pulsed ultrasound delivered NSAID (celecoxib; COX-2 inhibitor) in knee ligament healing. At two weeks, those treated with the standard pulsed ultrasound were about 30% stronger, stiffer, and about 50% more able to absorb energy before failure. Those treated with the NSAID could absorb about 33% less energy than those in the standardized group. However, there were no difference between groups after 4 and 12 weeks. The authors conclude that low-intensity pulsed ultrasound accelerated but did not improve healing, and that the NSAID treatment caused a delay but did not affect healing over time. Their clinical concern is that there might be a window of time for patients treated with pulsed ultrasound delivering an NSAID where re-injury is more likely to occur.

There is some evidence that conventional therapeutic ultrasound may be beneficial in accelerating fracture repair.<sup>87</sup> Animal studies have produced some interesting results. Although at 25 days after active treatment with ultrasound did not demonstrate any benefit over inactive ultrasound (control group), at 40 days there was a demonstrated benefit compared to those not treated with continuous ultrasound: a 17% increase in bone mineral content at the fracture site in those treated with the active ultrasound. The ultrasound treated group had an 81% greater mechanical strength when compared to the nontreatment group.

## NONTRAUMATIC

### Patellofemoral Arthralgia and Chondromalacia

## Classic Presentation

The patient complains of anterior knee pain. The pain is worse with going up and down steps and sitting for long periods of time. There is often associated crepitus and pain going through any squatting maneuver.

## Cause

Patellofemoral arthralgia is thought to be primarily a soft tissue disorder associated with the consequences of a patellar tracking disorder. Researchers in a two-year prospective study evaluated 282 athletes, 24 of whom developed anterior knee pain.<sup>88</sup>

Anthropometric measurements, functional tests, EMG measure of reaction time, and mobility of the patella were measured as a baseline. For those who developed anterior pain, there were only four possible predictors:

1. A slowed vastus medialis/lateralis response time
2. A decrease in explosive strength
3. A shortened quadriceps
4. A hypermobile patella

Stress on stabilizing structures such as the VMO and medial or lateral retinaculum may be the primary cause. Other possible involvement occurs with pinching or irritation of the infrapatellar fat pad. Chondromalacia patellae is due to degeneration of the hyaline cartilage on the back surface of the patella. A gradual deterioration occurs, often related to maltracking or instability of the patella. Underlying predispositions appear to be an increased Q angle, underdevelopment of the femoral condyles or the patella, patella alta (high riding), and, more functionally, weak medial stabilizers (VMO) and tight lateral structures such as the vastus lateralis and ITB.

## Evaluation

Waldron's test is performed by having the examiner listen to and feel the patella as the patient goes through a squatting maneuver. If pain and crepitus are felt during a specific range, patellar involvement is likely. If the pain is felt only at the bottom of the squat, it is more likely to be due to meniscal pathology. The patellar inhibition test attempts to hold the patella down stationary with the knee at 10° to 15° extension while the patient contracts the quadriceps. Pain with grinding is indicative of chondromalacia patella. Other tests include the VMO coordination test, which tests the ability of the VMO to stabilize the patella through the last 15° of knee extension; Ober's test, designed to stretch the leg into adduction, thereby stretching the ITB (see below); and patellar stability tests. Palpation around the patella may reveal tenderness at the vastus insertions, retinacula, patellar meniscal ligaments, or a plica. Determination of biomechanical factors contributing to tracking problems includes measurement of the Q angle, checking for femoral anteversion and tibial torsion, and checking for pronation. Radiographs to detect patellar tilt incorporate the tangential (i.e., axial) view. They include the sunrise view, Merchant view, and Lauren view. Also, detection of past subluxation or dislocation may be visible on the flexed or extended lateral view.

## Management

The primary goal is to correct maltracking of the patella. This is usually accomplished through general knee-stabilizing exercises coupled with orthotic support ([Table 12-9](#)). Knee bracing at the patellar tendon may relieve some of the acute discomfort. Various patellar braces are available, based primarily on the principle of providing a support for the patella via a hole cut in the brace and/or strapping or internal padding. Taping involves the use of a strapping tape to pull the patella in the desired direction. Although this may not provide the stability intended, it does seem to provide a strong proprioceptive support to proper tracking.<sup>48</sup> McConnell and other taping approaches have been used successfully to decrease pain in patients with patellofemoral knee pain. There is some question though as to the mechanism by which this occurs. Does pain decrease due to mechanical stabilization of the patella or realignment? A study using computed tomography (CT) evaluated sixteen female patients with anterior knee pain and patellofemoral incongruence.<sup>89</sup> An axial CT of knee was taken prior to taping and after taping without quadriceps contraction and then with contraction. Patellar alignment was measured as patellar lateralization and patellar tilt. Although there was initial partial correction with taping, this was lost with quadriceps contraction. These findings indicate that mechanical stabilization or realignment of the patella likely is not the reason why pain relief occurs with this type of taping. It is more likely that a proprioceptive effect occurs as indicated in similar studies of ankle taping. In one study, researchers attempted to determine whether a standardized treatment program would make a difference in pain levels for patients with patellofemoral pain.<sup>90</sup> Seventy-one subjects, 40 years of age or younger with patellofemoral pain of one month or longer, were randomized into two groups. The treatment group received a standardized program of six treatment sessions including quad training, patellofemoral mobilization, patellar taping, and home exercises. The placebo group received sham ultrasound, light application of gel, and placebo taping. The trained group scored significantly higher on measures of pain reduction and disability. Orthotic support may also be needed in pronated patients. Chiropractic manipulations of the foot, ankle, hip, and knee are often used to guarantee a more fully functioning integrated lower extremity. Patients with true chondromalacia who fail a conservative approach for six months should be referred for surgical consultation. The primary surgical procedures include shaving of the posterior patella arthroscopically and a lateral release.

**Table 12-9** Rehabilitation of Patellofemoral Disorders

Parameter	Initial	Intermediate	Advanced
Criteria	Anterior knee pain with going up and down stairs or after sitting for extended periods; positive tests for ITB tightness and/or VMO coordination; possible positive patellar inhibition test or pain/crepitus while squatting.	Anterior knee pain reduced, ITB tightness improved, VMO facilitated.	No pain with activity.
Goals	Reduce pain and any associated retinacular tenderness; evaluate for need of foot orthotic support.	Continue to strengthen VMO; strengthen the knee with general knee-toning exercises; train patient in stair climbing.	Functionally train individual for specific sport activity.
Concerns	Possible chondromalacia, not visible on radiograph; failure to respond is suggestive.	Patient feels better and is not compliant or not able to be compliant with stair and squat restriction.	Overenthusiastic training.
Requirements for progression to next stage	Decrease in pain with ascending/descending steps; VMO strength increasing; ITB more flexible.	Accomplished intermediate stage of knee strengthening; able to ascend/descend steps properly without discomfort; VMO coordination test is negative.	
Manipulation/mobilization	Manipulation/mobilization of the patella into restricted ranges; manipulation of any corresponding lower extremity or lumbopelvic fixations.	Manipulation/mobilization of the patella into restricted ranges; manipulation of any corresponding lower extremity or lumbopelvic fixations.	Manipulation/mobilization of the patella into restricted ranges; manipulation of any corresponding lower extremity or lumbopelvic fixations.
Modalities	Ice, rest, EMS for VMO.	Ice after activity.	None.
External brace, support, etc.	Patellar stabilizing brace or McConnell taping; cast for orthotics if necessary or use temporary trial of medial heel wedge.	Patellar stabilizing brace or McConnell taping.	Wean patient off support.
ROM/flexibility	Stretch quadriceps, hamstrings, ITB, and triceps surae group.	Stretch quadriceps, hamstrings, ITB, and triceps surae group.	Stretch quadriceps, hamstrings, ITB, and triceps surae group.
Open-chain exercise	Extension through last 10° to 15° if tolerable; combine with adduction for better facilitation of VMO.	Extension through full range of pain and crepitus free; for additional support, strengthen abductors, adductors, and flexors using PRE or DAPRE approach.	Isokinetic exercises are added if appropriate.
Closed-chain exercise	Mini squats through crepitus/pain-free range (knee over toe).	Squats continue through an increased crepitus/pain-free range with elastic tubing resistance; perform lateral step-ups; train in single-stair-climbing technique.	Plyometrics may begin if patient passes test with single leg squats and hops.
Proprioceptive training	Begin wobble board (BAPS board) training; have patient cocontract with ramped EMS.	Progress with BAPS training and minitrampoline jumping; PNF diagonal training if patient is athletic.	Sports-specific PNF patterns.
Associated biomechanical items	Avoid low-seat position with bicycling; avoid knee extension or squats in crepitus/pain range.	Avoid low-seat position with bicycling; avoid knee extension or squats in crepitus/pain range.	Avoid low-seat bicycle positions.
Lifestyle/activity modifications	Avoid stair climbing, squatting, and prolonged sitting.	Minimal stair climbing, mini squats; take frequent breaks when having to sit for long periods (e.g., driving movies).	None.

Key: EMS, electrical muscle stimulation; BAPS, biomechanical ankle platform system (Medipedic [Jackson, Michigan]).

*Note:* Any time a chiropractic adjustive technique is used as treatment, an associated subluxation/segmental dysfunction code will be used.

## **Iliotibial Band Syndrome**

### **Classic Presentation**

The patient complains of lateral knee pain that gradually increased over a few days to weeks. The pain seems to be related to running (although sedentary individuals may develop similar pain). Specifically, downhill running seems to be aggravating and pain occurs when extending the leg just before heel strike. Some patients may hear a squeaking sound with flexion-extension of the knee.

### **Cause**

The cause of this syndrome is believed to be a tight ITB that rubs against the lateral epicondyle of the femur at approximately 30° to 40° of knee flexion. Predispositions included hyperpronation and downhill running. Recent evidence suggests the possibility that either a thicker or wider band predisposes patients to this syndrome. In addition, it appears that not all repetitive activity is predisposing. It appears that the longer one performs a repetitive activity with the knee flexed to 30° to 40°, the more likely ITB syndrome will develop. Therefore, downhill running or slower running (jogging) may be the major factor because these activities occur primarily with the knee in the “impingement” range. Running at faster speeds seems less likely a cause.

### **Evaluation**

Palpation for tenderness is targeted to the lateral epicondyle (approximately 3 cm proximal to the lateral joint line). Tenderness may be increased if pressure is applied at the lateral epicondyle while flexing and extending the knee. Tenderness increases in the “painful arc” of 30° to 40°. This is often referred to as Noble’s test. Ober’s test is designed mainly to detect tightness in the muscular attachments into the ITB, including the gluteus maximus and tensor fasciae latae or the band itself (**Figure 12-11**). The patient lies on his or her unaffected side. The examiner moves the bottom limb into flexion to avoid blocking of the following adduction movement. The top leg is then passively lowered over the back of the table to determine available adduction and any associated pain. It is crucial to stabilize the patient’s iliac crest to avoid stretching above the pelvis (isolate the stretch to the ITB). Pain may also be increased by bearing full weight onto the involved side with the knee bent to 30° to 45°. Wang et al.<sup>91</sup> used diagnostic ultrasonography to demonstrate that the modified Ober position is likely more effective at stretching the ITB. In another study Wang et al.<sup>92</sup> evaluated the benefit of using ultrasonography to measure the effects of stretching and found, for the width of the ITB, the examiner reliability was high.

### **Management**

The primary approach is to stretch the ITB and its muscular attachments using a postisometric relaxation technique. Modification of running/jogging activities is necessary during the acute phase. Sudden stretching of the ITB with side-posture adjusting should be avoided for one to two weeks. Because of the pelvic attachments of the ITB, tensor fasciae latae, and gluteus maximus, pelvic manipulation should be considered if consistent with chiropractic evaluation findings.

## **Popliteus Tendinitis**

### **Classic Presentation**

The patient presents with complaints similar to those of the patient with ITB syndrome, with a report of lateral knee pain following downhill running or walking.

## Cause

The popliteus functions as an internal rotator when the knee is non-weight-bearing. In addition, it plays a supportive role for both the posterior PCL and the LCL, preventing forward movement of the femur on the tibia and varus angulation, respectively. Finally, the popliteus acts to pull the posterior lateral meniscus posteriorly during knee flexion. The popliteus muscle takes its origin off the back of the tibia, spiraling around as a tendon under the LCL and inserting into the distal femur just in front of the LCL.

## Evaluation

A history of downhill walking or running is often found. Tenderness is found at the insertion point on the distal femur just anterior to the LCL attachment. Tenderness also may be found directly behind the LCL. Resisted internal rotation may cause pain at the lateral knee. Bearing full weight on the involved side with the knee bent 30° and then internally rotating the femur may increase the discomfort in some patients. Ancillary findings may include hyperpronation on the involved side.

## Management

In addition to ice and rest, cross-friction over the tendon section of the popliteus just in front of and just behind the LCL is often effective. Orthotic support may be needed for the hyperpronated foot and adjusting of any lower extremity fixations.

### Proximal Tibial-Fibular Subluxation

## Classic Presentation

The patient reports the sudden onset of lateral knee pain following a sudden dorsiflexion or plantarflexion injury at the ankle. Another presentation may be a patient who experiences pain less abruptly while performing leg curls (for hamstrings). The patient may have added complaints of instability or pain radiating down the side of the lower leg.

## Cause

The proximal tibial-fibular articulation is a synovial joint. Movement at this joint is influenced by movement at the ankle. When the ankle dorsiflexes, the proximal fibula moves superiorly and rotates outward; with plantarflexion, the fibula moves inferior and rotates inward. Sudden forced movements (in particular dorsiflexion) may force the fibula into a fixed position. With hamstring curls, the biceps femoris may draw the fibular head posteriorly, leading to fixation or, in some patients, chronic hypermobility. Due to the proximity of the peroneal nerve to the fibular head, compression or entrapment may occur with the result of radiating pain down the outside lower leg.

## Evaluation

Joint play assessment in the supine position is accomplished with the knee extended. Palpation at the fibular head should reveal normal movement with passive dorsiflexion and plantarflexion of the ankle. With the knee bent to 90°, the examiner may pull and push the fibular head to determine any sense of fixation or hypermobility.

# Management

The standard approach is to adjust the fibular head. In hypermobile joints, it may be necessary to impose one or two days of nonweight-bearing. Decreasing the amount of resistance on the leg curl may also be beneficial as a preventive approach.

## Patellar Tendinitis (Jumper's Knee)

### Classic Presentation

The patient is often an athlete complaining of anterior knee pain with activities that involve jumping or sprinting.

### Cause

Repetitive stress to the patellar tendon (ligament) is common with jumping and running sports. It appears that this is often an eccentric injury. The prevalence of jumper's knee in elite volleyball players is as high as 40%–50%.<sup>93</sup> Chronic patellar tendinosis may be due to increased spouting of nonvascular, sensory, substance P-positive nerve fibers, and a decrease in vascular sympathetic nerve fibers.<sup>94</sup>

### Evaluation

Pain is felt at the patellar tendon or at the attachments to the patella or tibial tuberosity. Resisted extension starting with the knee bent beyond 90° usually will increase pain at the tendon. Researchers, using diagnostic ultrasonography, evaluated 58 soccer players' patellar and Achilles tendons pre- and postseason.<sup>95</sup> Those with abnormal findings for the patellar tendon on preseason evaluation had a 17% risk of developing symptoms compared to those without abnormal findings. Computed tomography (CT) and magnetic resonance imaging (MRI) are also helpful in diagnosing this condition.

## Management

The mainstays of treatment are rest, ice, and stretch. After acute symptoms have been resolved, gradual eccentric training (avoidance of plyometrics) should be initiated. Patellar tendinosis can be a very difficult condition to deal with given that it occurs in athletes who are high performers. Rest or major modification to activity is often a difficult prescription. As a result, those who try to maintain their level may find themselves in a surgical scenario. One study<sup>96</sup> grouped patients according to a classification system similar to that used by Ferretti et al.<sup>97</sup> and Lian et al.<sup>98</sup>

Stage I designates those individuals who have pain only with activity and have no apparent functional impairment. Stage II designates those with discomfort with activity and after activity, although the individual can still perform at a satisfactory level. Stage III designates those individuals who have pain with activity and pain after activity is more prolonged. Stage III individuals cannot perform at a satisfactory level due to the pain. There were a total of 42 athletes; all were managed with NSAIDs, physical therapy, and exercise. Exercise was initiated with isometric quadriceps contractions and stretching of the quads, hamstrings, and adductors/abductors of the hip. There was also a focus on eccentric training of the quadriceps. At six months, 33 out of the 42 were asymptomatic and able to return to sports. Nine Stage III patients required surgery. At a mean follow-up of 4.8 years, all patients were doing well. Those with Stage II involvement fared better than those with Stage III. This may indicate that the earlier the athlete is managed in the course of involvement based on symptoms, the better the outcome. Shockwave treatment for tendon and fascial problems has gained momentum. A long-term follow-up by Vulpiani et al.<sup>99</sup> indicated that at two-year follow-up, satisfactory results were found with the majority of participants (specifically performing athletes), with

an average return-to-sport time of about six weeks. The protocol involved an average of four sessions at a 2/7-day intervals. Impulses were between 1,500–2,500 with energy varying between 0.08 and 0.44 mJ/mm<sup>2</sup>.

A Cho-Pat brace may provide some relief of symptoms, especially in the early stages. Cross-friction massage, active release technique, and Graston technique may also be beneficial alternative conservative treatments. Other conservative forms of treatment recommended include eccentric exercise, decline squat, therapeutic ultrasonography and iontophoresis. Surgical repair should only be performed in the Stage III athlete in which periods of conservative care have failed, and in Stage IV with complete rupture.

Another approach for tendinosis that is not responsive to eccentric training is sclerosing of neovessels that develop in the involved area of the tendon. Research thus far indicates promise in the short term.<sup>100</sup>

Surgery should be reserved for recalcitrant cases. Conservative approaches that have demonstrated some value in the literature include eccentric training and extracorporeal shockwave therapy. In one small study,<sup>101</sup> concentric training versus eccentric training was compared in active athletes with symptoms of patellar tendinosis. At 32-month follow-up, those in the eccentric group were satisfied with their results. The protocol consisted of a 12-week daily program that included a six-week cessation of all sporting activity. Eccentric training was on a decline board. All patients in the concentric trained group proceeded to either surgery or sclerosing injections. Another study<sup>102</sup> demonstrating improvement using a 25° decline board over a standard step protocol found that at a 12-month follow-up, although both groups improved, the decline-board group had greater clinical gains. The decline eccentric protocol required a 12-week intervention performed daily. The group performed single-leg squats on a 25° decline board utilizing a typical Curwin Stanish<sup>103</sup> protocol of three sets, 10–15 repetition approach with moderate pain occurring in the last set. The downward, or eccentric, component was performed using the symptomatic leg with the upward, or concentric, component performed by the well leg.

Other approaches include shockwave therapy and injection of platelet-rich plasma (PRP) (see [Chapter 1](#) for a broader discussion). Two recent studies indicated that both had value in the management of chronic patellar tendinitis, but PRP is still controversial, being banned in some countries and the International Olympic Committee at the time of this publication.<sup>104–106</sup>

## Patellar Dislocation and Subluxation

### Classic Presentation

A young female attempts to cut to the opposite direction while playing soccer. She falls, grabbing her knee. She says that she felt her knee “go out.” There is a large lateral mass (with dislocation).

### Cause

Patellar dislocation is not always due to malalignment. It is possible for the athlete to dislocate the patella by planting the foot in a flexed position while attempting to cut to the opposite direction. A valgus force is then created while the quadriceps is contracting strongly. Complications are common and numerous. Many of the soft tissue stabilizing structures for the patella are torn, such as the medial retinaculum, VMO, or even the quadriceps tendon. Other damage includes articular cartilage damage to the patella or femoral condyle (this often occurs when the patella relocates, hitting the lateral femoral condyle). Osteochondral fractures may also occur in the same setting, particularly in younger athletes.

Patellar dislocation is a common event in sports. Over the years a profile of a young, overweight, sedentary, adolescent girl as the prime victim has been developed. Researchers in one study<sup>107</sup> evaluated and followed 74 patients with acute lateral patellar dislocation. The results seem to indicate a profile that has some common characteristics but does not fit with the stereotype once assumed. The findings are summarized as follows:

- 69% of patients were under 20 years of age.
- 72% of patients had their dislocation occur with sports; 21% with activities of daily living, and 7% due to a direct blow.
- There was a 50% incidence of patella alta (a high-riding patella).

- All patients demonstrated a lateral hanging patella (patella laterally displaced as seen on a tangential view of the patella).
- There were no statistically significant relationships with a history of lower extremity problems as an infant or child, and no apparent relationship to a family history of dislocation.
- At 6 months, 68% of patients noted limitation with strenuous activities.

## Evaluation

Historical description by the patient normally reveals that the patient felt the knee go out of place (or back in place during reduction). Other signs and symptoms are variable depending on the number of damaged structures; however, medial knee pain and swelling are common. If there is sufficient swelling to disguise that the displaced patella and/or reduction has occurred, the examiner may initially miss the diagnosis. Patellar subluxation is similar in presentation and is often impossible to differentiate from spontaneous reduction of a dislocated patella. With spontaneous reduction there is usually an immediate hemarthrosis. Subluxation is common in those who have had dislocation in the past and in those who have damaged patellar restructuring tissues and allowed them to heal elongated. Testing should include the apprehension test first at 30°, then at full extension if negative.

## Management

In the acute setting, the displacement is readily apparent. Reduction is accomplished by carefully extending the knee. If unsuccessful, mild medial directed pressure is added. No other attempts should be made if the above maneuvers do not succeed. In all of the preceding scenarios, whether reduction has occurred or not, the knee should be packed in ice, splinted, and the patient sent for radiographs and treatment.

Treatment involves immobilization in a cylinder cast for four to six weeks. Patellar stabilization braces should be worn during activity. The vastus medialis obliques should be facilitated and strengthened.

## Osgood-Schlatter Disease

### Classic Presentation

The patient is often a young athlete complaining of pain and swelling at the tibial tuberosity.

### Cause

The tibial apophysis is susceptible to repetitive stresses. When adolescents are performing demanding activities such as running and jumping, the apophysis may undergo an inflammatory reaction. It is rare for the tendon to avulse the apophysis.

## Evaluation

The characteristic findings of a young athlete with tibial tuberosity pain, tenderness, and swelling are almost pathognomonic. Added testing may include resisted extension in an attempt to increase pain. It is not uncommon to develop Osgood-Schlatter disease bilaterally.

## Management

Rest, ice, modification of the inciting sport activity, and gradual quadriceps stretching are the primary approaches. It is often helpful to use an Osgood-Schlatter brace or taping at the patellar tendon during activity. The general rule of thumb is that if the athlete is able to reduce the discomfort with rest, the

injury will be self-resolving, and further evaluation with a radiograph is not necessary. However, if the athlete is experiencing pain that is unrelieved by rest, radiographs should be taken in an effort to determine whether there is an avulsion. A chiropractic or medical radiologist must review the radiographs because of the subtleties and variations of the apophyses.

## **Tennis Leg**

### **Classic Presentation**

The patient is often a middle-aged athlete playing tennis when she or he feels a sudden pain in the back of the upper calf followed by an inability to walk on the toes. The pain is often described as that of having been shot or hit on the back of the knee.

### **Cause**

Tearing of the musculotendinous junction of the medial head of the gastrocnemius is the most common cause.<sup>108</sup> This occurs when the knee is suddenly extended while the foot is dorsiflexed. Another mechanism may be sudden dorsiflexion of the foot/ankle with the knee already extended.

### **Evaluation**

Tenderness and some swelling are usually evident at the upper medial calf. The patient has increased pain on resisted plantarflexion of the foot or is unable to raise up on the sole and toes of the foot on the involved side.

### **Management**

Management depends on the degree of damage. A full tear may require a long leg cast with the knee in 60° of flexion and the foot in 10° to 15° of plantarflexion for several weeks. More mild injuries can be managed with crutch-supported walking with gradual return to weight-bearing with a temporary heel lift (6 to 12 mm) to take the stretch off the torn muscle. Gradual stretching after one week should progress to mild plantarflexion isometrics progressing to toe raises when tolerated.

## **Osteoarthritis**

### **Classic Presentation**

The patient with osteoarthritis (OA) complains of stiffness and knee pain that is worse with prolonged sitting or walking. She or he is generally older or has a past history of trauma or surgery to the knee. Recurrent bouts of mild swelling and a progressive bowlegged appearance may be accompanying complaints.

### **Cause**

Degeneration of articular cartilage is often secondary to meniscal tearing or degeneration. This occurs with age. Often significant, single trauma events or a past knee surgery (including ACL or meniscal surgeries) predispose the individual to early degeneration.

### **Evaluation**

A varus angulation of the involved knee may be apparent. Palpation may uncover osteophytic development at the joint line. Joint line swelling may also be palpable. Laxity testing with an anterior

drawer maneuver will often demonstrate a loose joint with early OA. Laxity in neutral is due to joint capsular laxity. Tightening on internal rotation indicates an intact ACL. In advanced OA less movement than normal is found on drawer testing. Radiographic evaluation must include a bilateral, PA, weight-bearing view usually taken with a 7 × 17 cassette. The patient faces the bucky with the knees bent 45° and the tube is angled caudad 10° to 15° with the central ray between the knees. Characteristic findings are varying degrees of decreased medial joint space, subchondral cysts, and osteophyte formation.

## Management

One study indicated that at an 11-year follow-up evaluation, most patients did not show significant progression of OA radiographically.<sup>109</sup> Those patients with radiographic evidence of OA and knee pain or OA of the contralateral side had the worse prognosis. Numerous studies<sup>110-113</sup> indicate the value of exercise for long-term management of OA of the knee. However, some studies indicate that the degree of varus/valgus laxity may decrease this strengthening effect.<sup>114</sup> Specifically, it has been found that low-intensity cycling is just as effective as high-intensity cycling for improving function and decreasing pain.<sup>115</sup> Aquatic exercise is a good initial approach that improves strength without the risk of weight-bearing exacerbation.

Three alternative approaches to managing OA of the knee include acupuncture, pulsed electrical stimulation, and prolotherapy (injection of growth factors or growth factor stimulators such as dextrose). All have been evaluated in a randomized trial and were shown to be of benefit.<sup>116-118</sup> A recent study seemed to indicate that those treated with platelet-rich plasma (PRP), one approach to delivering growth factors, demonstrated a slowing of degenerative changes as measured on MRI.<sup>119</sup> More studies are necessary given this is only one small study.

Towheed et al.<sup>120</sup> in a Cochrane review and other publications,<sup>121</sup> emphasize that using the Rotta formulation for glucosamine likely has benefit for osteoarthritis of the knee. However, many studies are of poor quality and five randomized controlled trials failed to demonstrate a positive change in pain, function, and stiffness using the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC). They speculate that either the Rotta product may be more standardized or that there is a difference in the type of glucosamine used. Finally, they remind the clinician that in a study by Clegg et al.,<sup>122</sup> the placebo effect evaluating pharmacotherapeutics with osteoarthritis has shown as high as a 60% positive response rate (this includes medications). Gregory et al.<sup>123</sup> reviewed the literature to date on dietary supplements for osteoarthritis in 2008 and concluded that there was only literature to support glucosamine and chondroitin sulfate. There was also some support for S-adenosylmethionine; however, the high cost and product quality may limit use. Another study reported improvement beyond placebo and also indicated more preservation of joint space radiographically.<sup>124</sup> It appears that bone marrow edema may be a risk factor for structural deterioration with OA of the knee.<sup>125</sup> This may be visualized on MRI.

Knee replacement surgery should be reserved for those unresponsive to a conservative regimen that includes exercise.

Some recent studies have attempted to determine the effectiveness of medical management of knee osteoarthritis. The results tend to question the value of the standard approaches. One study evaluated the effectiveness of corticosteroid injections versus hyaluronic acid injection.<sup>126</sup> There appeared to be no difference between the two groups with regard to pain relief or function at six months. Interestingly there was no control group of patients who were no-treatment or received a sham or placebo treatment. A more recent study using a placebo (saline) seems to confirm the same results; however, it indicated that those patients with radiologically milder disease at baseline may have had less progression of joint space narrowing when treated with hyaluronic acid.<sup>127</sup> Researchers in another study produced results that were somewhat controversial because this was a surgical study that incorporated a placebo of a “sham” surgery for osteoarthritis.<sup>128</sup> Patients were randomly assigned to receive arthroscopic debridement, arthroscopic lavage, or placebo surgery. Those undergoing placebo surgery received simulated debridement without having the arthroscope inserted. The results were that arthroscopic lavage or debridement was no better than placebo after a 24-month period follow-up. As evidenced in past studies, a Cochrane review<sup>129</sup> evaluated the benefit of arthroscopic debridement for knee OA and found that there was no value, especially over the long term.

Many studies have been conducted to determine the host of therapeutic options for osteoarthritis of the knee. A summary of some of these therapies and literature conclusions follows.

- Exercise is an effective management approach to OA of the knee with significant reductions in pain and improvements in function.<sup>130</sup> Specifically, researchers in one study evaluated the type of exercise and its sequence of prescription.<sup>131</sup> Their conclusion was that isotonic exercise was preferable as the initial strengthening approach due to decreased drop-out rate due to an increase in pain that was found with isokinetic exercise. They also conclude that isokinetic should follow an initial isotonic approach to increase joint stability and walking endurance. A meta-analysis, published in the Cochrane Database, concluded that there was no difference between the effect of high-intensity exercise versus low-intensity exercise.<sup>132</sup> When OA of the patellofemoral joint is the primary site of involvement, it appears from the results of one study that only small improvements occur in knee pain scores and quadriceps muscle strength after 10 weeks.<sup>133</sup>
- Taping and bracing may also be effective management approaches. A recent blinded, randomized controlled trial was conducted to evaluate the effectiveness of knee tape.<sup>134</sup> Those who were given therapeutic taping had significant improvement in pain compared to the control tape and no-tape groups. These effects were maintained after three weeks. Another study designed to evaluate the effectiveness of an elastic knee brace produced results that indicate small, short-term beneficial effects with acute exacerbations.<sup>135</sup>
- Use of glucosamine and chondroitin appears to have both an effect on symptoms and structural changes in the knee. The results from a recent meta-analysis indicate that both glucosamine and chondroitin improved both WOMAC scores, and it demonstrated improvements in joint space narrowing.<sup>136</sup>
- Low-level laser therapy is still a controversial approach that has been used for over 10 years. A recent Cochrane meta-analysis reported that because there are different types of lasers (Classes I, II, and III), there was lack of standardized outcome measures and different methods of application, so no conclusions could be drawn.<sup>137</sup> Despite some positive findings, there were no data on the effect of wavelength, treatment duration, dose, and site of application (over nerves or joints). The recommendation was to conduct more controlled studies with these variables in mind.

## Osteochondritis Dissecans (OD)

### Classic Presentation

A 14-year-old male athlete complains of an insidious onset of anterior knee pain that is now causing him to limp. He says that occasionally his knee locks and swells.

### Cause

OD is a defect in osteochondral bone and articular cartilage that usually affects the lateral portion of the medial femoral condyle. It may occur bilaterally in 20% of cases. Probably due to an inadequate or disturbed vascular supply, a divot of bone will separate and in some cases dislodge into the joint. Although mainly seen in young athletic boys, there is a secondary onset that happens in adults. The adult version is more likely to progress to surgical excision.

### Evaluation

Patients will complain of an insidious onset of pain. Later effects are mechanical from the dislodged area (if this occurs) and will include locking and swelling. A clinical test for osteochondritis dissecans (OD) is Wilson's test. Introduced in 1967, Wilson noted that children with OD walked with external rotation. He assumed this was due to condyle impingement with internal rotation that was relieved by external rotation. Based on these observations, he developed a test that was positive when the patient's knee was extended with internal tibial rotation, and somewhere between 90° and 30° pain occurs. The pain is then relieved by external tibial rotation. Until recently, this test was untested. Researchers in a recent study evaluated the clinical significance of Wilson's test comparing positive and negative results for patients with radiographically documented OD.<sup>138</sup> Seventy-five percent of individuals with radiographically positive OD had a negative Wilson's test, calling into question the

value of this testing procedure. The radiographic diagnosis is usually apparent on a tunnel view of the knee.

A similar process in older patients is referred to as spontaneous osteonecrosis (SONC) of the medial tibial plateau. This exclusively senior patient condition has varying outcomes, but most patients progress to significant degenerative disease.<sup>139</sup>

## Management

Rest and protection are the initial approaches. If no healing occurs, surgical excision may be necessary. A study by Jurgensen et al.<sup>140</sup> evaluated the rates of remission of arthroscopically versus nonsurgically treated osteochondritis (as noted on MRI). They found partial or complete remission in 30% of lesions and no change in 63% of lesions managed nonsurgically, while in those treated arthroscopically there was a remission of 37% and no change in 57%.

---

## The Evidence—Knee

### Translation into Practice Summary (TIPS)

The literature on history and examination of the knee is extensive. The literature points clearly to some valuable findings indicating the need for x-ray to determine if fracture is present posttrauma, and for the clinical examination, cruciate ligament injury, and to a lesser degree for meniscus tears and collateral ligament tears. The literature on patellofemoral tracking problems/dysfunction is mixed with good reliability of tests, but the clinical utility has yet to be determined. There is no literature on the history and examination for extensor disorders (e.g., Osgood-Schlatter's) regarding reliability or validity.

### The Literature-Based Clinical Core

- The Ottawa Knee Rule and Philadelphia Rule are good for determining the need for x-ray in detecting knee fractures.
- The American College of Radiology Criteria are a good prediction rule for ruling-in and potentially ruling-out osteoarthritis.
- The anterior-drawer test, pivot shift, and Lachman's are good for ruling in anterior cruciate ligament tears; however, the best test for ruling-out an ACL tear is Lachman's (best under anesthesia).
- Joint line tenderness and McMurray's, and the Thessaly test (although the CIs are wide) are reasonably good at ruling-in or ruling-out meniscus tears.
- The literature for end-feel evaluation (Cyriax approach) indicates poor reliability.
- The moving patellar apprehension test is good at ruling-in and ruling-out patellar instability.
- The combination of findings which include standard tests plus a history of trauma, difficulty bearing weight, and being over the age of 40 years is good at ruling-in but not ruling-out meniscus tears.

- Indicators of potential medial plica such as a palpable plica or medial patellar pain are not sensitive or specific for plica.
- Valgus testing for MCL tears is not good at ruling in or ruling out.
- Patellar alignment evaluation is poor, Q-angle testing is reliable; however, there is no proven clinical value to these findings.

### **The Expert-Opinion-Based Clinical Core**

- A history of popping heard at the time of injury with immediate joint swelling is a strong indicator of an acute anterior cruciate ligament tear.
- Knee trauma with effusion coupled with mechanical signs of catching or locking indicate a meniscus tear.
- Pain and tenderness at the tibial tuberosity with swelling in an adolescent are strong indicators of Osgood-Schlatter's.
- A Clark's or grind test performed at 15° to 20° of knee flexion may help eliminate false positives for chondromalacia.
- Popping and clicking at the hip may introduce false positives into McMurray's and other tests.

## **Appendix 12-2**

# Knee Diagnosis Table

Knee Diagnosis Table					
Diagnosis	Comments	History Findings	Positive Examination Findings	Radiography/Special Studies	Treatment Options
<b>Subluxation or Fixation of:</b> <b>Tibiofemoral Joint</b> <b>Tibiofibular Joint</b> <b>Patellofemoral Joint (functional)</b>	<ul style="list-style-type: none"> <li>Should be used when chiropractic manipulation is used as Tx for any knee problem/Dx.</li> <li>Can be primary Dx if patient is asymptomatic or mildly symptomatic (eg, mild stiffness or pain level &lt; 2/10).</li> <li>Must indicate chiropractic exam findings to support Dx.</li> </ul>	<i>Nonspecific</i>	<i>Palpation</i> —Local tenderness or other signs of subluxation <i>Ortho</i> —None <i>Neuro</i> —None <i>Active ROM</i> —Variable restriction <i>Passive ROM</i> —End-range restriction <i>Motion palpation</i> —Specific articular restriction or symptoms produced on end-range	<ul style="list-style-type: none"> <li>Radiography not required for the diagnosis of subluxation.</li> <li>Radiographic biomechanical analysis may assist in treatment decisions.</li> </ul>	<ul style="list-style-type: none"> <li>Chiropractic adjustive technique.</li> <li>Decisions regarding specifically which technique(s) is/are applied and modifications to the given approach will be directed by the primary Dx and patient's ability to tolerate pre-adjustment stresses.</li> </ul>
<b>Medial Collateral Ligament (MCL) Strain (specify degree)</b> <b>Lateral Collateral Ligament (LCL) Strain (specify degree)</b>	The vast majority of collateral ligament strains are the medial; the lateral is rarely involved.	<i>Mechanism</i> —Overstretch due either to a single acute event (valgus strain for MCL; varus for LCL) or chronic stretch due to biomechanical predisposition or repetition strain (e.g., over-pronation)	<i>Ortho</i> —Stability testing in full extension and at 20°–30° reveals either laxity or pain; instability in extension indicates full rupture; instability with no end-feel at 20°–30° = 3rd degree tear; instability with end-feel = 2nd degree; no instability but pain indicates 1st degree <i>Neuro</i> —None unless full rupture occurs, then variable sensory deficits may occur	<ul style="list-style-type: none"> <li>Radiography recommended to determine fracture or with children/adolescents where a distinction between epiphyseal plate injury at ligament rupture is accomplished through stress radiographs.</li> <li>When chronic, calcific deposition may indicate Pellegrini-Steida syndrome</li> </ul>	<ul style="list-style-type: none"> <li>Refer for surgery if instability is found at extension.</li> <li>Limited orthotic support (taping or brace) based on degree of injury; generally cylinder cast for 2nd degree; taping for 1st degree.</li> <li>Myofascial therapy.</li> <li>Biomechanical advice with regard to sports; possible recommendation of protective brace.</li> <li>Strengthening and preventive exercises.</li> </ul>
<b>Cruciate Ligament Tear</b> <b>Specify Anterior (ACL) or Posterior (PCL)</b>	<ul style="list-style-type: none"> <li>The vast majority of cruciate tears are anterior.</li> <li>Patients may appear with acute injury or chronic complaints of instability.</li> </ul>	<i>Mechanism</i> —ACL tears usually due to hyperextension or forced rotation with foot fixed and hit from outside; PCL tears usually due to hyperflexion or blow to flexed knee (anterior tibia) <i>Symptoms/Signs</i> —Often, pop heard at time of injury followed by immediate tense swelling and eventually a sense of instability	<i>Ortho</i> —Lachman's, drawer sign for straight instability (reverse tests for PCL), rotary stability tests such as pivot shift maneuver for multiple tissue damage In acute phase, testing may not be possible due to swelling	<ul style="list-style-type: none"> <li>Radiography necessary to rule out associated fractures (which are common).</li> <li>MRI may be needed at some point to determine degree of injury and associated injury to other structures such as meniscus.</li> </ul>	<ul style="list-style-type: none"> <li>In acute injury, non-weight-bearing and leg elevation to decrease swelling; if prolonged or if pain is severe, refer for aspiration and/or pain meds.</li> <li>Rehabilitation acceptable for less active or older individuals, focusing on hamstring strengthening; avoidance of leg extension exercises (open chain), substitute squats or leg presses.</li> </ul>
<b>Medial Meniscus Tear</b> <b>Lateral Meniscus Tear</b>	<ul style="list-style-type: none"> <li>Medial meniscus tears are most common and often associated with ACL tears.</li> <li>Generally tears are horizontal (often degenerative) or vertical (single trauma induced).</li> </ul>	<i>Mechanism</i> —Usually due to compression/rotation injury with foot fixed on ground <i>Symptoms/Signs</i> —Complaints of locking and swelling are common <i>Worse with specific ROM</i> —Terminal knee extension and flexion beyond 90° is painful	<i>Palpation</i> —Tenderness found anterior or as far as medial-posterior joint line <i>Ortho</i> —McMurray's and Apley's are primary tests <i>Passive ROM</i> —Flexion and end-range extension are limited and painful	<ul style="list-style-type: none"> <li>Radiography not usually necessary initially except to rule out fracture with acute trauma.</li> <li>Degenerative meniscus tears are indirectly determined through weight-bearing PA views.</li> <li>MRI may be necessary to determine the type and extent of tear and may help in surgical decision making.</li> </ul>	<ul style="list-style-type: none"> <li>If locked, distraction adjusting may be helpful.</li> <li>Limited orthotic support may provide some pain relief.</li> <li>Physiotherapy for pain and swelling control.</li> <li>Herbal recommendations for pain and swelling.</li> <li>If mechanical symptoms become more frequent, referral for surgical repair is recommended.</li> </ul>

Osgood-Schlatter's or Sinding-Larsen	<ul style="list-style-type: none"> <li>• Diagnosis is primarily through observation and palpation.</li> <li>• Remember that this does not represent an avulsion fracture.</li> <li>• Same process may affect distal or proximal pole of patella, called Sinding-Larsen's.</li> </ul>	<p><i>Mechanism</i>—Tension at the tibial tuberosity apophysis leads to inflammation; inciting activities are jumping and sprinting</p>	<p><i>Observation/Palpation</i>—Swelling at the tibial tuberosity with point tenderness (may be bilateral)</p> <p><i>Ortho</i>—Resisted extension increases pain at tibial tuberosity (or patella with Sinding-Larsen's)</p> <p><i>Neuro</i>—None</p>	<ul style="list-style-type: none"> <li>• Radiography may be used, but mainly to rule out other causes such as tumor or fracture (if trauma occurred).</li> <li>• Remember that there is great variation at the apophysis and that radiolucent areas are filled with cartilage (does not represent an avulsion fracture).</li> </ul>	<ul style="list-style-type: none"> <li>• Ice/stretch quads and hams; decrease inciting activity if possible.</li> <li>• Modify activity to decrease stress to tibial tuberosity.</li> <li>• Limited orthotic support with Osgood-Schlatter's brace, Cho-Pat or McConnell taping.</li> <li>• Preventive and strengthening exercises and stretches, including eccentric quad exercises.</li> <li>• Refer if pain is felt at rest in addition to activity (possible impending avulsion).</li> </ul>
Iliotibial Band (ITB) Syndrome	<ul style="list-style-type: none"> <li>• As a pure entity, most common cause of lateral knee pain (nontraumatic).</li> <li>• May also be involved with patellar tracking problems.</li> </ul>	<p><i>Mechanism</i>—Usually due to overuse (e.g., runner) due to a thick ITB (A to P and/or lateral to medial); band rubs lateral epicondyle at about 30°–40° of knee flexion; may be found in sedentary individuals who sit for long periods, functionally shortening ITB</p>	<p><i>Ortho</i>—Compression with Noble's test for pain and stretch with modified Ober's test are often positive</p>	<ul style="list-style-type: none"> <li>• Radiography not recommended.</li> </ul>	<ul style="list-style-type: none"> <li>• Stretch of ITB using post-isometric relaxation approaches.</li> <li>• Correct any suspected biomechanical faults such as overpronation.</li> </ul>
Patellar Tendinitis (Jumper's Knee) Tendinosis is a newer term used to indicate intra-tendinous degeneration due to atrophy (aging, microtrauma, vascular compromise, etc.). This is considered noninflammatory with hypocellularity, variable vascular ingrowth, local necrosis, and/or calcification, with accompanying fiber disorientation.	<ul style="list-style-type: none"> <li>• Found mainly in athletes who sprint or jump as main component of sport.</li> </ul>	<p><i>Mechanism</i>—Primarily due to eccentric strain of patellar tendon with repetitive activities</p>	<p><i>Ortho</i>—Resisted extension causes pain at quadriceps tendon</p> <p><i>Neuro</i>—None</p> <p><i>Active ROM</i>—Jumping aggravates</p>	<ul style="list-style-type: none"> <li>• Radiography not recommended.</li> </ul>	<ul style="list-style-type: none"> <li>• Ice and stretch after activity.</li> <li>• Counterforce brace or taping such as Cho-Pat or McConnell taping.</li> <li>• Preventive and strengthening exercises with focus on eccentric training (avoid plyometrics though).</li> </ul>
Pes Anserine Tendinitis or Bursitis	<ul style="list-style-type: none"> <li>• Often tender area, always check bilaterally.</li> </ul>	<p><i>Mechanism</i>—Either due to a direct blow to the medial proximal tibia or due to chronic stretching such as occurs in a hyperpronated individual</p>	<p><i>Observation/Palpation</i>—Swelling at proximal/medial tibia with associated tenderness</p> <p><i>Ortho</i>—Resisted challenge for gracilis, sartorius, or semitendinosis may increase pain</p>	<ul style="list-style-type: none"> <li>• Radiography not recommended.</li> </ul>	<ul style="list-style-type: none"> <li>• Conservative trial of ice and stretching.</li> <li>• Reduce swelling with pulsed ultrasound or comparable physiotherapy.</li> <li>• Correct any biomechanical contributors with heel lifts, medial heel wedges, or taping.</li> </ul>
Chondromalacia Patella Patellofemoral Arthralgia (PFA)	<ul style="list-style-type: none"> <li>• Chondromalacia must be distinguished from patellofemoral arthralgia (PFA): chondromalacia represents actual patellar pathology, whereas PFA represents a soft tissue of pain such as occurs with medial retinacular or fat pad irritation.</li> </ul>	<p><i>Mechanism</i>—Patellar maltracking causes damage to posterior patellar cartilage</p> <p><i>Signs/symptoms</i>—Patient complains of pain on ascending/descending steps or sitting for long periods (movie sign)</p>	<p><i>Ortho</i>—Pain with crepitus going through a squat; may be indirect indicators, such as an increased Q angle or other indicators of maltracking</p>	<ul style="list-style-type: none"> <li>• Radiography not usually indicated; there are many investigational approaches to determine patellar tracking using modified tangential views; not generally necessary.</li> <li>• Definitive Dx requires CT or MRI.</li> </ul>	<ul style="list-style-type: none"> <li>• Conservative trial of ice and quad, ham, and tibialis anterior stretching.</li> <li>• Bracing or taping may help temporarily, while patellar stability and tracking are improved through training and strengthening.</li> <li>• Correct any biomechanical contributors with heel lifts, medial heel wedges, or taping.</li> </ul>

Diagnosis	Comments	History Findings	Positive Examination Findings	Radiography/Special Studies	Treatment Options
Myofascitis	<ul style="list-style-type: none"> <li>Used when specific trigger points are identified on physical examination.</li> <li>Also may be used if a strain is not evident from the history but there are indicators of muscle tenderness, stiffness, or pain.</li> </ul>	<p><i>Onset:</i> Nonspecific regarding onset</p> <p><i>Symptoms:</i> Patient usually complains of pain, aching, and/or tenderness in specific muscle or tendon areas that may radiate pain in non-dermatomal pattern</p>	<ul style="list-style-type: none"> <li>Trigger points are evident as localized tenderness in a muscle that corresponds to traditional (Travell/Simons) trigger point charts; these points may be local or refer pain when compressed</li> </ul>	<ul style="list-style-type: none"> <li>Not required or recommended.</li> </ul>	<ul style="list-style-type: none"> <li>Myofascial approaches such as myofascial stripping, trigger point massage, or spray and stretch approaches are the standard.</li> <li>Home stretching and modification of activity suggestions.</li> </ul>
Laxity Hypermobility		<p>A history of a single event, traumatic injury to the joint is not found; however, overuse (microtrauma) or generalized inherent looseness is evident</p>	<ul style="list-style-type: none"> <li>Capsular or ligament testing reveals "looseness" that falls within the physiologic range of normal</li> </ul>	<ul style="list-style-type: none"> <li>Not usually recommended unless when differentiating pathological laxity from congenital or overuse acquisition.</li> </ul>	<ul style="list-style-type: none"> <li>Strengthening program.</li> <li>Bracing or functional taping during rehabilitation or during strenuous activities.</li> </ul>

# CHAPTER 13

## Lower Leg Complaints

### Context

Lower leg disorders range from benign to life threatening. A history that includes any apparent trigger such as trauma, overuse, or disuse will usually narrow down the limited list of disorders affecting the lower leg. In older patients, calf pain should always suggest the possibility of deep vein thrombosis (DVT). This potentially life-threatening disorder is not always easily differentiated from a minor traumatic swelling or muscle strain.

Exercise-induced lower leg pain is common among athletes. Unfortunately, the terminology is confusing because of the clinical overlap and lack of identification of specific pathologic lesions in many cases. *Shin splint* is a commonly used term; however, some clinicians will include this diagnosis under the broader category of compartment syndromes or subdivide shin splints (i.e., medial stress syndrome).<sup>1</sup> Biomechanical imbalances at the foot will often strain the calf musculature; therefore, an evaluation of excessive pronation or supination should be included in the evaluation.

In addition to pain, patients also complain of leg cramps and lower leg edema. Lower leg edema is discussed in more depth in [Chapter 25](#). Cramps are often the result of excessive diuretic use, lack of hydration, or need for electrolytes.

## General Strategy

### History

- Determine the type of complaint: pain and/or swelling, numbness/tingling, cramping, cosmetic concern, or skin lesions.
- Distinguish between a traumatic onset and a nontraumatic onset.
- Determine whether the pain is diffuse or well localized.
- With a traumatic onset, determine whether there was minor trauma—mild sprain or DVT—or major trauma—fracture or compartment syndrome. Sudden onset without trauma would suggest muscle or tendon rupture (posteromedial knee—tennis leg; heel—Achilles rupture).
- Evaluate for vascular claudication when pain occurs in the leg with walking after 10 minutes in an older patient.
- With an overuse history determine whether the pain is felt only with activity (muscle/tendon strain or compartment syndrome) or initially with activity but now also at rest (stress fracture).
- With women ask about menstrual irregularities (stress fracture) or chronic use of birth control pills (DVT).
- With athletes determine whether there was a sudden change in training (i.e., increased mileage, change in running surface, hill training).
- When swelling is the chief complaint (see [Chapter 25](#)) determine whether the onset was traumatic or nontraumatic.

### Evaluation

- Attempt to pinpoint an area of tenderness or swelling.
- Test with stretch and contraction to detect a specific muscle or tendon.
- When a stress fracture is suspected, obtain a radiograph first and proceed to a bone scan if necessary; for DVT refer for Doppler ultrasound; for Achilles tendon rupture or possible partial rupture, diagnostic ultrasound or magnetic resonance imaging (MRI) is appropriate; for compartment syndrome, refer for measurement of compartment pressure.

## Management

- Refer cases of DVT, Achilles rupture, or acute compartment syndrome.
- Manage stress fractures with rest, increased calcium intake, and modification of inciting activity; nonhealing fractures require referral for orthopaedic consultation.
- Achilles tendinitis may be helped with temporary taping, strengthening, and activity modification.

## Relevant Anatomy

The lower leg is often discussed in reference to four fascial compartments:

1. Anterior—tibialis anterior, extensor digitorum longus, extensor hallucis, the deep peroneal nerve, and the anterior tibial artery and vein
2. Lateral—peroneus longus and brevis, and superficial peroneal nerve
3. Superficial posterior—soleus muscle, and tendons of the plantaris and gastrocnemius
4. Deep posterior—flexor digitorum and flexor hallucis longus, tibialis posterior, the peroneal and posterior

tibial artery and vein, and the tibial nerve

Exercise and trauma-related pain may be confined to one of these compartments.<sup>2</sup> When hypertrophy or inflammation exceeds the accommodations of the compartment, a compartment syndrome may result. Muscle function can also be related to the compartments. The anterior compartment muscles are the extensors, the lateral evertors; superficial posterior compartment muscles cause plantarflexion; and the deep posterior compartment muscles are the primary invertors and stabilizers against overpronation (**Figure 13-1**).

The anterior compartment muscles contribute to shock absorption; when they are eccentrically weak they may cause anterior shin splints.<sup>3</sup> The muscles in the deep posterior compartment are stabilizers; when they are eccentrically weak they may cause posterior (medial) shin splints.

**Figure 13-1** The anterior and posterior lower leg muscles.

## Evaluation

### History

Careful questioning of the patient during the history taking can point to the diagnosis (**Table 13-1**).

### Pain Localization

#### Anterior.

- Proximal tibia—pes anserinus bursitis (medially), stress fracture, tumor
- Middle and distal tibia—stress fracture, periostitis
- Anterolateral—anterior shin splints

#### Posterior.

- Upper medial tibia—tennis leg (medial gastrocnemius tear), flexor digitorum longus tendinitis
- Middle and lower third of tibia—stress fracture, posterior shin splints
- Calf muscle belly—muscle tear, DVT
- Achilles tendon—Achilles tendinitis
- Insertion of Achilles into calcaneus—retrocalcaneal bursitis, exostosis, Achilles tendinitis

When the patient reports a sudden onset of pain in the calf, it is important to identify whether there was direct trauma or a sudden movement. Direct trauma may result

from a blow to the leg or accidentally bumping the leg against an object (e.g., coffee table). Minor trauma in an older patient may initiate a DVT. A strong blow to the lower leg in any patient may result in fracture and/or initiate enough swelling to produce a compartment syndrome. Tearing of the medial gastrocnemius may occur with extension of the knee coupled with dorsiflexion of the ankle. The patient often reports a “pop” associated with a severe stabbing pain.

**Table 13-1** History Questions for Lower Leg Complaints

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Did the pain occur suddenly?	Tennis leg, DVT, fracture	Did you fall on or hit your leg?	Fracture, DVT
		Did you hear or feel a pop on the back of your leg while running or playing tennis?	Tennis leg (tear of medial gastrocnemius)
Did the pain appear without any particular trauma or activity?	DVT, shin splints	Are you taking birth control pills (for females) or have you been immobilized for a long time?	DVT
		Do you stand or walk on hard surfaces?	Shin splints
Does the pain occur mainly with activity?	Shin splints, stress fracture, Achilles tendinitis, chronic compartment syndrome, claudication	Did this occur with running? A sudden increase in speed, distance or duration?	Stress fracture, shin splints
		Do you work, walk, or run on hard surfaces?	Shin splints
		(For runners) Does the pain occur at a consistent distance or timing?	Compartment syndrome
		Is it worse with walking small distance; does it improve with rest?	Claudication (differentiate vascular from neurogenic causes)
		Is the pain close to your heel and worse when you go up on your toes?	Achilles tendinitis
Is the complaint one more of swelling?	Compartment syndrome, DVT, stress fracture, congestive heart failure (CHF)	Is the swelling localized to an inch or two?	Stress fracture; maybe DVT
		Is the swelling localized to one side of the lower leg?	Compartment syndrome
		Does the swelling improve with leg elevation?	Yes—vascular No—lymph
		Does the swelling involve the entire lower leg in both legs?	CHF, fluid retention due to renal problems, salt retention, liver disease

Overuse injuries cause varying degrees of tendon irritation, bone irritation, and swelling or hypertrophy in the corresponding compartment. Patients who have just begun an exercise routine or work standing or walking on a hard surface may develop shin splints. Athletic patients who suddenly increase duration, intensity, or speed are prone to stress fractures.<sup>4</sup> With female athletes, it is important to determine menstrual status. Amenorrhea coupled with endurance-type training suggests stress fracture as a cause of tibial pain. Runners who complain of aching, cramping pain always occurring at a specific distance or timing is suggestive of chronic compartment syndrome. All of the above exercise-induced problems gradually will become worse. Distinction is based more on palpation findings; in some cases radiographic imaging (stress fracture), bone scans (stress fracture), or measurements of compartment pressure (compartment syndrome) are needed.

## **Claudication**

Patients who complain of leg pain that occurs with walking and is relieved with rest likely have a form of claudication. The distinction clinically is between vascular and neurogenic claudication. Neurogenic claudication is secondary to spinal stenosis. Compression of nerves and/or the blood supply to nerves causes leg symptoms that are related to exertion. Patients will often have associated low back pain or radiation into the leg(s). The distinction between vascular and neurogenic claudication is not always clear; however, in general, it is related to posture. Patients with neurogenic claudication are more likely to be able to walk or ride a bicycle farther before the onset of leg pain when in a flexed position. Vascular claudication involves stenosis of peripheral blood vessels compromising the blood supply to muscles. This is most evident with increased demand as

occurs with walking. Atherosclerotic blockage is most common. Risk factors include smoking, diabetes, hypertension, and hypercholesterolemia. The patient may be found to have diminished pulses, pallor, reduced capillary fill, trophic skin changes and hair loss, and in severe cases, nonhealing ulcers or gangrene. Continuous-wave Doppler is used to measure arterial pressures, determine the ankle-brachial index (ABI) and segmental systolic pressures, and assess specific Doppler waveforms. The ABI is a ratio comparing the brachial pressure to the ankle pressure. This ratio is normally 1. Ratios in patients with vascular claudication are often between 0.5 and 0.8. Segmental systolic pressures should remain generally the same in the leg. A difference of  $> 20$  mm Hg indicates blockage. Management strategies include controlling risk factors such as smoking cessation and control of diabetes, hypertension, and hypercholesterolemia. Ironically, a crucial factor to management is exercise. Walking should be gradually increased to a goal of 30 to 90 minutes per day for five days at a rate of about 2 miles/hour.

## **Examination**

The examination focuses on palpation of the tender or swollen area. A general rule of thumb is that stress fractures, although causing a diffuse tenderness, often have a discrete localized area that is extremely tender. Percussion distal or proximal to this site often will cause pain at the site of the stress fracture.

When swelling is present, the distinction between localized and diffuse swelling may be helpful. A diffuse pattern of swelling that resolves with leg elevation is indicative of a vascular cause (venous drainage). Swelling localized to a specific compartment of the leg is suggestive of compartment syndrome. Localized swelling is suggestive

of DVT if found more in the belly of the triceps surae group. Localized swelling on the tibia or fibula may represent a stress fracture. Defects are occasionally visible or palpable at the medial leg with tennis leg and several centimeters proximal to the insertion of the Achilles tendon with rupture. With Achilles rupture, squeezing of the calf muscle fails to produce passive plantarflexion (Thompson test).<sup>5</sup>

Passive plantarflexion of the ankle may increase pain in the calf with DVT or calf strain. Adding resistance may increase the pain with muscle involvement, less with DVT. Further functional testing may indicate an involved muscle. For example, placing stretch on a tendon/muscle and then asking the patient to contract against the examiner's resistance may localize the problem.

When passive dorsiflexion causes severe posteromedial pain or when plantarflexion produces severe anterior pain, a related compartment syndrome is likely.

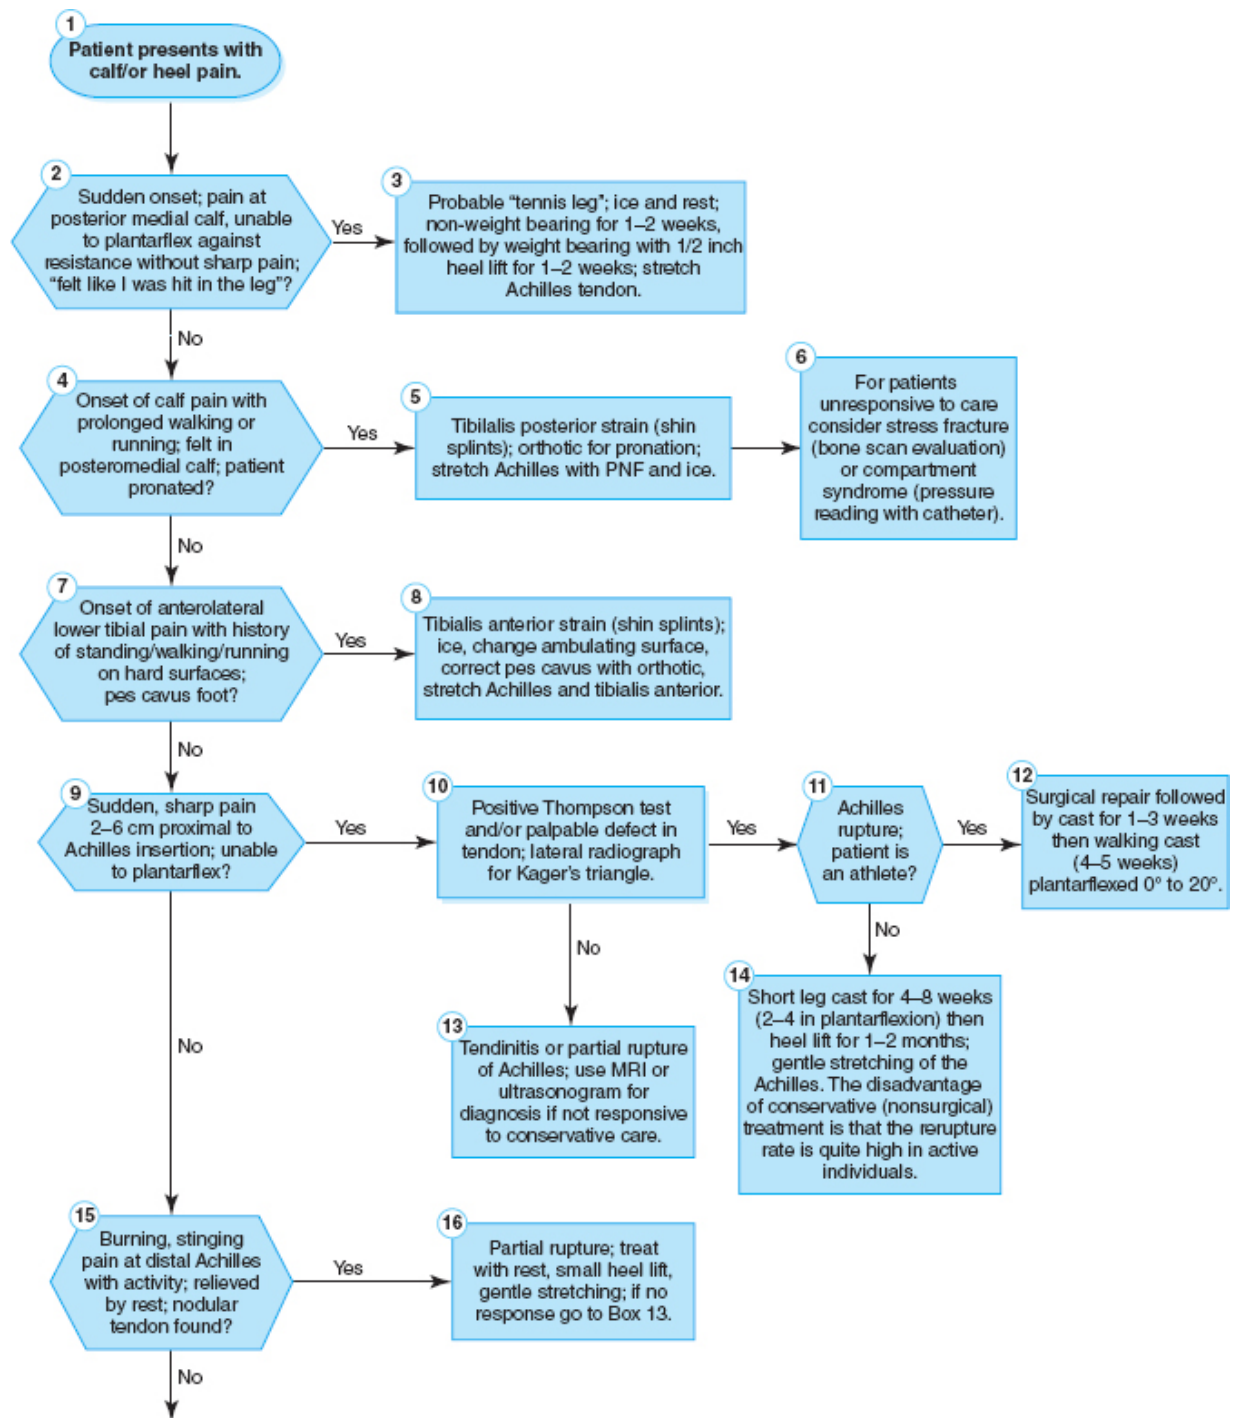

Further evaluation is strongly based on the suspected disorder. If a stress fracture is suspected, radiographs may demonstrate a healing callus or a periosteal reaction. However, it will often take two to three weeks for the callus to appear, if at all. Oblique views of the area may be needed to visualize the healing process. The definitive tool is a bone scan. If the suspicion is DVT, Doppler ultrasound is a decent alternative to venography, the gold standard.<sup>6</sup> When Achilles tendon pathology is suspected, soft tissue ultrasonography may be valuable but is operator-dependent. When Achilles rupture is suspected, disruption of Kager's triangle (a radiolucent area composed of the posterior flexors, tibia, and Achilles tendon) on a lateral radiographic view may be visible.<sup>7</sup>

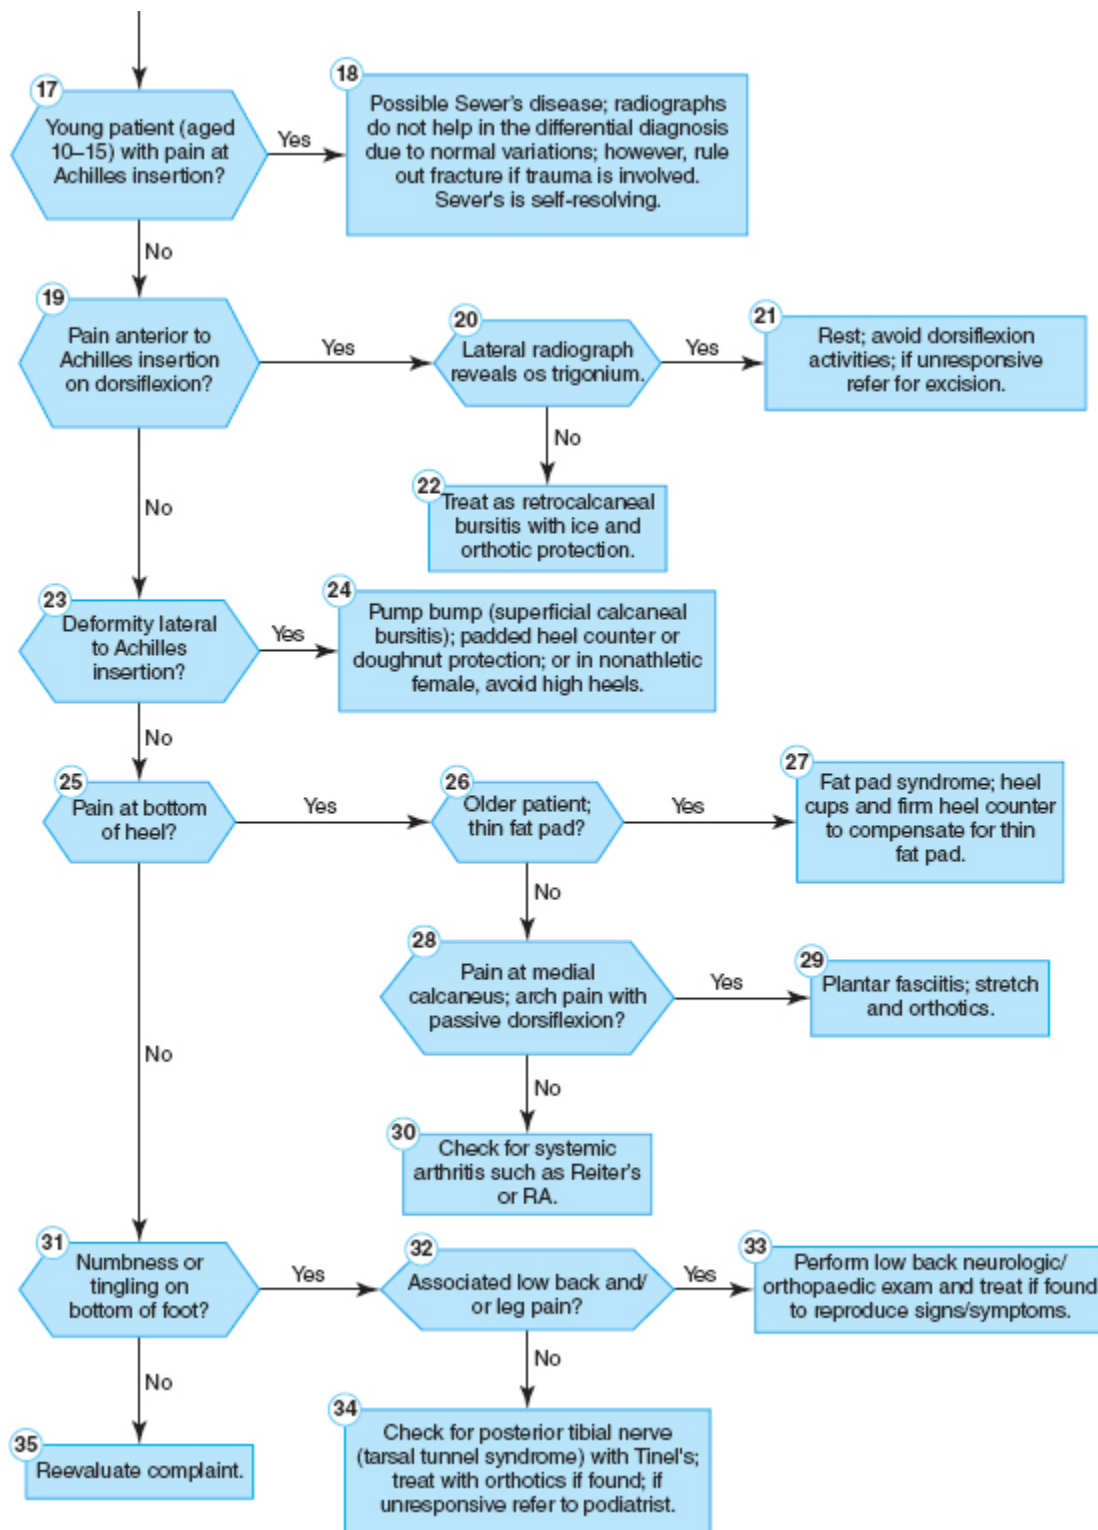

## Management

- Suspicion of DVT requires medical referral for further evaluation and possible anticoagulant therapy.
- If compartment syndrome is suspected, referral for compartment pressure measurement is suggested.
- Achilles tendon rupture requires surgical management in most cases; if the patient is older and not active, nonsurgical management, including a period of casting and non-weight-bearing may be sufficient; however, the re-tear rate is high in active or athletic individuals.<sup>8</sup>
- Achilles tendinitis can be managed with modification of activity, gentle stretching, ice after activity, and an elastic strapping support with the foot in plantarflexion; a graduated eccentric training program is often helpful.
- Stress fractures of the tibia usually will heal well with avoidance of impact loading from running or jumping for a period of a few weeks followed by low-impact conditioning for four to six weeks before returning to the full sport activity. Calcium intake should be increased to 1 g daily during the healing process and maintained at 800 mg daily during training.<sup>9</sup> Shock-absorption materials in the shoes may help dissipate impact forces.

## Algorithm

An algorithm for evaluation and management of calf/heel pain is presented in **Figure 13-2**.

**Figure 13-2** Calf/Heel Pain—Algorithm

# Selected Disorders of the Lower Leg and Posterior Heel\*

## Intermittent Claudication

### Classic Presentation

An older patient complains of leg pain after walking for a few minutes, and must stop and rest before continuing. The description may be of a cramping, tightening, or tiredness in the legs. The relief from resting is almost immediate. The patient has indications of cardiovascular risk factors.

### Cause

Peripheral vascular disease (PVD) due to atherosclerosis may be symptomatic or asymptomatic. Most patients with PVD are asymptomatic. Only about 20% of patients report symptoms of intermittent claudication.<sup>10</sup> The most common area affected is the superficial femoral artery demonstrating either stenosis or occlusion.

### Evaluation

In older patients with a presentation of walking-induced leg pain that improves with rest, a measure of all cardiovascular risk factors is important for long-term management. Use of a bicycle test with patient in a flexed position may be helpful in distinguishing between spinal stenosis caused symptoms (i.e., pseudoclaudication or neurogenic claudication). The physical examination must include the ankle-brachial index.<sup>11</sup> Blood pressure is taken in both arms and both legs. A ratio is determined by dividing the highest ankle pressure by the highest arm pressure. Above 0.90 is considered normal; 0.71–0.90 is considered mild; 0.41–0.70 is considered moderate; and 0.00–0.40 is considered severely obstructed. When clinically suspected, it is important to retest patients who appear to have a normal index. The blood pressure is again measured to determine the index after the patient either performs a number of toe raises or walks on a treadmill. This retest after exercise is important to develop a pressure gradient in those patients who have blockage of the distal aorta or iliac arteries. Otherwise, the index may

appear normal in these patients. If there is still doubt, or if a surgeon is considering revascularization, other imaging that may prove useful (each has its associated cost and sensitivity characteristics) includes duplex ultrasonography, computed tomographic angiography (CTA), or magnetic resonance angiography (MRA). Although CTA and MRA results are similar, CTA is less expensive.

## Management

Management is multifactorial including reducing, or attending to, cardiovascular risk factors, exercise therapy, recommendations for aspirin use at 75 mg for the antiplatelet effect, and in selected cases, additional pharmacological treatment (e.g., cilostazol), and revascularization using endovascular or surgical approaches. There is strong evidence that an exercise program is an effective approach for many patients. This includes a Cochrane review<sup>12</sup> and other meta-analyses.<sup>13</sup> Additionally, one randomized controlled study indicated no difference in outcome between patients managed with exercise versus those who had surgery. Even the guidelines of the TransAtlantic Inter-Society Consensus (organized by the American College of Cardiology and the American Heart Association) recommend surgical and other invasive treatment only for those patients who do not respond to exercise or pharmacological approaches.<sup>14</sup> The exercise program works best if patients are asked to walk until pain is near maximum, and with walking sessions that last longer than 30 minutes. Supervised programs work better than unsupervised. This approach must be performed three or more times per week for at least six months with the benefits taking between one to two months to be noticed. Regarding conservative treatment through nutritional and other oral supplementation, one study indicated that oral vasodilating prostaglandins, vitamin E, and chelation therapy with EDTA did not appear to have an effect on reducing symptoms.<sup>15</sup> Medical approaches are controversial with regard to effectiveness but include implantation of stents or revascularization (surgery or percutaneous transluminal angioplasty [PTA]).<sup>16</sup>

## Shin Splints

## Classic Presentation

The patient complains of anterior or posterior lower leg pain that is often insidious in onset. If asked, the patient may remember walking or running on a hard surface. The pain is a deep ache that is often worse with weight-bearing.

## Cause

Shin splints are ill defined. It appears that tendinitis, periostitis, muscle strain, or interosseous membrane strain have all been implicated. There are generally two types. The anterior shin splint involves the tibialis anterior, extensor hallucis longus, and digitorum longus. These muscles are used for shock absorption; when they are weak or placed under increased demand as in walking or running on hard surfaces or when the shoe has no shock-absorbing quality, the force is transmitted to the tibia and its attachments. The posterior type of shin splint involves the tibialis posterior, flexor hallucis longus, and flexor digitorum longus muscles. The soleus has also been implicated. These muscles act as ankle stabilizers and appear to be overstrained when the patient is hyperpronated.<sup>3</sup>

## Evaluation

The pain is often at the middle or lower third of the tibia. Anterior shin splints are tender just lateral to the middle tibia. Pain and tenderness for posterior shin splints is posteromedial to the middle or lower tibia. Pain may be increased by stretch or contraction of the involved muscles. It is important to check the patient's shoes for proper shock-absorption capabilities. Stress fractures may appear similarly, yet the pain is usually more localized and on the tibia itself. With shin splints, the radiographs are usually normal. If the patient does not respond to treatment or there are enough historical clues to suggest stress fracture, such as endurance training in a young athlete or menstrual irregularities in a female athlete, referral for a bone scan is warranted.

## Management

The acute care of shin splints involves rest from the inciting activity, ice, and support provided by elastic tape that is applied in an upward spiral pattern toward the area of tenderness. Support at the foot is also important and can be given temporarily by foot taping and/or medial heel wedges. Orthotics will often be needed if shin splints are recurrent (**Table 13-2**). Simply throwing away worn-out shoes and replacing them with a good shock-absorbing pair is often all that is needed. One study indicated that dietary calcium intake should be increased in those individuals with shin splints.<sup>9</sup>

**Table 13-2** Shin Splint Management

Parameter	Acute	Subacute	Symptom-Free Stage
Criteria for diagnosis of staging	Anterior shin splints—pain/tender just lateral to middle tibia; posterior shin splints—pain/tender at posteromedial middle or lower tibia.	Pain is not constant, able to bear weight without pain; prolonged standing or walking may still cause pain.	No pain with walking and standing.
Goals and timing within each stage	Decrease pain and inflammation; approximately 1–3 days.	Strengthen and stretch lower leg muscles; increase shock absorption of shoe with anterior shin splints; support foot with posterior shin splints; about 1 week.	Emphasis on eccentric training, orthotics support, endurance training begins; 3–4 weeks.
Concerns	Pain may be due to stress fracture; consider bone scan if unresponsive.	Pain may be due to stress fracture; consider bone scan if unresponsive.	Overperformance of eccentrics.
Requirements for progression to next stage	Pain and tenderness decrease; isometric contraction not painful.	Proper shoe is chosen; concentric strength is present without pain.	No pain with eccentric training.
Manipulation/mobilization	Emphasis on tibial, calcaneal, and foot manipulation/mobilization.	Emphasis on tibial, calcaneal, and foot manipulation/mobilization.	As needed.
Modalities	Ice, compression, TENS, or high-volt galvanic (80–120 Hz/20 min/2–3×'s/1–2 days).	Ultrasound for 5–6 min/1.5 wt/cm <sup>2</sup> for 2–3 days; ice after any prolonged standing or walking.	Ice after activity.
External brace, support, etc.	Elastic taping from opposite side drawing around and up to painful area.	Elastic support as before; extra support with weight-bearing using strapping tape for arch support.	Wean patient off support.
ROM/flexibility/massage	Mild stretching of involved muscles; gentle stripping massage of involved muscles.	Stage 3 or 4 MRT to gastrocnemius; continue postisometric stretching of all lower leg muscles.	Maintain flexibility.
Open-chain exercise	Mild isometrics.	Isometrics at every 20°–30° arcs against resistance of wall or opposite leg progressing to elastic tubing training.	Continue through endurance phase of elastic tubing training.
Closed-chain exercise	None.	Standing toe raises (emphasize eccentric phase).	Continue eccentric training using three sets of 10.
Proprioceptive training	Diagonal PNF patterns without resistance.	Diagonal PNF patterns with resistance from examiner or elastic tubing; wobble board training begins; minitrampoline two-legged jumping.	Wobble board while bouncing a ball; minitrampoline, single-leg jumps for balance and strength.
Associated biomechanical items	Look at shoes to determine shock absorption and wear pattern.	Cast for orthotics if deemed necessary; temporarily support with taping or heel wedges.	Fit orthotics.
Lifestyle/activity modifications	Avoid running and standing for long periods on hard surfaces.	Progress to jogging or minitrampoline running; avoid prolonged standing.	Avoid prolonged standing on hard surfaces; educate patient regarding shoe wear and need for buying a new pair of shock-absorbing shoes at the appropriate time.

Key: TENS, transcutaneous electrical nerve stimulation; PNF, proprioceptive neuromuscular facilitation; MRT, myofascial release technique.

## **Tibial Stress Fracture**

### **Classic Presentation**

The patient is usually an active individual who develops insidious onset of tibial pain. Overuse from running or prolonged activity on hard surfaces may be evident in the history.

### **Cause**

If a repetitive stress is applied to bone such as with running, the ability to remodel may be overwhelmed because of inadequate healing time. There is still debate as to whether stress to bone is due to weak muscles or fatigue that causes increased bone loading or more to the forceful repetitive contraction of muscles and the imposed stress at their origins onto bone. A recent study evaluated risk for recurrent stress fractures and found that for men, the most common fracture sites were the tibia and fibula (70%), and for females the foot and ankle (50%) were the most common fracture sites.<sup>17</sup> Sixty-one percent were runners. Forty percent of females reported menstrual irregularities. Biomechanical risk factors included high arch (pes cavus), leg-length inequality, and forefoot varus. An early stage of this microtrauma event has been called the medial tibial stress syndrome; when a fracture has not occurred, however, there is enough of an inflammatory and remodeling process to cause pain.<sup>18</sup> Tibial stress fractures account for half of all stress fractures occurring in athletes.<sup>19</sup> The location varies depending on the underlying inciting activity. Runners are more likely to have middle and distal third tibial fractures; ballet dancers, the middle third; and military recruits, the proximal tibia. Middle shaft fractures as seen in dancers have a reputation for delayed union or continuing on to full fractures (sometimes called the “dreaded black line” radiographically).<sup>20</sup>

### **Evaluation**

The clinical presentation of an athlete who first notices shin pain at the end of a run that gradually becomes incapacitating over several days of running is highly suggestive. Additionally, menstrual irregularities in a patient complaining of shin pain is a clue to possible underlying osteopenia. Pain is often better initially with rest, but returns with any impact loading. Tenderness is often found at a discrete area on the tibial shaft. Percussion or tuning-fork testing at a distance either proximal or distal to the site may cause reproduction or worsening of the pain at the fracture site. Although stress fractures are difficult to diagnose in the early stages, attempts at using

in-office approaches such as therapeutic ultrasound have not been shown to be helpful. In one recent study, therapeutic ultrasound was tested for its ability to detect stress fractures.<sup>21</sup> Continuous 1 Mhz ultrasound application was used on both the involved and uninvolved tibias at seven increasing intensities for 30 seconds each. Coupled with this approach was the use of a visual analog scale. None of the subjects found to have a stress fracture on MRI was diagnosed by the ultrasound approach. Radiographically, a small radiolucent line may be seen, or a localized periosteal new bone formation may be evident. Oblique films are often necessary. Definitive diagnosis may require a triphasic bone scan when radiographs are equivocal but the presentation suggests stress fracture.

## **Management**

Most stress fractures can be managed conservatively with restriction of impact loading for several weeks. Immobilization usually is not necessary unless the athlete or patient refuses to stop the inciting activity. Crutches may be necessary in some patients who are symptomatic with walking. For the elite athlete, conditioning with bicycle riding or pool training with a water vest are good alternatives for maintaining aerobic fitness. Gradual return to activity begins with low-impact training over several weeks prior to full return.

Orthotic support, nutritional recommendations (especially calcium), and modification of activity are important for prevention. Ultrasonography and pulsed electromagnetic field therapy to accelerate healing time have been suggested but are unproven at this time.

## **Compartment Syndrome**

### **Classic Presentation**

The presentation varies depending on the compartment involved and whether it is acute or chronic. Typically, the patient often is an athlete complaining of aching or cramping of the leg following exercise. Pain is relieved by rest initially. There may be complaints of numbness/tingling into various parts of the foot.

### **Cause**

The lower leg is divided into four compartments: (1) anterior, containing the tibialis anterior, extensors of the toes, anterior tibial artery and vein, and deep peroneal nerve; (2) deep posterior, containing the posterior tibialis and toe flexors and the posterior tibial artery and vein; (3) superficial posterior,

containing the soleus, gastrocnemius, and plantaris; and (4) lateral, containing the peroneal muscles and nerve. Increased pressure in any of these fascial compartments may lead to damage to the muscles. Increased pressure also may cause numbness and paresthesia into the distribution of the corresponding nerve due to ischemia.<sup>22</sup> The most common cause is exercise induced; however, in acute situations, compartment syndrome may develop secondary to local trauma or fracture.

## Evaluation

In athletes, the symptoms usually occur within 10 to 30 minutes of exercise. The pain will subside over minutes or hours following activity; initially the patient will remain pain-free until the next exercise session. The examination is often normal between exacerbations. Tenderness and swelling may be evident over the involved compartment. Pulses are often normal distally; however, some sensory changes may be evident in the distal distribution of the involved nerves. Fascial defects with muscle herniation are evident in approximately 40% of patients, but they may not be evident unless the athlete runs for several minutes. The definitive tool is measurement of compartmental pressure while resting and after exercise. Elevated levels reach 80 mm Hg, compared with the normal of 30 to 40 mm Hg following exercise. Levels above 40 mm Hg that remain elevated for 15 to 30 minutes or longer indicate compartment syndrome.<sup>2</sup>

## Management

For chronic compartment syndrome a period of rest for four to eight weeks may be successful. For acute syndrome and patients who do not respond to conservative care, fasciotomy is the treatment of choice.

## Achilles Tendinitis

## Classic Presentation

The patient is often an athlete who complains of pain in the Achilles tendon following jumping or running activities.

## Cause

The Achilles tendon is covered by a peritenon composed of mainly fatty areolar tissue. The area most affected is approximately 2 cm proximal to the

calcaneal insertion. The demands on the tendon are high in running and jumping sports. Interestingly, the tendon has been shown to function with as little as 25% fiber continuity. Insertional problems include irritation of the retrocalcaneal bursa and irritation leading to a Haglund's deformity. Additionally, seronegative arthritides such as Reiter's syndrome and ankylosing spondylitis cause an enthesopathy at this site. Pain and tenderness at the calcaneus may indicate Sever's apophysitis in a younger athlete.

## Evaluation

Chronic degeneration (tendinosis) may be evident as a knotty swelling, with more acute damage evident by local tenderness made worse by stretch and/or stretch and contraction. Palpable defects in the tendon may indicate impending rupture in an athlete complaining of sharp stabbing or burning pains at the site. Researchers using diagnostic ultrasonography evaluated the patellar and Achilles tendons of 58 soccer players at pre- and post-season.<sup>23</sup> Those with abnormal findings for the Achilles at pre-season had a 45% risk of developing symptoms. Triceps surae tightness may be a contributing factor. Passively dorsiflexing the ankle with the knee extended should demonstrate a normal angle of 20° to 30°. This is a measure of gastrocnemius tightness. To test the soleus, the knee is flexed and the ankle is dorsiflexed. For dorsiflexion of the ankle, 30° to 35° should be available. The Thompson test is performed on patients suspected of having a rupture. This would occur in an on-the-field scenario. If squeezing the calf in the prone relaxed patient does not produce passive plantarflexion of the foot, Achilles rupture is likely. When partial ruptures are suspected, MRI can help differentiate between tendinitis and partial rupture.<sup>25</sup>

## Management

Achilles tendinitis is managed with rest, ice, and modification of the inciting activity. Taping the ankle in plantarflexion with an elastic support is helpful in the early stages. Heel lifts may also decrease the stretch effect on the injured Achilles. Long-term goals are to modify faulty training activity and to gradually and consistently stretch the triceps surae group. Orthotics may be necessary in those individuals with hyperpronation. Training should consist of a graduated eccentric loading program. An example would be to begin initially with toe raises with emphasis on slowly lowering the body weight. Additional weight can be carried to increase the training effect over time.

One RCT<sup>24</sup> demonstrated that the combination of low-energy shockwave therapy with eccentric exercise was better than eccentric exercise alone at four months follow-up. Two reviews<sup>26,27</sup> of eccentric exercise for Achilles tendinosis come to the conclusion that more studies using larger patient populations are needed. There is also the implication in one review that the effects are simply due to time. However, this is contradicted by most studies

demonstrating that a “wait-watch-and-see” approach is less effective than eccentric exercise or shockwave therapy.<sup>28</sup> One study,<sup>29</sup> though, did indicate that at one year, patients performing a stretching regimen had similar success to those doing the eccentric approach. Fahlstrom et al.<sup>30</sup> found that a 12-week eccentric training protocol based on the Curwin–Stanish protocol resulted in a satisfactory result in 89% of participants with mid-portion Achilles tendinosis, whereas only 32% of participants with chronic insertional tendinosis had a satisfactory result. One study<sup>31</sup> indicates that nonathletes do not enjoy the same benefits as athletes with an eccentric training approach. This difference in effect may be due to the finding that healthy control tendons do not seem to have any change in collagen metabolism with eccentric training versus a noted increase in collagen synthesis rate in symptomatic athletes.<sup>32</sup> A novel approach being used in tendinosis throughout the body is a locally placed transdermal patch of nitric oxide.<sup>33</sup> This approach offers a conservative option that may be effective. Another approach involves the injection of a sclerosing agent into neovessels in the involved section of the tendon. The studies<sup>34</sup> performed to date indicate a good result, especially for those nonrespondents to eccentric training. An eight-year follow-up study of 83 of 107 patients diagnosed with acute or subchronic tendinopathy determined what happens to these patients over time.<sup>35</sup> Twenty-nine percent needed surgery; 84% of the total group recovered to previous activity levels; 93% were asymptomatic on the involved side even with strenuous exercise, although 41% started to suffer from problems on the noninvolved side. Injectable treatments include a host of components and techniques that include platelet rich plasma (PRP), sclerosing agents, protease inhibitors, and corticosteroids. A recent review judged the evidence for each still wanting.<sup>36</sup>

Yet not all agree. A review from 2013 suggests there may be some value without much risk.<sup>37</sup> More high-quality studies with comparison to control groups need to be performed.

Achilles ruptures may be managed with cast immobilization in nonathletic or older individuals. However, in athletes the re-rupture rate is quite high; therefore, surgery is the recommended treatment.<sup>22</sup> Recovery from surgery involves a walking cast, with full return taking several months.

# **CHAPTER 14**

## **Foot and Ankle Complaints**

### **Context**

The foot and ankle must provide support and shock absorption while at the same time balancing the body. This requires both mobility to adapt to varying terrain and stability to allow supported contact and push-off from the ground. Shock absorption occurs as a result of the dissipation of forces through complex movements at the foot and ankle and imposed adaptation through mainly rotation in the lower extremity at the knee, hip, and pelvis. Therefore, dysfunction at the feet may have consequences throughout the entire body. Foot problems may be local or referred; however, the need for lower-extremity compensation may result in more proximal pain, including low back pain.

As the most distal site of the body, the foot is also commonly affected by vascular disorders. Arterial occlusive disorders block blood flow. Valvular insufficiency in veins, coupled with gravity, may lead to a pooling effect and vascular stasis. Neurologic dysfunction associated with metabolic neuropathies such as seen with diabetes is often felt first distally in the feet. The bare foot is exposed to possible trauma and infection. The supported foot is vulnerable to the pressure effects and biomechanical alterations of footwear. When compromised by vascular and/or sensory deficits, a patient is more prone to the long-

term consequences of unnoticed or unattended lesions. This is most often seen with the diabetic patient.

The most common conditions involving the foot and ankle are biomechanical in nature and include the following:

- First toe—hallux valgus/rigidus, turf toe, gout, and sesamoiditis
- Metatarsals—Morton's neuroma, metatarsalgia, "dropped metatarsal," and stress fractures
- Medial longitudinal arch—pronation/supination effects, navicular subluxation, and plantar fasciitis
- Lateral foot—cuboid subluxation, peroneal tendinitis, and fracture of the base of the fifth metatarsal
- Ankle—inversion and eversion sprains
- Achilles tendon/heel—tendinitis, bursitis, and fat pad syndrome

The majority of foot complaints are due to lack of proper support or inappropriate footwear. Points of overpressure or irritation from shoes may result in corns or calluses, sesamoiditis or aggravation of hallux valgus at the first toe, or fat pad syndrome at the heel. Tight-fitting shoes may also cause compression of metatarsals or cause damage to toenails (i.e., black toenails). If the foot is too mobile (i.e., hyperpronated), lack of support may cause plantar fasciitis and strain of the tibialis posterior and other tendons. Therefore it is requisite that shoes be examined and that the foot be evaluated for any predisposition to overstrain due to forefoot or hindfoot abnormalities (i.e., varus or valgus).

Ankle sprains are common. The most common are plantar flexion/inversion sprains. Although most injuries are dismissed as a simple sprain, it is important to rule out associated injury, including various fractures and ligament ruptures. Chronic ankle pain or instability (or both) is not uncommon following repeated ankle sprains. Therefore, it is important not only to manage the acute injury but also to

attempt to prevent future occurrences. This often requires a determination of the needs of the associated activity or sport coupled with strict adherence to a postinjury rehabilitation program.

## **General Strategy**

### **History**

- Determine whether the complaint is one of pain, stiffness, popping/snapping, crepitus, locking, weakness, or numbness and tingling.
- Determine whether the patient had a traumatic onset or whether there is an obvious overuse history.
- With overuse, determine the type of activity, the types of shoes worn, and the type of surface on which the patient works or exercises.

### **Evaluation**

- With trauma, palpate for points of tenderness and obtain radiographs for the possibility of fracture/dislocation if the patient is unable to bear weight or bony tenderness is found.
- With ankle sprain, challenge for stability posterior to anterior (drawer test), into inversion (lateral ankle), and into eversion (medial ankle).
- Examine the patient's shoes and feet for signs of excessive wear on the soles of both shoes and feet.
- When the onset is nontraumatic, challenge the musculotendinous attachments with stretch, contraction, and a combination of contraction in a stretched position.

- When trauma or overuse is not present, evaluate the patient's foot and ankle for swelling and deformity (bursitis, gouty tophi, osteoarthritis [OA], etc.).

## **Management**

- Displaced or nonhealing fractures must be referred for medical management.
- Ankle sprains can be managed with mobilization/manipulation, use of a stabilizing brace or taping, and gradual return to weight-bearing with emphasis on prevention.
- Tendinitis and muscle strain can be managed conservatively with taping support, gradual stretching, ice, and activity modification.
- The patient should be educated regarding proper fitting of shoes and the special needs for specific sports requirements and type of foot (pes planus versus pes cavus).
- Orthotics may be a helpful preventive measure when biomechanical abnormalities are found, such as hindfoot or forefoot varus or valgus.
- Diabetic foot problems should be referred to the primary treating physician.

## **Relevant Anatomy and Biomechanics**

Terminology used to describe foot architecture and deformity can be confusing. Basically, the foot is divided into a hindfoot, a midfoot (midtarsal), and a forefoot. Dysfunction in one part of the foot is often accommodated or compensated by movement in another portion of the

foot. Following is a brief description of the joints in each section of the foot and definitions of functional or structural deviations that may occur:

- **Hindfoot**—The hindfoot includes the distal tibiofibular joint. In addition to several ligaments, the two bones are joined by a flexible interosseous membrane. The distance between the bones may widen with dorsiflexion of the ankle, as the talus wedges between the malleoli. With this movement the interosseous membrane is stretched, causing superior movement of the proximal tibiofibular joint with accompanying external rotation; the opposite occurs with plantarflexion. The talar/malleolar joint is referred to as the talocrural joint. The subtalar joint consists of the talus and calcaneus. Stability of this area is provided in part by the ligamentous support of the tibia and fibula, dorsiflexion of the ankle, or supination of the subtalar joint. Ligamentous support at the ankle is provided laterally by three ligaments: (1) the anterior talofibular ligament (supports the ankle against inversion and anterior-to-posterior movement), (2) the posterior talofibular ligament (prevents mainly excessive ankle dorsiflexion and adduction), and (3) the calcaneofibular ligament (a major stabilizer for inversion). The medial side of the ankle is supported by the deltoid ligament, which consists of the tibionavicular, tibiocalcaneal, and anterior and posterior tibiotalar ligaments. These ligaments act together to prevent excessive eversion of the ankle (**Figure 14-1**).
- **Midfoot**—The midtarsal joints are the interconnections between the talus and calcaneus and the midtarsal bones, including the cuboid, navicular, and cuneiforms.

**Figure 14-1** (A) Major bones and joints of the foot (lateral view); (B) major bones and joints of the foot (medial view); (C) major ligaments of the ankle joint (lateral view).

- Forefoot—The forefoot is made up of the distal articulations of the metatarsal, metatarsophalangeal (MTP), and interphalangeal joints.

The close-packed position for most of the foot is supination with the exception of the phalanges, which are close-packed in extension. Supination involves a triplanar movement of adduction, plantarflexion, and inversion. Pronation involves a triplanar movement pattern of abduction, dorsiflexion, and eversion. These movement patterns can occur independently in the foot and are often compensatory to each other. For example, supination in the hind-foot may be compensated by pronation in the forefoot.

- Forefoot varus—When the forefoot is held in an inverted position while the subtalar joint is in a neutral position, forefoot varus occurs. This deformity occurs in only 9% of the population.<sup>1</sup> If not compensated for, the first toe would not reach the ground during midstance and toe-off. Forefoot varus is usually compensated for by pronation of the subtalar joint, making this clinically similar to pes planus (flattened medial longitudinal arch).
- Forefoot valgus—When the forefoot is held in an everted position while the subtalar joint is in a neutral position, forefoot valgus occurs. This deformity occurs in 44.8% of a symptomatic population.<sup>2</sup> The midtarsal joint must supinate in an effort to bring the fourth and fifth metatarsal heads to the ground. This will cause the foot to appear high arched (pes cavus) during ambulation.
- Hindfoot varus—The calcaneus is held in an inverted position while the subtalar joint is in neutral with

hindfoot (rearfoot) varus. This is often due to a developmental abnormality of the tibia in which it is bowed outward (tibia varum). The result is that the subtalar joint must rapidly pronate through an inordinate range of motion (ROM) in an effort to bring the medial condyle of the calcaneus toward the ground during ground contact. This produces excessive torque in the foot and lower extremity.

- Hindfoot valgus—The calcaneus is held in an everted position while the subtalar joint is in neutral with hindfoot (rearfoot) valgus. The major difficulty with this position is lack of stability at heel contact.
- Equinus (talipes equinus)—Simply put, this is a restriction to dorsiflexion at the talocrural joint. Most often this is due to contracture of the soleus or gastrocnemius; however, developmental or acquired damage to the talus may also create this problem.
- Plantarflexed first ray—Normally the metatarsal heads are in alignment in the transverse plane when they are dorsiflexed. When the first metatarsal head is lower, the great toe is in contact with the ground while the other metatarsal heads are not, leading to a biomechanical problem similar to that in forefoot valgus. This problem is associated with a high-arched (pes cavus) foot.

Gait is often divided into an ipsilateral swing and a stance phase. The stance phase is divided into contact, midstance, and propulsion subphases. The time spent in each phase is dependent on whether an individual is walking, jogging, or running. With walking, the stance phase is approximately 62% of the total cycle. The contact and propulsion subphases account for 25% of the stance phase each, with the remaining 50% of time spent in the midstance subphase.<sup>3</sup> A basic description of the biomechanics of walking and running may help explain the

impact that properly functioning feet have on the lower extremities and the rest of the body.

Support is needed for the split-second contact when the heel first touches the ground and when the foot leaves the ground at toe-off. Immediately after heel contact and during half of the foot-flat phase, the foot must dissipate the ground reaction force and accommodate to different terrain. This is accomplished through a “universal joint” reaction at the subtalar joint. The talus is everted by internal rotation of the tibia, unlocking themidtarsal, talocalcaneal joint and creating pronation. Associated with this internal rotation is flexion of the knee. The combination of these actions helps to dissipate ground forces. External rotation causes the opposite effect of talar inversion and the consequent rigid, locked position of supination.

The subtalar and midtalar joint complex (talocalcaneal, talonavicular, and calcaneocuboid joints) determines movement of most of the foot. However, the medial segment consisting of the first metatarsal and first cuneiform generally moves in a direction opposite that of the rest of the foot. Therefore, even when the hindfoot is structurally normal, compensations may result from abnormalities of the forefoot. Forefoot varus implies that the medial forefoot (the first toe in particular) does not contact the ground unless the foot pronates to bring it down. This is called a compensated forefoot varus. Forefoot valgus has the opposite effect, with the first metatarsal in contact with the ground without contact of the fifth and fourth metatarsals.

Muscle function across the foot and ankle is quite complex during ambulation. Without reference to weight-bearing, the dorsiflexors of the foot/ankle are the tibialis anterior and peroneus tertius (see **Figure 13-1**). The plantarflexors are the peroneus longus and brevis and the tibialis posterior. Eversion of the foot/ankle is primarily due to the peroneals; inversion, primarily the tibialis anterior

and posterior. These are simple uniplanar movement patterns; however, the foot functions more in a triplanar mode. From the standpoint of subtalar joint pronation and supination, tendons that pass medially to the subtalar joint axis are supinators, including the extensor hallucis longus, extensor digitorum longus, tibialis anterior and posterior, and flexors hallucis longus and digitorum longus. Those muscle tendons that pass laterally to the subtalar joint axis are pronators, including the three peroneal muscles. The peroneus longus may act as either a pronator or a supinator based on the position of the first metatarsal.

At heel contact, most lower leg muscles function eccentrically to decelerate imposed pronation. These include the tibialis anterior and posterior, extensor hallucis longus and digitorum, and the soleus/gastrocnemius group. This function indirectly acts as a shock-absorbing strategy by the body and when not optimum leads to anterior shin splints.<sup>4</sup> During midstance there is a dual function of many muscles based on the subphase of midstance. Early in midstance, the tibialis posterior and soleus act eccentrically and in the later phase they contract concentrically to supinate the subtalar and midtarsal joints. In the early midstance phase, the toe flexors also fire eccentrically, assisting the tibialis posterior and soleus in decelerating forward movement of the tibia. During push-off (propulsion) all of the intrinsic foot muscles act to stabilize the foot firing concentrically. The peroneus longus fires concentrically to plantarflex the first ray, as does the flexor digitorum longus. Other first toe muscles fire eccentrically to assist in stabilizing the first metatarsal joint.

## **Evaluation**

## **History**

Careful questioning of the patient during the history taking can point to the diagnosis (**Table 14-1**).

Clarify the type of complaint.

- Is the complaint one of pain, stiffness, looseness, crepitus, deformity, or a combination of complaints?

**Table 14-1** History Questions for Foot/Ankle Complaints

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Did you injure your foot?	Inversion or eversion sprain, strain, fracture	Sprain your ankle?	Inversion sprain likely with lateral pain; eversion with medial pain
		Twist ankle with foot planted?	Possible distal tibial or fibular fracture or diastasis
		Did your big toe get forced backward?	Turf toe (capsular sprain of first MTP joint)
		Sudden outside foot pain with pushing-off (e.g., jumping)?	Possible cuboid subluxation or metatarsal fracture (fifth)
		Stubbed toe and still painful?	Fracture of toe
Acute onset of pain with no trauma?	Rheumatoid or crystalline arthritides, plantar fasciitis	Heel pain landing from a jump?	Fat pad irritation, bone bruise, fracture
		Heel pain associated with hand pain?	Rheumatoid arthritis
		Heel pain associated with sacroiliac or low back pain?	Reiter's syndrome or ankylosing spondylitis
Gradual onset of first toe pain?	Hallux valgus, hallux rigidus, sesamoiditis	Sudden pain in arch?	Plantar fasciitis
		Hurt more when you pull your big toe back?	Hallux rigidus
		Is your big toe deviated out?	Hallux valgus (associated bunion)
Gradual onset of pain in other parts of the foot?	Stress fracture, neuroma, tarsal subluxation, metatarsalgia	Pain on the bottom of your big toe?	Sesamoiditis
		Stand for long periods of time on hard surfaces or run a lot of miles?	Stress fracture
		Pain on bottom of ball of foot?	Dropped metatarsal (subluxation) or neuroma
Numbness and tingling in foot?	Nerve root, tarsal tunnel syndrome, interdigital neuritis	Pain worse with tight shoes?	Metatarsalgia
		Associated with low back pain?	Nerve root
		On bottom of your foot?	Tarsal tunnel syndrome
		In between your toes?	Interdigital neuritis
			Diabetes
			B12 deficiency

Key: MTP, metatarsal phalangeal.

- Localize the complaint to the ankle, midfoot, or forefoot and then determine whether it is anterior, posterior, medial, or lateral.

Clarify the mechanism if traumatic.

- Plantarflexion/inversion injury to the ankle—Consider inversion ankle sprain with injury to the anterior talofibular, calcaneofibular, and (rarely) posterior talofibular ligaments.
- Dorsiflexion/eversion injury to the ankle—Eversion ankle sprains tear the deltoid ligament and are often associated with dislocation.
- Twisting injury at the ankle with foot fixed (ski boot type injury)—Consider distal tibial and fibular fracture or diastasis.
- Sudden dorsiflexion of the first toe—Turf toe is a sprain of the first MTP joint; the opposite mechanism occurs with sand toe.
- “Stubbing” the toe (especially the fifth toe)—Consider sprain or fracture.
- Lateral foot pain with push-off while jumping—Consider cuboid subluxation and metatarsal fracture.
- Heel pain when landing from a jump—Consider fat pad irritation and bone bruise to the calcaneus; when excessive force is applied, a calcaneal fracture is possible.

Determine whether the mechanism is one of overuse.

- In what position does the patient work? Does the patient stand or walk on hard surfaces?
- What type of footwear does the patient wear? Unsupportive footwear allows foot sprain/strain, high heels force the toes into the toe box and allow shortening of the Achilles tendon.

- If the patient is an athlete, determine the training program, running surface, and type of shoe.
- Are the demands of the sport or activity matched by the shoe design? Cleats may provide support in some settings and in others anchor the foot, causing injury; high-top shoes may provide some ankle stability in some sports while limiting needed motion in others.
- How often does the athlete replace his or her shoes? For high-level activity, every four to six months may be best; at the very least, every nine months.

Determine whether the patient has a current or past history/diagnosis of the foot/ankle complaint or other related disorders.

- Are there associated low back, pelvis, hip, or knee complaints or diagnoses?
- Does the patient have gout, diabetes, arterial insufficiency, varicose veins, or familial predisposition to hallux valgus?

## Pain Localization

The following are possible causes of pain based on localization (**Figure 14-2**, A to C, and **Table 14-2**):

### Forefoot

- First MTP joint
  1. Acute traumatic—turf toe, sesamoiditis
  2. Nontraumatic—hallux valgus, hallux rigidus, gout
- Fifth metatarsal
  1. Acute traumatic—transverse (Jones) fracture, avulsion fracture, spiral fracture

- 2.** Nontraumatic—peroneus brevis insertional tendinitis, Iselin's disease (traction apophysitis)
- Metatarsals
  - 1.** Acute traumatic—stress fracture
  - 2.** Nontraumatic—interdigital neuroma (between second and third interspaces), Freiberg's (second metatarsal), stress fracture

## **Midfoot**

- Medial
  - 1.** Acute traumatic—fracture, rupture of plantar fascia, navicular subluxation
  - 2.** Nontraumatic—accessory navicular, Köhler's disease, navicular subluxation, stress fracture, plantar fasciitis

**Figure 14-2** (A) Lateral aspect of ankle and foot; (B) medial aspect of ankle and foot; (C) dorsal aspect of ankle and foot.

**Table 14-2** Foot and Ankle Pain Localization

#	Significant Structures	Overt Trauma	Insidious or Overuse
1	Peroneus longus and brevis tendons; sural nerve	Contusion of structures	Peroneal tendinitis
2	Anterior tibiofibular ligament	Diastasis with possible associated damage to interosseous membrane	Scar formation from previous ankle injury; talar subluxation
3	Anterior talofibular ligament	Inversion ankle sprain	Scar tissue from previous ankle sprains
4	Peroneus tertius, extensor tendons, superficial peroneal nerve	Contusion of structures	Peroneus tertius or extensor tendinitis
5	Calcaneofibular ligament, peroneal tendons and retinaculum	Inversion ankle sprain with possible torn ligament or retinaculum	Snapping peroneal tendons dislocating due to retinaculum looseness or rupture
6	Extensor digitorum brevis, distal calcaneus, bifurcate ligament	Bifurcate ligament rupture; avulsion fracture of distal calcaneus	Strain of extensor digitorum brevis
7	Cuboid	Cuboid subluxation	Cuboid subluxation
8	Base of fifth metatarsal; peroneus brevis insertion	Avulsion fracture (often secondary to inversion sprain); transverse (Jones) fracture	Iselin's disease (apophysitis), insertional tendinitis
9	Metatarsal shaft	Metatarsal fracture	Stress fracture
10	Fifth MTP joint	Fracture of phalange	Tailor's bunion
11	Achilles tendon	Achilles rupture	Achilles tendinitis
12	Subcutaneous and retrocalcaneal bursae, Haglund's process	Bursitis	Chronic bursitis, pump bump caused by irritation from Haglund's process
13	Tibialis posterior tendon; tibial nerve	Rupture of tibialis posterior tendon	Tibialis posterior tendinitis; tibial nerve compression
14	Deltoid ligament	Eversion ankle sprain	Ligament sprain from overpronation
15	Navicular tubercle	Secondary to eversion sprain; subluxation	Subluxation; accessory navicular, tarsal coalition
16	Tibialis anterior tendon	Strain from plantarflexion injury	Tendinitis
17	Dorsal first MTP joint	Turf toe (hyperextension) or sand toe (hyperflexion) injury to joint capsule	Hallux rigidus
18	Sesamoids	Sesamoid fracture or sesamoiditis	Sesamoiditis
19	Lateral aspect of first MTP joint	Capsular sprain	External bunion associated with hallux valgus; gout
20	Plantar fascia	Plantar fascia rupture	Plantar fasciitis
21	Calcaneus, fat pad	Calcaneal fracture	Fat pad syndrome or inflammation associated with rheumatoid arthritis and Reiter's syndrome
22	Metatarsal heads	Metatarsal subluxation	Morton's neuroma; subluxation
23	Interdigital space	Interdigital neuritis	Interdigital neuritis
24	Metatarsals; extensor tendons	Metatarsal fracture, subluxations	Stress fractures, tendinitis
25	Extensor retinaculum, joint capsule, talus	Capsular sprain, talar subluxation, retinaculum sprain	Capsular sprain, talar subluxation, retinaculum sprain

Note: See [Figure 14-2](#) for localization of numbered areas.

- Lateral
  1. Acute traumatic—fracture, cuboid subluxation

- 2. Nontraumatic—cuboid subluxation, peroneus brevis tendinitis
- Anterior
  - 1. Acute traumatic—fracture, subluxation
  - 2. Nontraumatic—talar exostosis, anterior tibial nerve compression, subluxation

## **Hindfoot**

- Posterior
  - 1. Acute traumatic—Achilles rupture, Achilles tendinitis
  - 2. Nontraumatic—pump bump, Achilles tendinitis, retrocalcaneal bursitis, blisters
- Plantar
  - 1. Acute traumatic—calcaneal fracture, bone bruise
  - 2. Nontraumatic—fat pad syndrome, plantar fasciitis, subluxation, Sever's disease

## **Traumatic and Overuse Injuries**

With direct trauma from a blow or dropping an object on the foot, it is always important to consider fracture of the impacted bone. When a sudden pain is felt following landing on the ball or heel, fracture should be suspected. A sudden propulsion (such as quick, forceful push-off for a sprint or jump) may on occasion cause a spiral fracture of the fifth metatarsal. When the pain is located at the first toe, it is important to determine whether there was a hyperextension or a hyperflexion of the toe, each of which is suggestive of capsular sprain.

With ankle injury it is always important to determine the position of the foot: plantarflexed/inverted (lateral stabilizing ligaments) or dorsiflexed/everted (medial stabilizing ligaments). It is extremely important to

determine the ability of the patient to bear weight, and the degree and onset of swelling. All of these are important screening questions and observations in determining the need for radiographic screening for fracture. Generally, the inability to bear weight associated with significant swelling correlates with the degree of damage.

Overuse injuries are often subtle. It is important to determine the types of shoes worn by the patient and the types of ground surfaces encountered. It is important in athletes to review the specific requirements of the sport and the ability of the shoes to accommodate. How often does the athlete replace worn-out shoes? Many overuse injuries will be uncovered as a shoe problem (too flexible or loss or lack of shock absorption); too soft or too hard a ground surface; or, in the examination, an underlying varus/valgus deformity of the rearfoot or forefoot. If there is an underlying biomechanical problem, the repetitiveness and frequency of participation become important modifiers.

## **Weakness**

Weakness may be less appreciable directly but indirectly evident because the toes catch on rugs or hit a curb or step when climbing stairs. This indicates neural compromise, especially when the condition is nonpainful. Inability to dorsiflex the ankle indicates primarily tibialis anterior (L4-L5) weakness or perhaps inability to dorsiflex the toes (extensor digitorum) or the big toe (extensor hallucis longus, L5). The physical examination should focus on differentiating between nerve root and peripheral nerve damage. Inability to rise up onto the toes is suggestive of S1 nerve root involvement, especially when nonpainful. Other rare possibilities are rupture of the tibialis posterior in an elderly patient or a patient with rheumatoid arthritis (RA), or Achilles tendon in an athlete.

# **Instability**

Instability is primarily an ankle-related complaint. It is important to determine the number and severity of ankle sprains in the past. It is also important to determine whether footwear relieves this complaint.

# **Restricted Motion**

Restricted motion is not a common foot complaint. The primary occurrence is at the first MTP joint. This is suggestive of hallux rigidus, especially when dorsiflexion is stiff and painful. When the patient complains of ankle stiffness, it is important to determine whether there is any associated pain or crepitus. Pain suggests mechanical blockage from a talar or calcaneal exostosis or scar tissue from a previous ankle injury. When dorsiflexion of the ankle is limited, contracture of the Achilles is likely; however, some equinus deformities due to congenital malformation of the tarsal bones are possible. This is differentiated in the exam through postisometric attempts at increasing movement. The patient may also claim that stretching makes no difference when there is an underlying congenital cause. When end-range positions feel blocked, the examiner should be directed to test for accessory motion restrictions.

# **Superficial Complaints**

There are numerous dermatologic complaints of the feet. It is important first to determine whether the patient is diabetic or has signs/symptoms suggestive of diabetes. Next, it is important to ask about shoe wear. Black toenails and other compressive consequences are common when the

shoe is too short and the patient is athletic. Fungal infection between the toes is common and is usually responsive to over-the-counter medications. The patient should be questioned regarding showering in public facilities, the environment of the shoes during activity (are the shoes made of a material that “breathes”?), and how hot/sweaty the feet become with activity. All may be predispositions for fungal growth.

When the patient complains of deformity, the location is often pathognomonic. A bunion at the first MTP indicates hallux valgus. Bony protrusion at the anterior ankle is often due to talar exostosis. Deformity at the posterior heel suggests Haglund’s deformity (prominent postero-superior lateral border of the calcaneus) or a pump bump (associated retrocalcaneal bursa).

Numbness and tingling on the bottom of the foot should suggest nerve root or peripheral nerve compression. It is again important to determine whether the patient is diabetic. When the symptom is on the bottom of the foot, an S1 nerve root problem (especially when associated with low back pain complaints) is likely. When the numbness/tingling extends across the bottom of the foot, tarsal tunnel syndrome due to posterior tibial nerve compression is likely. This is often associated with an overpronated foot. When numbness occurs between the toes, interdigital neuritis due to transverse compression of the metatarsals is likely. This is often due to too narrow a shoe.

<b>Examination</b>
--------------------

## **The Foot**

Prior to examining the feet, it is often helpful to examine the patient’s footwear. If the patient is an athlete, it is important

for him or her to bring in training shoes. Looking at wear patterns on the shoe may be helpful. Generally, the normal wear pattern is at the ball of the foot and at the lateral heel. Excessive lateral wear at the heel coupled with a caved-in appearance of the inside of the shoe would suggest pes planus, the opposite for pes cavus. The inside of the shoe should be examined to determine whether any irregularities may act as friction sources to the skin or underlying tendons. Check the shoe for flexibility and shock-absorption characteristics. Is there a firm heel counter? The fit of the shoe is also important to gauge while the patient is standing. Is there sufficient toe room? Is the shoe supportive of the medial longitudinal arch? Does the lacing fit too tightly over the talus or extensor tendons?

Much can be gained through observation of the foot. Look for indications of wear and tear on the foot. These are often clues to various foot deformities.

- Callus or corn formation at the dorsal aspect of the proximal interphalangeal (PIP) joint is seen with both hammer toes (flexion deformity of the PIP joint) and claw toes (dorsal subluxation of the MTP joint). A callus is also found at the plantar MTP joint with claw toes. Mallet toe (flexion contracture of the distal interphalangeal [DIP] joint) causes callus formation at the DIP joint and distal toe.
- Bunion development on the medial aspect of the first MTP joint is indicative of hallux valgus.
- Bunion development is also seen on the fifth MTP joint and is referred to as a tailor's bunion or a bunionette. It is often due to forefoot valgus.
- Callus formation under the second through third or fourth metatarsal heads is found with forefoot varus.
- Callus formation under the first, second, and sometimes third metatarsal heads is found with forefoot valgus.

If the patient is complaining of numbness and/or tingling of the foot, a search for neural irritation begins with a test of nerve root integrity with deep tendon reflex testing and sensory testing. The foot is primarily innervated by the L4-S2 nerve roots. If intact, a search for local nerve irritation focuses on the patient's localization. When there is numbness/tingling on the bottom of the foot, Tinel's test (tapping) of the posterior tibial nerve behind the medial malleolus may reveal tarsal tunnel syndrome. If the location of the symptom is more in the toes (possible associated motor loss), Tinel's test is performed at the anterior ankle at the anterior tibial branch of the deep peroneal nerve. If the patient's symptom extends from the medial knee down through the medial foot, testing with compression at the adductor tunnel or Tinel's test performed below the medial joint line of the knee may reveal saphenous nerve involvement. If sensation is decreased between the first two toes, the deep peroneal nerve is compromised. If there is numbness between the other toes, interdigital nerve compression is likely. When there is pain and numbness and tingling on the bottom of the ball of the foot, palpation for a neuroma between the second and third or third and fourth metatarsal spaces should be performed. Passive extension of the toes may increase the complaint, and some relief may be provided by passive flexion.

Determination of forefoot and rearfoot valgus and varus is usually performed with the patient prone. The opposite leg is brought into flexion on the table to neutralize rotation of the examined extremity. The initial positioning of the foot is an attempt at finding subtalar neutral (**Figure 14-3**). The approach is described generally in two ways:

**Figure 14-3** Neutral position of foot. Palpating the talus with the index finger and thumb, the examiner pronates and supinates the foot until the talus is felt equally by both contacts. The fourth and fifth metatarsal heads are then passively dorsiflexed.

1. The foot is grasped at the fourth and fifth metatarsal heads and passively dorsiflexed until resistance is felt. The foot is then supinated and pronated until a point is found where slightly more movement in either direction causes the talus to “fall off” to one side or the other. This is the neutral position.
2. The foot is grasped at the fourth and fifth metatarsal heads and distracted downward to remove dorsiflexion. The foot is then passively inverted and everted while the examiner palpates the talus with the thumb and middle finger. There will be a point at which the talus is felt by both thumb and finger or not at all by either. This is the neutral position.<sup>5</sup>

At this point a determination of the degree of hind-foot varus and valgus can be determined by connecting

intersecting lines through the tibia (Achilles) and the calcaneus. If the calcaneus is within 2° to 8° of varus, the leg-to-heel alignment is normal. When the heel is inverted, hindfoot varus is present; if everted, hindfoot valgus is present. Through the use of a plastic goniometer placed against the metatarsal heads, the degree of forefoot valgus or varus should be measured.<sup>6</sup>

The patient can also be examined from behind in the standing position. The angle formed by the lower third of the Achilles and the calcaneus can be determined, indicating statically a tendency toward pronation (hindfoot valgus) or supination (hindfoot varus). When the patient is asked to raise onto his or her toes, a medial longitudinal arch should form. If there is no arch in this position, tarsal coalition (fibrous or bony connection between tarsal bones) or rupture of the tibialis posterior tendon is likely. Various forms of navicular positioning testing have been suggested. One is the Feiss line. This line represents a connection between the apex of the medial malleolus and the length of the first metatarsal. The navicular tuberosity is usually at a point along this line. When the patient stands with equal weight between the feet (about 6 in. apart), the navicular should remain in close proximity to this line. The farther it drops away, the more pronated the individual. A similar test is the navicular drop test (**Figure 14-4**, A and B). A paper card is placed alongside the foot with the patient not bearing weight. The navicular tuberosity position is marked on the card. The patient then bears his or her weight onto the foot and the distance between the original mark and the mark of the new navicular tubercle position is measured. Greater than about 0.5 in. implies a hyperpronated foot.

Radiographic assessment of the foot is dictated by whether the intention is a search for fracture or whether a biomechanical appreciation of the foot is desired. Fracture is usually evident on non-weight-bearing views. The standard series consists of an anteroposterior (AP [dorsiplantar])

view, an oblique (lateral aspect of foot elevated 30°) view, and a lateral view. On the AP view, the forefoot and part of the midfoot are well visualized. The oblique view gives an excellent alternate perspective of the metatarsals. The talonavicular and calcaneocuboid joints and sinus tarsi are also demonstrated on this view. Calcaneonavicular coalition (bony bridging) is best seen on the medial oblique view. The lateral view is excellent for viewing the calcaneus, talus, navicular, cuboid, first cuneiform, and head of the fifth metatarsal. In addition to fractures, bony exostosis may be seen on the talus, calcaneus, or fifth metatarsal head. Additional views are designed to visualize the phalanges, sesamoids, calcaneus, and talus.

**Figure 14-4** The navicular drop test for pronation. (A) The patient's navicular tubercle is marked while the patient is not bearing weight. (B) The position is then again marked when the patient bears weight onto the foot. If the difference between marks is greater than  $\frac{5}{8}$  in., the patient is probably functionally a pronator.

If the intention is to obtain a more functional perspective of the foot, weight-bearing films are often used. Numerous lines of mensuration are used to evaluate the biomechanical relationship of the foot on these views, a description of which is beyond the scope of this text. However, the most commonly used is the Cyma line.<sup>7</sup> On the lateral view, the articulation between the talonavicular and calcaneocuboid (Chopart's joint) forms a continuous S-shaped line. A break

in the line anteriorly at the talus indicates pronation; a break posteriorly indicates supination.

## The Ankle

The ability to bear weight is an important screening maneuver with ankle sprains. If the patient is able to bear weight, palpation of specific bony landmarks including the malleoli, navicular, and cuboid areas will help determine the need for radiographs.<sup>8</sup> The ankle is tested primarily for stability. Three tests are commonly used. The first is the anterior drawer test (**Figure 14-5A**). This test is performed with the patient supine and the ankle plantarflexed 15° to 20°.<sup>9</sup> This position places the anterior talofibular ligament perpendicular to the tibia. The examiner pulls forward by stabilizing on the anterior distal tibia with one hand and the other hand pulls forward while cupping the calcaneus posteriorly. While analogous to the anterior drawer test of the knee, the more collateral ligamentous system is being tested in the ankle. With an inversion sprain the anterior talofibular ligament may be damaged. The anterior drawer test will reveal some laxity when compared with the opposite ankle. To eliminate stabilization from the Achilles, testing with the knee in 90° of flexion may be more sensitive. If the ankle is felt to be unstable in dorsiflexion, damage to the collateral and deep system of ligaments is likely. The talar tilt test is simply an inversion stress applied to the ankle. The best position is side-lying with the patient's knee flexed 90° with the hands cupped around the ankle, imparting an inversion force (**Figure 14-5B**). The talar tilt tests for integrity of the calcaneofibular ligament. The Kleiger test is an eversion test of the ankle.<sup>10</sup> With the patient seated on the examination table, the non-weight-bearing foot is everted out to test for the medial deltoid ligament complex.

The stabilizing function of muscles and the presence of tendinitis may be evaluated by basic resisted movement patterns coupled with stretch patterns. Also, resisting the movement pattern starting from the stretched position will reveal tendinitis not evident from neutral position testing.

- Dorsiflexion/eversion—mainly due to the peroneus tertius; stretching into plantarflexion/inversion may also increase pain.
- Dorsiflexion/inversion—mainly due to the tibialis anterior; stretching into dorsiflexion/eversion may also increase pain.
- Plantarflexion/eversion—mainly due to the peroneus longus and brevis; stretching into plantarflexion usually is more painful than dorsiflexion.

**Figure 14-5** (A) The anterior drawer test. With the knee flexed and the ankle flexed to 15°, the examiner stabilizes the tibia while pulling forward on the calcaneus. (B) Inversion test for lateral ankle stability.

- Plantarflexion/inversion—mainly due to the tibialis posterior; stretching into dorsiflexion may also increase pain.

Radiographic assessment of the ankle is primarily used to rule out associated fracture. Ankle injury is extremely common, yet only 15% of patients will be found to have a fracture. The authors of the study have estimated that approximately \$500 million is spent on ankle radiographs in the United States and Canada each year. According to this study, if the rules or guidelines were used, there could be an estimated savings of over \$100 million without loss of quality of care.<sup>11</sup> Due to many factors—including the fear of malpractice, patient demands, and habit—radiographs are ordered on the majority of patients. The team of physicians who designed the Ottawa Ankle Rules found that the only consistent (sensitive and specific) history and examination findings that were relevant were pain in the malleolar region and either (1) tenderness at either malleolus or (2) the inability to bear weight immediately after the injury or in the emergency department.

For the mid-foot, the relevant findings were pain in the mid-foot area and either (1) tenderness at the base of the fifth metatarsal, (2) tenderness at the navicular, or (3) the inability to bear weight immediately after the injury or in the emergency department (**Exhibit 14-1**).

No significant fractures were missed when these rules were used at two major hospital emergency departments or outpatient clinics evaluating more than 2,300 adults. A significant fracture is defined as greater than 3 mm in breadth. Many small malleolar tip fractures do not require casting or pinning.

Researchers in a recent study used a modified version of the Ottawa Rules, called the “Buffalo” Rule, which switched the site of tenderness from the posterior borders of the malleoli to the midline away from ligament attachments to

avoid false-positive responses.<sup>12</sup> Of 153 patients, there were six clinically significant fractures. Sensitivity for the ankle was 100%, with a specificity of 40%; specificity for foot fractures was 79%. There were no false-negative results. Potential reduction in ankle x-rays was 46%; for foot x-rays it was 79%. Standard views include an AP, a lateral, and a mortise view (AP with 20° of internal rotation of the foot). Stress views may be indicated when there is a need to distinguish between a single-ligament and a two-ligament injury. The talar tilt is the degree of opening between the tibia and talus when stressed into inversion as viewed on an AP view. More than 10° of tilt indicates injury to the anterior talofibular and calcaneofibular ligaments (positive predictive value between 85% and 99%).<sup>13</sup> The mortise view is helpful in revealing osteochondral fracture of the talus (seen less clearly on the straight AP view) and diastasis due to interosseous membrane rupture between the tibia and fibula.

## **The Heel**

The primary differential of plantar heel pain is between plantar fasciitis and fat pad syndrome. In patients with a history of rheumatoid conditions, radiographs may prove helpful in detecting characteristic changes, yet these conditions would rarely present solely as heel pain. The primary distinction between fat pad syndrome and plantar fasciitis is the location of tenderness. Fat pad tenderness is directly in the middle of the heel. This tenderness is decreased by squeezing the bottom of the heel together and pressing over the same tender area. By squeezing the heel together, the remaining fat pad is approximated, providing more cushioning; tenderness should decrease substantially. Plantar fasciitis is painful at the medial heel because of the attachment to the medial tuberosity of the

calcaneus. Pain or tenderness may be increased through passive tension. This is accomplished by dorsiflexing the first toe and, if not positive, adding dorsiflexion of the ankle. The pain with plantar fasciitis is often across the bottom of the foot along the medial longitudinal arch.

### **Exhibit 14-1 Schematic representation of the Ottawa Ankle Rules**

An ankle x-ray series is required only if there is any pain in the malleolar zone and any of these findings:

1. Bone tenderness at A  
or
2. Bone tenderness at B  
or
3. Inability to bear weight both immediately and in emergency department.

Reproduced from Stiell IG, Greenberg GH, McKnight RD, Wells GA. The “real” Ottawa Ankle Rules. *Ann Emerg Med.* 1996;27:103-104, with permission from Elsevier.

Radiographic examination is warranted if there is trauma such as landing on the feet, if the patient is an adolescent (Sever’s disease), or if there is a history of rheumatoid disease. Radiographs for plantar fasciitis are usually misleading because of the appearance of a heel spur. The heel spur is falsely accused of being the cause of the patient’s pain. Resolution of pain without changes in the spur is the usual course of events. It is believed that the spur is a consequence of plantar fascial tension rather than a cause of plantar fasciitis.<sup>14</sup>

## Management

### Traumatic Injury

- Most fractures of the foot and ankle should be referred for reduction and casting; some exceptions include small, nondisplaced avulsion fractures at the fifth metatarsal or lateral malleolus (period of immobilization may be needed) and most toe fractures, which can be buddy-taped for two to three weeks.
- Sprains of the MTP capsules can be managed with appropriate taping, mild mobilization, and support.
- Ankle sprains are managed based on the degree of injury. Even full-ligament rupture (third-degree) can be managed conservatively with a cast and graduated return to weight-bearing and activity, although comanagement or previous experience is suggested prior to following this approach (**Table 14-3**).

### Overuse and/or Biomechanical Injury

- Overuse injuries are often treated symptomatically with ice, myofascial stretching, and modification of activity; long-term management includes modification of footwear, terrain, maintenance of proper accessory motion, functional training of supportive muscles focusing on eccentric or concentric needs, and possible prescription of orthotic support.
- Stress fractures can be managed by immobilization with non-weight-bearing for two to six weeks, depending on activity level; aerobic conditioning may be continued with non-weight-bearing activities (e.g., pool running).

**Table 14-3** Ankle Inversion Sprain Rehabilitation

Parameter	Acute Stage	Subacute Stage	Chronic Stage
<b>Criteria</b>	Lateral ankle swelling is dependent on degree of injury; pain and possible instability found with ankle inversion stress; radiograph to rule out fracture.	Swelling has decreased; some lateral ankle pain with inversion stress.	No swelling, mild lateral ankle pain on inversion stress.
<b>Goals</b>	Reduce swelling and pain; avoid full weight-bearing.	Progress to full weight-bearing through the use of crutches and ankle support (Air-Splint, taping, or brace).	Proprioceptively stabilize the ankle; correct any underlying predispositions; consider taping with aggressive sport activity.
<b>Concerns</b>	Possible fracture of tibia, fibula, talus, metatarsals; bifurcate ligament rupture; peroneal tendon dislocation.	Talar dome fracture not evident on radiograph.	Too early a return to sports activity; during restrengthening athlete needs external support.
<b>Requirements for progression to next stage including approximate time needed</b>	Partial weight-bearing possible; reduction in swelling and pain; 1–3 days.	Full weight-bearing without crutches; no swelling evident; full ROM 2–3 days.	Able to balance on one leg and hop on one leg without pain; 1–2 weeks.
<b>Manipulation/mobilization</b>	Based on the degree of injury; general talar or tibial adjustment (opposite position of injury-dorsiflexion/eversion) may assist.	General talar or tibial adjustment may assist.	Determine need for navicular, cuboid, calcaneal, and talar adjusting.
<b>Modalities</b>	Ice 3–5 times/day for 20 minutes (1 hour in between); rest, elevation, TENS or EMS (high-volt galvanic at 80–120 Hz with ice for 20 min/1–2 times/day).	Ice after activity; combination ultrasound/EMS at 1.0 watt/cm <sup>2</sup> , 1–15 Hz for 6–8 minutes.	Ice after activity.
<b>External brace, support, etc.</b>	Air-Splint or open Gibney type of ankle taping, or Unna boot splint; crutch walking with toe touching only.	Air-Splints or lace-up brace; patient weaned off crutches after 1–2 days of gradual weight-bearing.	Figure-of-eight elastic bandage support with walking if necessary; taping for sports activities.
<b>ROM/flexibility</b>	Mild passive ROM.	BAPS board begun with the patient seated; postisometric relaxation approach to stretching.	Continue stretching with postisometric approach.
<b>Open-chain exercise</b>	Mild isometrics in neutral.	Isometrics at end-range into dorsiflexion and eversion; passive PNF diagonal patterns; side-lying straight leg raises for peroneals and hip abductors.	Elastic tubing exercises for dorsiflexors and evectors; resisted PNF diagonal patterns.
<b>Closed-chain exercise</b>	None.	Gradual two-legged toe raises and half squats	Toe raises against resistance.
<b>Proprioceptive training</b>	Toe touching with crutch use.	Consider weight-bearing with TENS application; taping or support acts as a proprioceptive stimulus.	Progression to weight-bearing exercises on BAPS (wobble) board; follow progressive training.

Associated biomechanical items	Check for weakness of hip abductors; evaluate for pronation or supination.	Shoes should contain a rigid heel counter; orthotic prescription should be performed if deemed necessary and swelling has decreased enough for casting.	Orthotic fitting.
Lifestyle/activity modifications	Crutch walking only for first 1–3 days with grade 2 injuries.	Crutch walking should involve partial weight-bearing, continuing to elimination of crutch use.	Stretch prior to activities such as running and jogging.

Key: ROM, range of motion; TENS, transcutaneous electrical nerve stimulation; EMS, electrical muscle stimulation; BAPS, biomechanical ankle platform system (Medipedic [Jackson, Michigan]); PNF, proprioceptive neuromuscular facilitation.

## Preventive Management

- Preventive management for ankle sprains includes isometric training of the peroneals, hip abductors, and tibialis anterior with stretching of the Achilles; proprioceptive training using taping, proprioceptive neuromuscular facilitation (PNF) techniques, or balance exercises with balance boards.
- Patient education regarding proper selection of shoes and foot hygiene is an important tool by which to avoid future problems.

An in-depth discussion of shoe design and prescription is beyond the scope of this text; however, some basics can be reviewed (**Figure 14-6**). The commonly used terminology and maxims for shoe construction are as follows:

**Figure 14-6** The basic structure of an athletic shoe.

- The heel counter should be deep and firm to provide stability and cushioning.
- The shank should be strong and should not deform with weight-bearing (the shank represents the portion on the bottom of the shoe that corresponds to the medial longitudinal arch).
- The toe box should be spacious enough to avoid compression of the metatarsals.
- The shoe should be long enough to avoid compression of the toes at the end of the toe box.
- If used in a sporting activity, the shoe should be specific to the sport.

The mold upon which the shoe is constructed is referred to as the *last*. There are essentially two types, straight last and curved last. The straight last is a better design for the pronated foot. The curved last design is for a forefoot angled medially. This shoe design is better for the supinated foot and/or those with hallux valgus. There are generally three types of last construction: (1) the board-lasted shoe,

(2) the slip-lasted shoe, and (3) the combination-last shoe (**Figure 14-7**). When a patient's foot is severely pronated, the board-lasted shoe is usually best because of the support provided by a hard fibrous material placed on the inner surface of the shoe. The slip-lasted shoe is constructed by stitching the upper into a one-piece moccasin and then gluing it to the sole. This provides a lighter, more flexible shoe; however, it has less stability. This shoe construction is probably better for the cavus foot. The combination-last shoe combines a board-lasted heel with a slip-lasted forefoot, the best of both worlds. This shoe construction is best for those with rearfoot varus or mild pronators.

**Figure 14-7** Types of shoe construction: (A) board-lasted shoe, (B) slip-lasted shoe, (C) combination last shoe.

A prescription for orthotics is often given to the patient with foot pain. An orthotic is a device that is usually placed in the shoe to accommodate for biomechanical abnormalities or to cushion painful areas. The biomechanical orthotic can be constructed according to individual need or purchased as an off-the-shelf product. The type of orthotic is often based on the seriousness or complexity of the problem and the patient's ability to

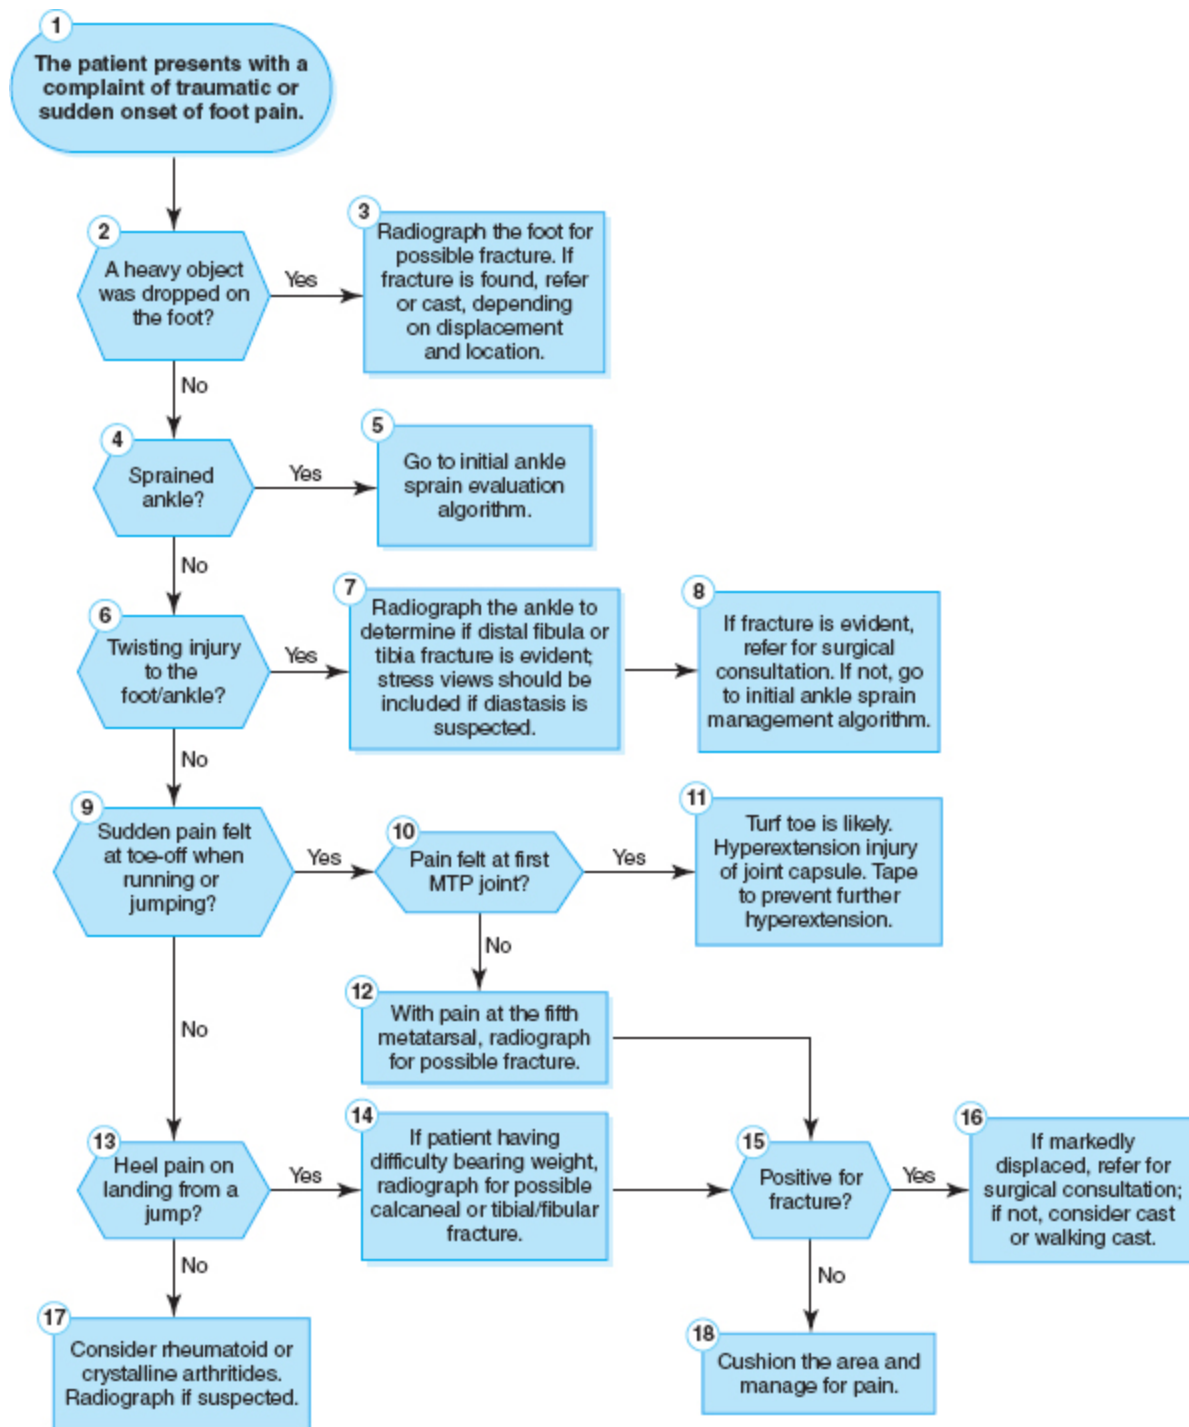

purchase the product. The three common types of customized orthotics are the non-weight-bearing, casted orthotic; non-weight-bearing, vacuum-applied orthotic; and weight-bearing foam impression orthotic. There is much emotional debate as to the best way to cast the feet. The foam impression orthotic supporters claim that it is a “functional” orthotic giving an individual impression of the patient’s foot in a closed-packed position. The argument against this approach is that the feet are casted in an imperfect position and allowed to splay and elongate with weight-bearing. The non-weight-bearing cast proponents claim that the foot is casted in the neutral “perfect” position and that the type of orthotic and the measurements used in the prescription allow for more individualized approaches through the use of forefoot and rearfoot posting. Also, if the individual has exostosis, bunions, or other abnormalities, the orthotic can be modified to accommodate.

There are generally two types of posting, rearfoot and forefoot. A rearfoot varus (medial) post is used to control or limit the calcaneal eversion and associated internal rotation of the tibia shortly after heel strike. Of course, the opposite principle is used for rearfoot valgus (lateral) posting; it is used to evert the calcaneus and therefore bring the subtalar joint closer to the optimal neutral position. Forefoot varus may be compensated for by a medial post, whereas forefoot valgus is best supported by a lateral post. This is particularly helpful when rearfoot compensation occurs to accommodate for forefoot abnormalities. Heel lifts are occasionally used for problems involving the Achilles tendon. When the Achilles tendon is tight, it may augment the effect of rearfoot problems. The use of a heel lift (3 to 6 mm) may decrease the tension of the Achilles and therefore its effect on rearfoot motion. A partial heel lift, referred to as a medial or lateral wedge, may also be used temporarily as an insert to test the feasibility of posting for patients who

are reluctant to purchase the more expensive casted orthotic.

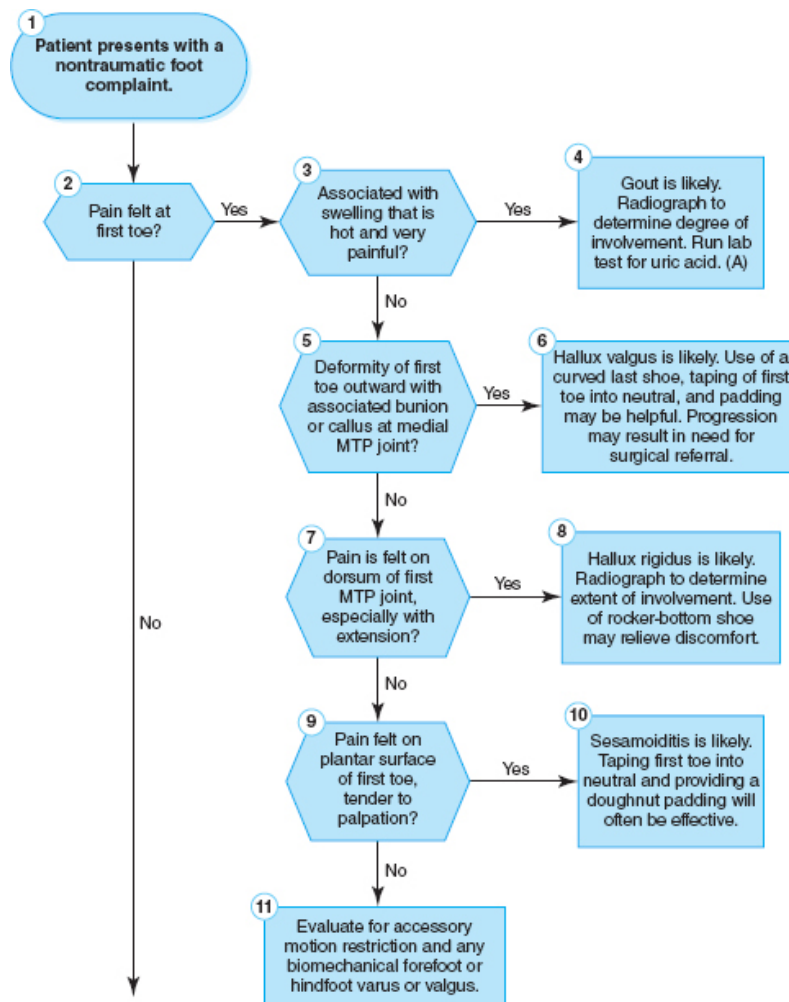

## Algorithms

Algorithms for traumatic or sudden onset of foot pain, nontraumatic or insidious onset of foot pain, and initial ankle sprain evaluation are presented in **Figures 14-8** through **14-10**.

**Figure 14-8** Traumatic or Sudden Onset of Foot Pain—Algorithm

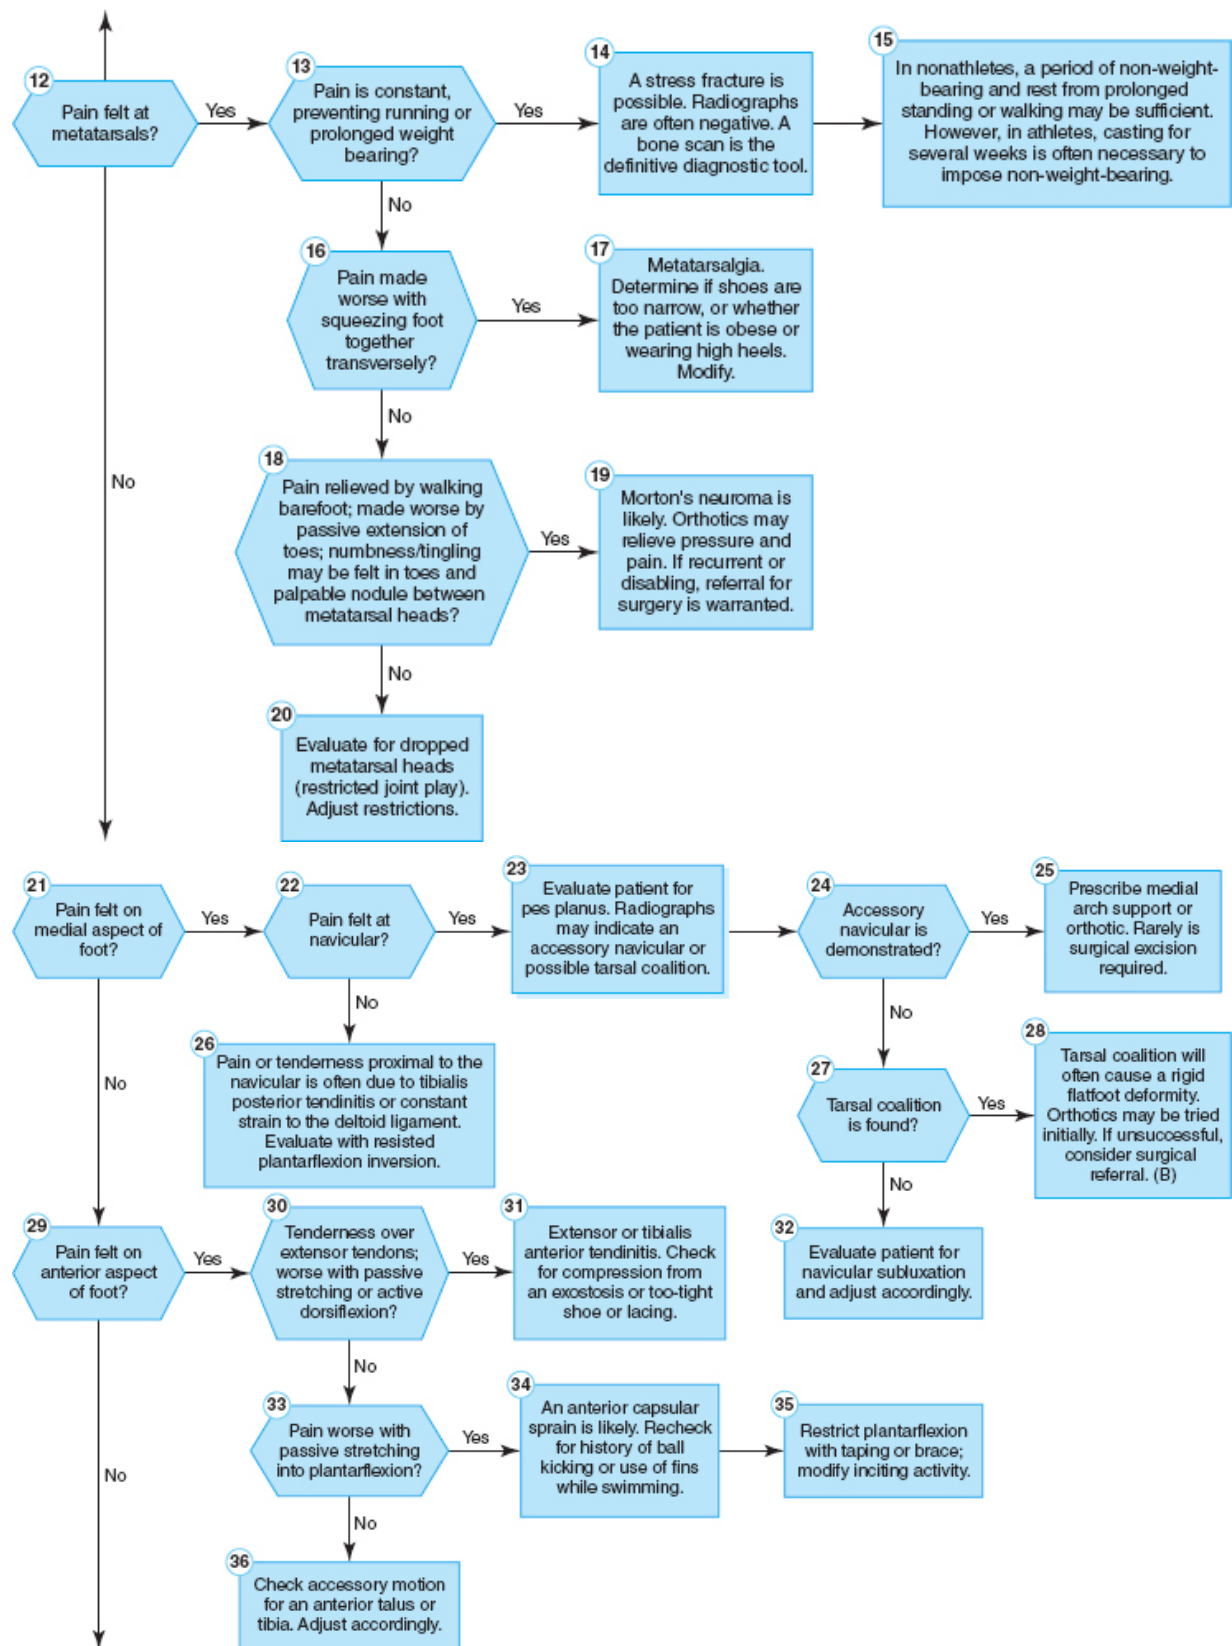

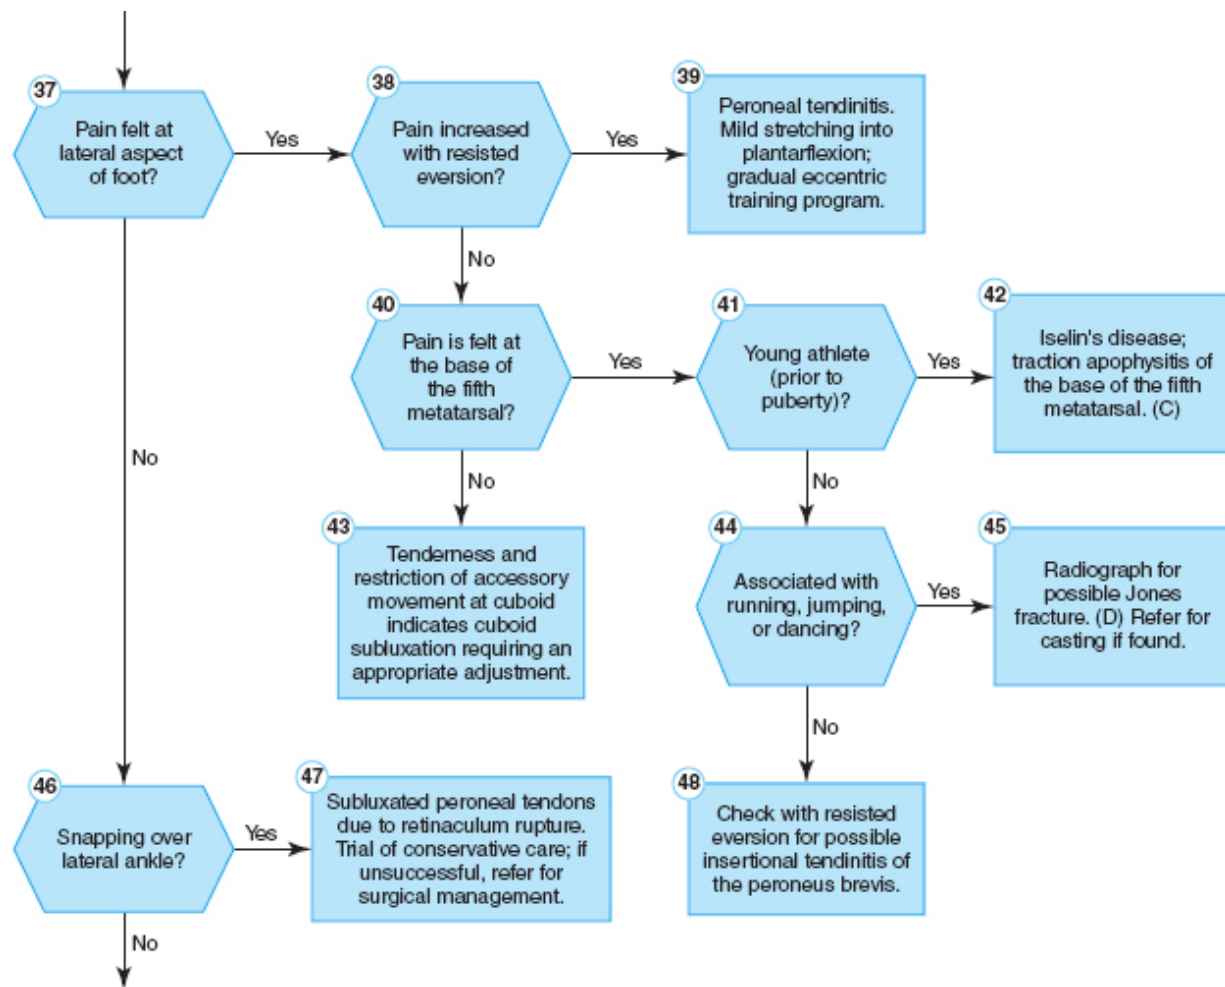

#### Annotations

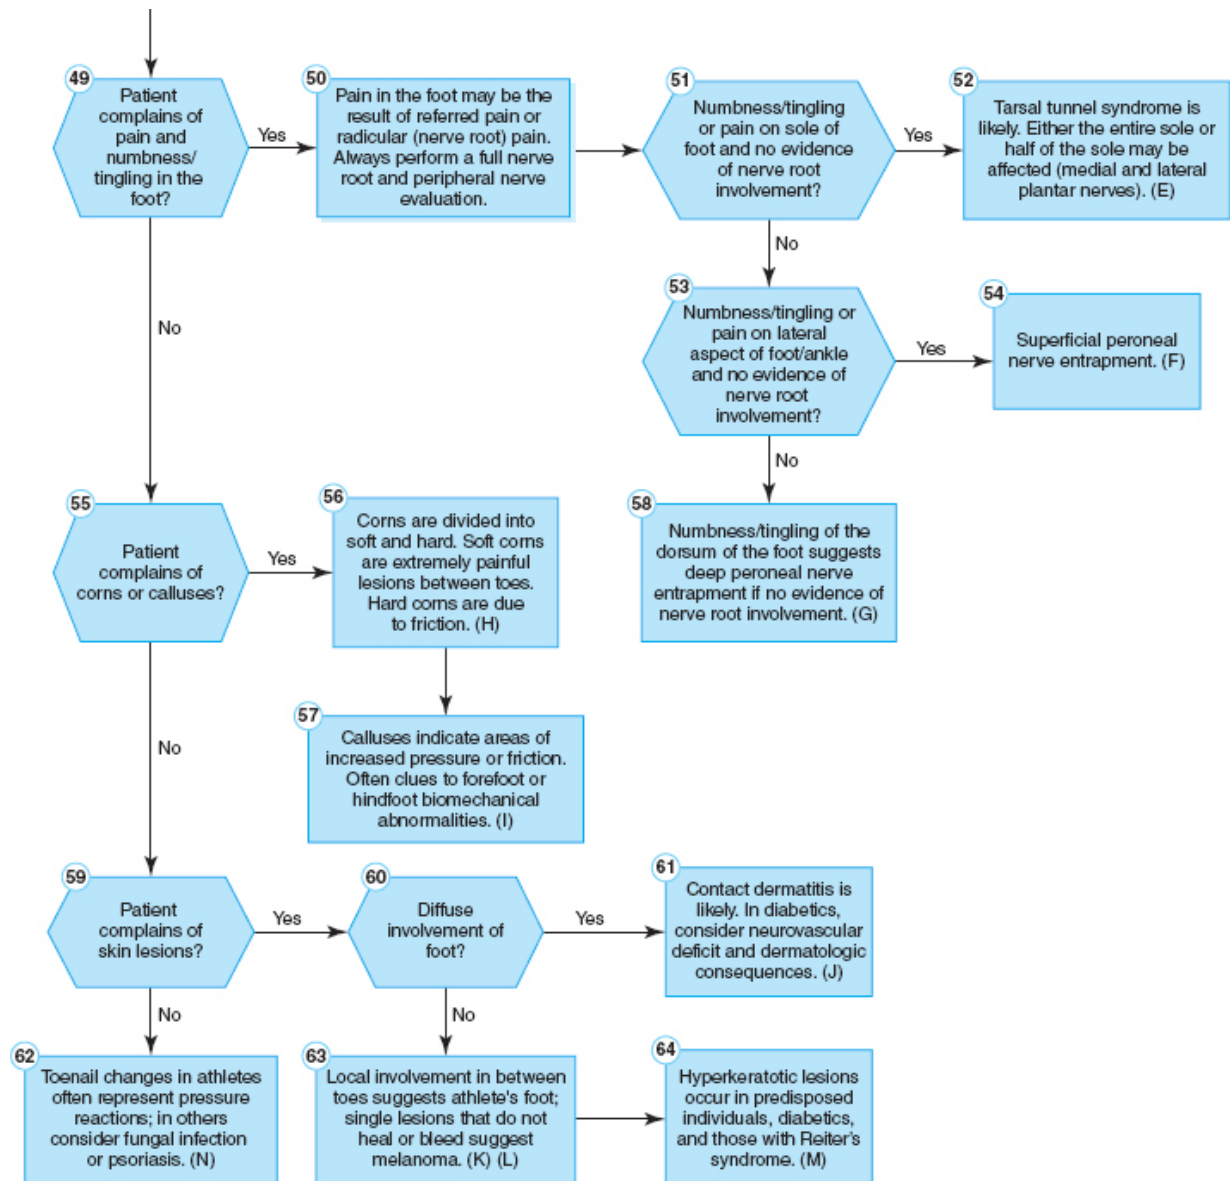

- A. Gout is a metabolic disease associated with excessive urates in the body. Deposition of urate crystals at the first toe (podagra) causes an acute inflammatory reaction. Late changes on radiograph include punched-out areas (radiolucent urate tophi).
- B. Tarsal coalition is a congenital condition where fibrous, cartilaginous, or osseous bridging occurs between two or more tarsal bones. CT is often needed to visualize because many coalitions are not ossified. A flat-foot deformity due to coalition may be responsive to orthotics, but the success rate is not high; surgery is often needed in active individuals.
- C. Iselin's disease is a traction apophysitis of the base of the fifth metatarsals. It is a rare disorder that, like Osgood-Schlatter disease of the knee, responds to taping or other support, and modification of the inciting activity.
- D. A distinction must be made between Jones fractures and avulsion fractures. Avulsion fractures are usually due to inversion ankle sprains where the peroneus brevis may avulse part of the base of the fifth metatarsal. These are relatively stable and displacement is small. Transverse or Jones fractures are usually slightly distal to the base and are known for a higher potential of nonunion.

continues

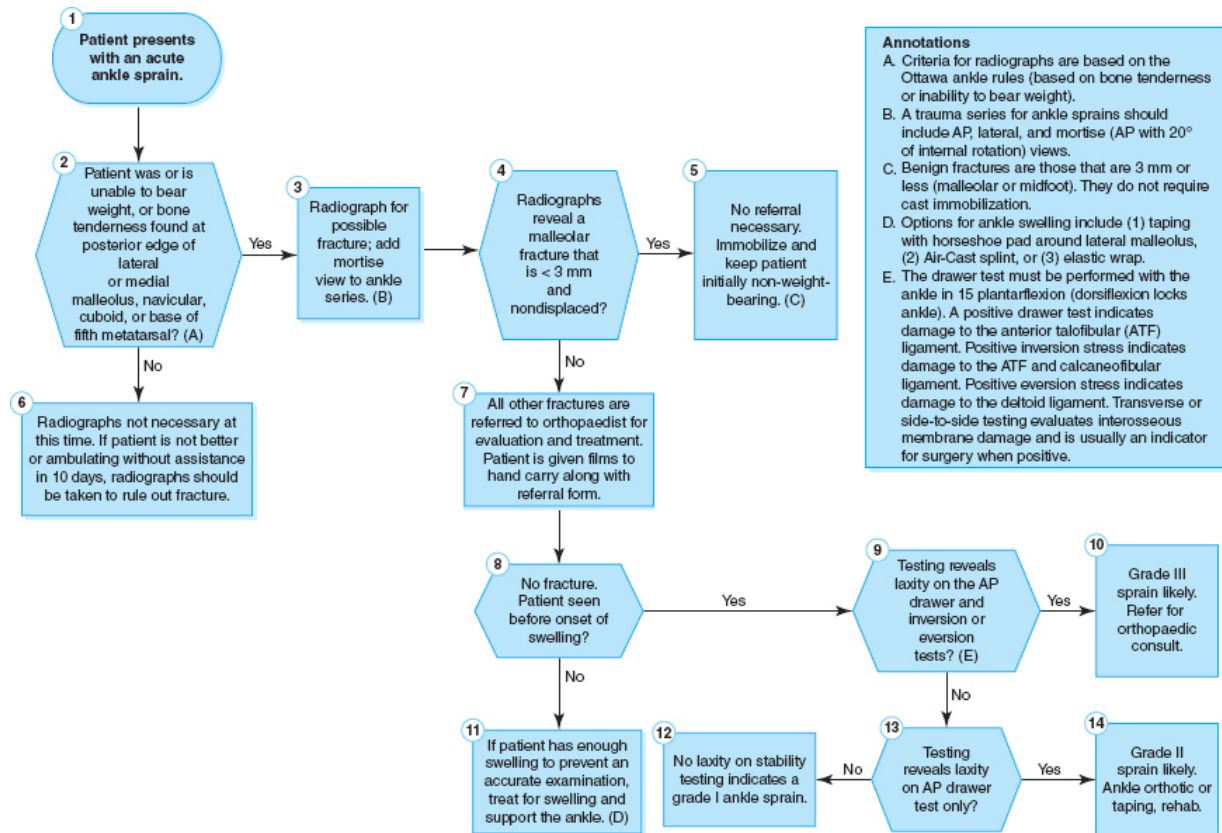

**Annotations (continued)**

- E. Tarsal tunnel syndrome may be due to trauma or hyperpronation. Orthotic management with appropriate foot manipulation is usually effective. However, surgical decompression may be necessary with causes other than pronation.
- F. Involvement of the superficial peroneal nerve is usually due to ankle sprains. If orthotic support is ineffective, refer for lidocaine/cortisone injection.
- G. The deep peroneal nerve may be compressed by tightly laced shoes or talar osteophytes. Shoe modification may be effective. Talar osteophytes may need surgical excision.
- H. Hard corns are seen with hammer toes and claw toes; especially at the fifth toe. Treatment involves paring and padding the area, and shoe modification.
- I. Calluses under the first metatarsal head is found with forefoot valgus; under the second, third, and fourth with forefoot varus.
- J. The diabetic foot is prone to vascular insufficiency and infection. Neurologic compromise often eliminates the painful warning needed to alert the patient to a problem.
- K. Athlete's foot is a fungal infection that occurs mainly in the lateral toeweb. Made worse by toe approximation from shoes, warm weather, and activity. Try OTC drugs first. Keep feet dry and use shoes that can aerate.
- L. Malignant melanoma is rare; however, any bleeding lesion or nonhealing lesion requires dermatologic referral.
- M. Hyperkeratosis may be hereditary or acquired. Fissures may develop and predispose the diabetic to infection. Fissures may be glued together (Krazy glue); general treatment is with topical keratolytics and buffing away thick layers.
- N. When the shoe box is too tight, pressure on toenails may result in "black" toenails or other changes. Psoriatic involvement usually occurs on all the toes. Fungal infection usually occurs with "skipped" normal nails.

**Figure 14-9** Nontraumatic or Insidious Onset of Foot Pain—Algorithm

**Figure 14-10** Initial Ankle Sprain Evaluation—Algorithm

# Selected Foot Disorders\*

## FIRST TOE

### Sesamoiditis

## Classic Presentation

The patient presents with pain on the bottom of the great toe. He or she may remember the onset occurring while pushing-off with the toe or after forced dorsiflexion.

## Cause

Either direct trauma or overpull from the flexor hallucis brevis may cause irritation of the sesamoids. The sesamoids serve as anchors and help to form the pulley for the flexor hallucis longus. They are the attachment points for the flexor hallucis brevis and adductor hallucis and abductor hallucis.

Predisposition to sesamoiditis appears related to concomitant hallux valgus, too-flexible footwear, and repetitive running or walking on hard surfaces.

These small bones may be associated with many processes, including a local bursitis, chondromalacia, fracture, stress fracture, bipartite development, OA, and secondary involvement with collagen/vascular, rheumatoid, or gouty processes.

## Evaluation

Tenderness is felt at the plantar surface of the first MTP joint. Of the two sesamoids, the medial is often involved and more tender to palpation.<sup>15</sup> This is particularly evident when the first toe is passively dorsiflexed. Radiographs may reveal an underlying process such as a stress fracture, osteochondritis, bipartite sesamoids, or OA.

## Management

The treatment for sesamoiditis is to tape the toe to prevent dorsiflexion and to use initially a doughnut-shaped padding to relieve direct pressure on the sesamoids. If there is an associated hallux valgus, it may be helpful to tape the great toe into adduction. Preventive measures are to determine the need for a less flexible shoe and recommend against playing or working on hard surfaces if this is a viable option. There are surgical procedures, but they are rarely needed.

## **Hallux Valgus**

### **Classic Presentation**

The patient presents with a complaint of deformity and pain on the medial side of the first MTP joint. The patient often is a middle-aged woman.

### **Cause**

Hallux valgus involves lateral deviation (abduction) of the proximal phalanx of the first toe. There is a strong hereditary component with accelerating factors such as forefoot varus, Morton's deformity, inflammatory arthritis, and the frequent wearing of high heels. The deviation causes pressure to occur at the first MTP joint with subsequent development of a localized bursitis and bunion formation. Further deviation creates a sling effect whereby pull of the flexor hallucis longus and brevis and extensor hallucis longus tendons creates more deviation.<sup>16</sup>

### **Evaluation**

The deformity is apparent, with the first toe deviating outward and the medial MTP joint visibly enlarged. If there is an apparent inflammatory process occurring or a history of a rheumatoid condition, a radiograph may be necessary.

### **Management**

When deviation progresses, the patient must decide whether or not to have surgery. There are many different types of surgeries, and the recovery time with each varies. Conservative options are usually an attempt to slow the process of deviation. Taping to bring the first toe into neutral and padding over the bunion area are often tried first. Keeping the joint mobile with adjustments may be beneficial. Additional approaches include paring down

the bunion, buying shoes with larger toe boxes, and avoiding the wearing of high heels. Some practitioners suggest a restraining device worn during sleep.

## **Hallux Rigidus**

### **Classic Presentation**

The patient presents with first toe pain felt on the dorsal surface. The patient is usually elderly or may be an athlete with repetitive capsular sprains.

### **Cause**

Osteoarthritic and capsular changes occur at the first metatarsal joint as a result of aging or repeated capsular sprains.<sup>17</sup> Other causes may be an underlying inflammatory arthritic or systemic disease. When this process occurs at other metatarsal heads, it is referred to as Freiberg's infraction—aseptic subchondral cancellous bone necrosis. Hallux rigidus is analogous to or may be Freiberg's infraction of the first toe.

### **Evaluation**

The patient has decreased flexion and extension at the first MTP joint. Pain is reproduced with motion, especially into dorsiflexion. A dorsal bunion also may be evident. Radiographically, there is often a dorsal ring of osteophytes at the metatarsal head.

### **Management**

Mobilization may free up some motion at the joint. The mainstay of conservative management is the use of a stiff-soled shoe or a rocker-bottom shoe that artificially creates toe-off through a rounded metatarsal bar. Failure to resolve usually requires surgical excision of the osteophytes.

## **Turf Toe**

### **Classic Presentation**

The patient often is an athlete complaining of first toe pain especially when the toe is bent back. There may be a history of a trauma that forced the toe into dorsiflexion.

## Cause

Turf toe is a sports term for a hyperextension (dorsiflexion) injury of the first toe. The plantar capsule of the MTP joint is sprained.<sup>18</sup> The cause is either sudden dorsiflexion or chronic dorsiflexion through wearing shoes that are too flexible. It may also occur as a result of trips or falls. A similar condition found with sports played on sand, such as beach volleyball, involves forced plantarflexion that causes a sprain of the dorsal capsule (sand toe). Here the toes are rolled under during the injury.

## Evaluation

The evaluation is rather straightforward with a suggestive history and pain on dorsiflexion (or plantarflexion with sand toe).

## Management

Treatment involves taping of the toe to prevent the aggravating movement pattern and the use of stiff-soled shoes. If these are not successful, immobilization in a cast for several days may be necessary.

## Gout

## Classic Presentation

The patient is usually middle-aged or older complaining of an acute attack of first toe pain. The toe appears swollen and red.

## Cause

Gout is a metabolic disease characterized by retention of urates in the body. The urates accumulate in various body sites as crystalline depositions referred to as tophi. These serve as irritative foci, causing an inflammatory arthritis with eventual bone destruction after repeated attacks. Tophi are deposited in the first toe, the knee, the olecranon bursal area, and behind the

ears. Gout can be secondary to other conditions that interfere with renal clearance, such as chronic renal disease, multiple myeloma, and diuretic use.<sup>19</sup>

## Evaluation

The location of pain and the severity of this monoarticular attack usually make the diagnosis clear. When acute, the joint is red, swollen, and very tender. Laboratory evaluation often will demonstrate a high uric acid level, especially in the acute phases ( $> 7.5$  mg/dL). Early radiographic changes may not be visible. Later changes include punched-out areas in bone (urate tophi are radiolucent). Identification of urate crystals in joint fluid or tophi gives the definitive diagnosis.

### Management

During acute attacks, the use of nonsteroid anti-inflammatory drugs is the most effective treatment. Prophylactic management involves avoidance of specific foods or alcohol that appear to incite attacks; however, the general contribution of a diet high in meat is less important than once believed. One of the most important measures is consistent maintenance of a high fluid intake (not diuretic liquids such as coffee, tea, or sodas) and avoidance of diuretic medication. Medication strategy varies depending on the suspected cause. Allopurinol blocks xanthine oxidase, reducing uric acid formation, whereas colchicine inhibits the inflammatory reaction to urate crystals but does not lower uric acid levels.<sup>20</sup>

## METATARSALS Metatarsalgia

### Classic Presentation

The patient complains of pain on the bottom of the foot, specifically at the sole.

### Cause

Metatarsal pain may be due to a number of factors. It appears that chronic stretching of the transverse ligaments may be the underlying reason.<sup>21</sup> This may be the result of excessive weight, repetitive activity, hammer toes, or pes planus or cavus. Direct trauma from jumping or landing on the toes with running or jogging, or standing for long periods of time in high-heeled shoes may contribute to metatarsal pain. Shoes with too narrow a toe box will also

cause compression and pain. Subluxated metatarsal heads may be the cause or part of the problem.

## Evaluation

Increased stress at the metatarsals may be evident with calluses or corns (especially over the second metatarsal head). Evaluate the foot for pes planus/cavus, “dropped” metatarsal heads, and toe deformity.

## Management

Remove or modify any underlying problems such as repetitive trauma or inappropriate footwear. During the acute phase, use of a metatarsal pad placed just proximal to the metatarsal heads, leaving room for the first and fifth metatarsal heads, is often successful. Local ultrasound may also be of some benefit. Adjustment of metatarsal heads is warranted when restricted movement is determined.

### Morton’s Neuroma

## Classic Presentation

The patient complains of pain on the bottom of the sole. The onset was insidious. The patient notices less pain when barefoot.

## Cause

The process often begins as an entrapment neuropathy with progressive degeneration and deposition of amorphous deposits on the nerve fibers.<sup>22</sup> Entrapment occurs most commonly on the plantar surface by the intermetatarsal ligament.

## Evaluation

There is pain often in the second or third intermetatarsal space. Occasionally, a mass may be palpated in this space, representing the neuroma. Although transverse compression may increase the pain, it is nonspecific (other causes could include a stress fracture or subluxation). Passive extension of the MTP joints or interphalangeal joints may increase pain or create a sense of

numbness/tingling or burning into the related toes. Plantarflexion of the joints often will relieve this response.

## **Management**

Conservative management includes forefoot mobilization and a temporary metatarsal pad. If unsuccessful, casted orthotics may be of benefit. Acute management also may include the use of phonophoresis with cortisone (if allowed by individual state law). Preventive measures are to buy shoes that are long enough to prevent cramming of the toes and to ensure a proper-sized toe box and forefoot areas. Surgical excision is an option in recalcitrant cases.

## **Stress Fractures**

### **Classic Presentation**

The patient presents with a complaint of rather constant pain of the forefoot, especially with weight-bearing. There is almost always a history of prolonged walking or running.

#### **Cause**

Stress fractures occur over time when the bone resorptive process exceeds osteoblastic activity. This will occur when constant stressors are applied without sufficient unstressed periods to heal or when the stresses consistently exceed the structural integrity of the bone. The second metatarsal is most affected because of its length and position in serving as a biomechanical axis.

### **Evaluation**

The bone may be tender to touch and pain may be increased with squeezing the foot together. Tuning fork evaluation probably will not significantly increase pain. The high level of suspicion based on the history and the location of the pain warrants radiography, but it is usually unrevealing. A bone scan is the definitive tool in detecting stress fractures, revealing an increased uptake at the fracture site.

## **Management**

For a nonathlete, it may be sufficient to use a stiff shoe or rigid orthotics for several weeks. If pain persists, non-weight-bearing with crutches for a few

weeks is necessary. For the athlete, it may be necessary to prescribe a walking cast or to cast the foot in order to impose a non-weight-bearing period for several weeks. Calcium intake should be increased during this period, and long-term bone status should be evaluated in serious female athletes.

## **Fifth Metatarsal Fractures**

### **Classic Presentation**

The patient often will complain of a sudden onset of lateral foot pain following an inversion ankle sprain. Other patients may report sudden lateral foot pain during running or jumping.

### **Cause**

There are generally three types of fractures possible. The least common is a spiral fracture. An avulsion fracture of the styloid process of the base of the fifth metatarsal is usually the result of a sudden peroneus brevis pull during an inversion ankle sprain. A transverse fracture of the proximal diaphysis of the fifth metatarsal (Jones fracture) is usually due to repetitive stress.

### **Evaluation**

There is point tenderness and pain at the proximal fifth metatarsal. The definitive diagnosis is radiographic.

### **Management**

Avulsion fractures usually heal well with the symptomatic treatment of the associated ankle injury. There is a caution that if there is wide displacement of the fragment, a painful bump will form. Therefore, displacement necessitates an orthopaedic consultation. Transverse fractures have a reputation for nonunion.<sup>23</sup> If the patient is placed early enough in a short leg cast for six to eight weeks, healing usually will be acceptable; delayed healing, however, may require as much as three months of casting. Spiral fractures should be referred for orthopaedic consultation because of the variety of rotational patterns that affect the healing process; however, it has been demonstrated that nonsurgical management is often possible.<sup>24</sup>

## **OTHER CONDITIONS Osteochondrosis of the Navicular**

### **Classic Presentation**

The patient is usually a child (average age of six years) who complains of inner foot pain. The parent reports that the child walks on the outer side of the foot.

### **Cause**

The cause of this condition is still being debated. Some authors believe that it is a normal variant of ossification; others think that it is an avascular necrosis. There may be a history of trauma. It is also referred to as Köhler's disease.

### **Evaluation**

There may be tenderness at the navicular. The definitive diagnosis is radiographic. The bone will appear more radiopaque and underdeveloped. These radiographic changes develop over two to four years.

### **Management**

The symptomatic presentation often self-resolves in three to nine months.<sup>25</sup> During this period, use of arch supports will often relieve the discomfort. In rare cases, a below-knee walking cast is required. The natural history of the disorder is entirely benign with no apparent increase in degenerative joint disease.

### **Fat Pad Syndrome**

### **Classic Presentation**

An older individual presents with a complaint of heel pain. The pain is in the middle of the heel; it is much worse with weight-bearing.

### **Cause**

As an individual ages, the fat pad on the bottom of the heel degenerates, leaving little shock absorption for the calcaneus. Shoes that do not have firm heel counters and/or are too wide allow the remaining fat pad to flatten out, decreasing the thickness and therefore shock absorption.<sup>26</sup>

## Evaluation

Pain and tenderness are found in the middle of the heel. When the fat pad is supported on either side and pressure is reapplied, the pain is decreased. Plantar fasciitis is more often at the medial aspect of the calcaneus, not in the middle. Stretching of the plantar fascia or dorsiflexors of the first toe or ankle does not increase pain with fat pad syndrome. Radiographs are rarely needed unless the patient is not responsive to care.

## Management

Both support of the remaining fat pad and substitution of the pad are the two approaches used. Use of various heel cups may be helpful. The heel cup is often made of shock-absorbent material and provides some medial/lateral support. Some patients do better with a more rigid support in the heel counter of the shoe to prevent splaying of the fat pad. Misdiagnosis of plantar fasciitis is common, so many patients are subjected to unnecessary cortisone injections and surgery.

### Plantar Fasciitis

## Classic Presentation

The patient complains of a sharp heel pain that radiates along the bottom of the inside of the foot. The pain is often worse when getting out of bed in the morning.

## Cause

Either pronation or supination may be the cause. The flatfoot (hyperpronation) with associated forefoot abduction has a stretching effect on the plantar fascia, leading to repetitive tension overload. The high-arched foot (supinated) is relatively rigid. Forces usually absorbed through movement of the foot and ankle are transmitted to the plantar fascia and lower leg. In this way plantar fasciitis can be analogous to shin splints.

# Evaluation

Pain or tenderness is increased with direct pressure over the medial tubercle of the calcaneus (the fascial insertion). This pain often will radiate along the bottom of the foot. It is also possible to reproduce the pain through stretching of the first toe into dorsiflexion alone or coupled with dorsiflexion of the ankle. Plantar fasciitis is estimated to be found in 10% of runners. A calcaneal spur is found in 50% of patients, but also found in 10% to 27% of asymptomatic patients; symptoms may be bilateral in 10%. More than 80% improve within 12 months regardless of type of care. Radiographs usually are not necessary. Although heel spurs often are seen, they are not the cause but the reaction to chronic fascial tension.<sup>27</sup> Laboratory testing is reserved for patients with known rheumatic disease or a situation where suspicion is raised by other joint complaints.

# Management

Support of any underlying biomechanical predispositions includes orthotics for pronation or supination. This is based on the frequency of pain or the degree of incapacitation when pain does occur. Temporary solutions include taping the arch for support (low-dye taping) and gradual stretching. Myofascial release to the plantar fascia may be helpful. Underwater ultrasound coupled with stretching appears to be effective in many cases. Adjusting of any foot subluxations (especially navicular and first MTP joint) and strengthening of foot-support musculature should be a part of the treatment plan. Ninety-five percent of patients respond to conservative care.<sup>28</sup>

Several treatment approaches have gained popularity, including the use of magnetic insoles and the use of shockwave therapy (similar to lithotripsy for kidney stones). A recent randomized, controlled trial on the use of magnetic insoles found that there was no difference between patients wearing magnetic insoles and those wearing sham-magnetic insoles.<sup>29</sup>

A recent study involved researchers testing the use of shockwave therapy for plantar fasciitis.<sup>30</sup> A “placebo” group was treated with a less-than-therapeutic intensity. Five prior studies indicated good results; however, in this randomized, controlled trial, both groups improved at 6 and 12 months measured by pain, function, and an SF36. The researchers concluded that there was no difference between the sham treatment and “real” treatment over a one-year period. The question that still exists is whether short-term relief may be an advantage of shockwave therapy, returning patients to a more functional, pain-free level sooner than 12 months. A more recent study<sup>31</sup> indicated that there was a small difference in improvement over time with about 61% of patients treated with shockwave therapy versus 42% of patients with placebo who improved over a couple of months. Various injectables are utilized in an attempt to solve long-standing plantar fasciitis

problems. There seems to be some emerging evidence for the use of platelet-rich plasma (PRP) for the management of chronic plantar fasciitis.<sup>32,33</sup> This injection of platelet concentrated autogenous fluid might provide the ingredients for better healing. More studies are needed.

## **Tarsal Tunnel Syndrome**

### **Classic Presentation**

The patient complains of numbness and tingling across the bottom of the foot, often at the sole or first toe. The onset is insidious and not associated with low back or leg pain.

### **Cause**

The posterior tibial nerve may be stretched or compressed in the tarsal tunnel, a fibro-osseous tunnel formed by the flexor retinaculum, calcaneus, distal tibia, and malleolus. The contents of the tunnel include the tendons of the posterior tibialis, flexor digitorum longus, and flexor hallucis and the posterior tibial artery, vein, and nerve. Due to highly variable anatomy, the distal branches of the posterior tibial nerve (the medial calcaneal, medial plantar, and lateral plantar nerves) may be selectively affected.<sup>34</sup> Hyperpronation is often the cause of tarsal tunnel syndrome due to tightening of the flexor retinaculum or arch of the abductor hallucis. However, trauma, swelling, ganglions, and anatomic variation of blood vessels or the abductor hallucis may also cause compression.

### **Evaluation**

Neurologic testing for nerve root involvement is negative. Numbness and tingling may be reproduced by percussion over the posterior tibial nerve just behind the medial malleolus (Tinel's sign) or along a line that continues to the navicular tuberosity, continuing down into the medial arch. In one study that evaluated patients with documented tarsal tunnel syndrome, 45% reported numbness, 39% reported pain, and 16% reported both.<sup>35</sup> Symptoms were produced in 82% of patients, usually within 10 seconds, by applying a passive dorsiflexion of the ankle and toes with eversion of the ankle. This testing approach may be a helpful addition to standard Tinel testing. Sensory deficit may occur in the medial (medial plantar nerve) or lateral (lateral plantar nerve) plantar surface of the foot. Usually two-point discrimination is decreased or hypoesthesia to pinprick are found. Motor weakness is less common. With difficult cases, nerve conduction studies may be needed.

# Management

If trauma or swelling is involved, the initial course of care is to reduce the swelling with ice, compression, elevation, and physical therapy modalities. If pronation appears to be the cause, a trial use of orthotics will often solve the problem. Associated adjusting of restricted navicular, calcaneal, or talar movement may be beneficial. If a trial of several weeks is unsuccessful, referral for podiatric consultation is suggested for possible need of surgical release of the retinaculum or excision of a ganglion or other compressive structure.

## Talar Osteophytes

### Classic Presentation

Talar osteophytes may be anterior or posterior. Patients with anterior osteophytes complain of pain on dorsiflexion of the foot and occasionally numbness/tingling or weakness in the toes. Patients with posterior osteophytes complain of pain on forced plantarflexion of the foot.

### Cause

Osteophytes on the neck of the talus or anterior tibia may cause an impingement of the local synovium leading to a hypertrophy and swelling.<sup>36</sup> With tight shoes, the anterior type of osteophyte may compress the deep peroneal nerve; however, this is more common with entrapment under the inferior extensor retinaculum.<sup>37</sup> Posterior compression may occur as a result of an os trigonum (small nonunited bone) or an elongated lateral process of the posterior tubercle of the talus (Stieda's process).<sup>38</sup> When there is pain on forced plantarflexion or dorsiflexion, lateral radiographs will usually reveal osteophytes or accessory bones that may represent the offending structure. If sufficient trauma is involved, it is important to consider a possible avulsion fracture.

## Management

Surgical excision is usually necessary for the anterior talar osteophyte; however, the pain with posterior processes may resolve with activity modification; if not, lidocaine injection or surgery should be considered.

## **Ankle Sprains**

### **Classic Presentation**

A 20-year-old patient (could be any age) presents with a complaint of ankle pain and swelling following a twisting injury. He does not recall how it happened but now it is swollen, and he has difficulty placing weight on it.

### **Cause**

The vast majority of ankle sprains are plantarflexion inversion sprains involving the lateral ligaments in a sequence of injury: the anterior talofibular ligament, calcaneofibular ligament, and then the posterior talofibular ligament. The more rare eversion sprain damages the medial ligament complex referred to as the deltoid ligament. Causes may include stepping on an uneven surface, landing on the outside heel, or running with too much cross-over or over-supination. Ligament laxity plays an important and ever-increasing role with subsequent sprains.

A number of complications and co-injuries may occur, which prolong recovery due to persistent pain or mechanical interference in the performance of rehabilitation exercises. Commonly seen complications are:

- Osteochondral fracture of the talar dome or loose body
- Subluxating or dislocating peroneal tendons
- Bifurcate ligament sprains
- Fracture of the base of the fifth metatarsal
- Achilles tendon injury

What is often not appreciated is the potential injury to the distal stabilizing elements of the tibia and fibula; the inferior tibiofibular ligament. This is also referred to as an ankle syndesmosis injury. Like all ligament damage, there are varying degrees of tearing and a variety of subsequent reactions in the tissue to attempt healing and stabilization. When full rupture occurs, fracture and/or dislocation is likely. This is referred to as diastasis and is easily viewed on radiographs. Lesser degrees of injury are notoriously difficult to assess both clinically and radiographically, yet may result in a prolonged recovery time. A sequelae to damage to the distal syndesmosis is synostosis. Although this is commonly secondary to fracture, it may occur as a result of damage to the inferior tibiofibular ligament. Pain is worse with the push-off. Persistent pain or swelling after activity is common. Dorsiflexion with the ankle in neutral is significantly restricted. Radiographically there is clear evidence of ossification between the distal tibia and fibula. Soft tissue impingement is possible. There is an extra distal fascicle of the anteroinferior tibiofibular ligament, which can cause impingement at the distal fibula and talus, causing damage to the talar surface. Pain is increased at the distal ankle with passive

dorsiflexion and relieved by plantar flexion. Patients often report an anterior popping sensation.

## Evaluation

The Ottawa Ankle Rules were founded on the basis that the only consistent (sensitive and specific) history and examination findings that were relevant were pain in the malleolar region and either (1) tenderness at either malleolus, or (2) the inability to bear weight immediately after the injury or in the emergency department.

For the midfoot the relevant findings were pain in the midfoot area and either (1) tenderness at the base of the fifth metatarsal, (2) tenderness at the navicular, or (3) the inability to bear weight immediately after the injury or in the emergency department. Depending on the timing in relationship to the injury, swelling may neutralize the value of stability testing. Stability testing includes the anterior drawer test followed by inversion testing if the drawer testing is positive (i.e., indicating a torn anterior talofibular ligament that allows strain to the lateral restraint of the calcaneofibular ligament). Caution must be used in ruling out any other injury that often complicates recovery, including tearing of the lateral retinaculum (which binds the tendons of the peroneals to the lateral malleolus), bifurcate ligament injury, interosseous ligament injury in the tarsal tunnel, and foot and ankle fractures.

Radiographs, if taken, should include the standard series plus an ankle mortise view to search for an osteochondral fracture.

There are several tests used to evaluate the syndesmotic injury:

1. Syndesmosis ligament palpation—Palpation over the anterior talofibular ligament causes an increase in pain if the test is positive.
2. Squeeze test—Manually compressing the fibula to the tibia above the midpoint of the calf increases pain over the distal tibiofibular ligament area if the test is positive.
3. External rotation test—With the patient sitting with the knee at 90° flexion and the ankle held in neutral, pain is increased with passive external rotation of the foot and ankle if the test is positive.
4. Passive dorsiflexion test—This test was modified to indicate whether limited range of motion or increased pain on passive dorsiflexion could be affected by an examiner adding compression externally while the passive dorsiflexion was repeated. A positive result is an increase in ankle range of motion or a decrease in end-range pain with external examiner compression at the distal tibiofibular joint.
5. Moving the calcaneus and talus side-to-side in an effort to elicit a “thud” as the talus abuts against the fibula or tibia. This indicates excessive movement due to a torn tibiofibular ligament. The external rotation test had the highest degree of interrater reliability. Positive test results for the combination of the external rotation test and the dorsiflexion-compression test correlated with a prolonged recovery time. A 2013 systematic review<sup>39</sup> of the literature on the value of these tests

concluded that an inability to hop, syndesmosis ligament tenderness, and the dorsiflexion-external rotation stress test (sensitive findings) may be combined with pain out of proportion to the injury and the squeeze test (specific findings) to arrive at a high level of suspicion.

### **Management (see Table 14-3)**

The standard approach is ice, elevation, and compression. Weight-bearing should be protected, with use of crutches for more serious injury. The main goal is to enable the patient to bear weight as soon as possible. Strengthening for plantarflexion inversion injury includes primarily the tibialis anterior and peroneals.

The focus in managing ankle sprains has switched to prevention. Following are some new concepts. Ankle sprains account for 25% of time lost in athletics. And money, too—some football teams spend as much as \$50,000 annually on tape! One study evaluated the maximum resistance to inversion under weight-bearing conditions.<sup>40</sup> Although there was a 10% increase in resistance initially, it was lost after 40 minutes of vigorous activity. This is consistent with other studies. What is unique about this study is that the use of prewrap and tape together increased resistance to inversion by an additional 10%. This is counter to what is traditionally taught about the effect of prewrap.

In an interesting study testing the proposition that taping has a proprioceptive effect more than a structural one, 22 university students with functional instability of the ankle were randomized into two groups for training on an ankle disk.<sup>41</sup> Both groups trained for 10 minutes daily for 10 weeks. Group 1 trained with strips of tape over the lateral ankle while group 2 trained without tape. Group 1 achieved decreased sway patterns after four weeks of training, returning to normal at six weeks, while group 2 took two weeks longer for both aspects. The results suggest that taping may increase stability due to a proprioceptive training effect.

Boyce et al.<sup>42</sup> found in a prospective, randomized trial that patients improved faster with the use of an elastic bandage compared to those with no compressive support when measuring swelling and pain scores at 10 days postinjury. In a different randomized, controlled, clinical trial patients with Grade I and II ankle sprains were assigned to Air-Stirrup braces alone, elastic wraps alone, combined Air-Stirrups with elastic wraps, or walking casts.<sup>43</sup> Patients with the combined brace and wrap had an earlier return to preinjury function compared to the other groups.

In one small study of 12 athletes with a history of ankle sprains within the previous six months, both injured and uninjured ankles were evaluated for laxity, dorsiflexion range of motion, and joint play.<sup>44</sup> Posterior talar glide was significantly reduced in the injured ankles. Although dorsiflexion returned to normal, posterior talar glide remained restricted.

There is an increased number of literature reports of manipulation used for ankle sprains. One report<sup>45</sup> evaluated the effect of a Mulligan-type mobilization on subacute, Grade II lateral ankle sprains. This approach is

referred to as mobilization with movement (MWM). A posterior talar glide is applied while the patient actively dorsiflexes the ankle. The intent is to provide a pain-free acquisition of previously unattainable movement. Although there was an increase in talocrural dorsiflexion, there was no effect on pain. This approach was again tested in individuals with recurrent ankle sprains and was found to improve weight-bearing dorsiflexion more than controls.<sup>46</sup>

A similar mechanical effect was demonstrated in a study by Lopez-Rodriguez et al.<sup>47</sup> Changes in posterior load, measured by a standing device, were found in subjects who had ankle manipulation (talocrural caudal manipulation or posterior glide manipulation). There was no mention of a measure of pain, swelling, or other symptoms. A literature review of mobilization and exercise for ankle sprains indicated that there was value in using exercise for prevention of recurrence.<sup>48</sup> The evidence for ankle mobilization was focused on increased talocrural motion or posterior glide but no improved clinical outcome was reported.

A small study involving osteopathic manipulation of the ankle in an emergency department setting indicates significant symptom improvement.<sup>49</sup> Patients managed with single osteopathic manipulation and standard ankle care were compared to those who simply received standard care. Those who received the manipulation had immediate results that were significant for improvement in edema, pain, and range of motion. In a follow-up, both groups improved. However, the manipulation group appeared to have better range of motion.

The results from a small case series by Jennings et al.<sup>50</sup> suggest that cuboid manipulation may have a role in patients with lateral ankle pain following an ankle sprain. The patients who responded had a history of ankle sprain from one to six weeks prior to presentation.

Another study attempted to determine the effect of using a standard talar adjustment on range of motion.<sup>51</sup> This randomized, controlled, blinded study evaluated 41 subjects (21 experimental, 20 for control); all were asymptomatic. Pretest and post-test measurement of dorsiflexion was performed. Ankles were adjusted with a standard prone gapping maneuver. Adjusting did not increase dorsiflexion ROM. Ankles that demonstrated the greatest pretest dorsiflexion were more likely to cavitate.

A single-blinded comparative study evaluated the outcome of treating Grade I and II ankle sprains with an ankle mortise separation adjustment or detuned ultrasound (placebo).<sup>52</sup> Both groups improved over a period of four weeks; however, there was significantly more improvement in the adjusted group for pain, range of motion, and function. A recent review summarizes the literature, which indicates a benefit for manipulation in the management of ankle sprains.<sup>53</sup>

In one recent study, researchers attempted to evaluate the cross-over effect of training either the dominant or nondominant ankle in 10 uninjured subjects.<sup>54</sup> Training involved isokinetic, concentric, and eccentric training in all four motions three times per week for eight weeks; a control group did no

training. At the end of the eight weeks, the control group showed no improvement in torque strength. The trained group showed up to a 40% increase in peak torque and a cross-over benefit of 19% for eccentric inversion.

From a recent Cochrane review by Kirkhoffs et al.<sup>55</sup> it appears that there is insufficient evidence for either surgical or conservative management of acute lateral ligament complex injuries. Given the cost of surgery and potential complications, it would seem that, for the time being, conservative approaches would initially be preferred.

In one study,<sup>56</sup> there were several factors predictive of chronic ankle instability following ankle sprain. These include increased inversion laxity, anterior laxity, balance problems, and decreased plantarflexion and dorsiflexion peak torque. It was suggested by the authors that these could be avoided with proper initial rehabilitation.

## The Evidence

### Translation into Practice Summary (TIPS)

There is little literature evidence for the history and examination of the foot and ankle with the exception of ruling-in the need for radiographs to determine if fracture is present. There is no literature on the evaluation of ankle instability although there are numerous tests.

### The Literature-Based Clinical Core

- The Ottawa Knee Rule and Burnese are good for determining the need for x-ray for foot/ankle fractures. The addition of a tuning fork applied to the distal fibula may add to the specificity.
- The impingement sign is good for both ruling-in and ruling-out anterolateral ankle impingement.
- There is no evidence regarding the reliability or validity of testing for ankle instability.

- Assessment of static foot alignment, proprioception, sensation, swelling, and functional testing are all relatively reliable; however, they are of unknown clinical value.
- Dynamic measurement of hindfoot motion during gait is not of clinical utility due to the poor reliability and undetermined validity.

### **The Expert-Opinion-Based Clinical Core**

- A history of recent plantarflexion/inversion injury with swelling is a strong indicator for lateral ankle sprain.
- A history of recent eversion injury with swelling is a strong indicator of medial ankle sprain.
- Stress testing positives of laxity for the anterior drawer and inversion stress indicate increasing severity of ligament damage including anterior talofibular to anterior talofibular to posterior talofibular damage. Eversion testing tests for the deltoid ligament complex.
- High-ankle sprains (syndesmotic injury) should be considered with all ankle sprains. Testing that may be of value includes passive external rotation, passive dorsiflexion test, and squeeze tests to demonstrate instability at the distal tibiofibular joint or recreate/exacerbate pain.
- Tarsal tunnel syndrome testing involves Tinel's and passive dorsiflexion of the ankle and toes with eversion. Tests seem sensitive but may not be specific.
- Midheel pressure for fat pad syndrome is a good test for distinguishing between planter fasciitis and fat pad syndrome.
- The Thompson test (calf squeeze) is a good first test for screening for Achilles rupture.
- Homan's test is not valuable in an ambulatory population in distinguishing between deep vein

thrombosis and calf strain.

- In-office gait analysis may be good at picking up asymmetrical functional issues but is of unknown value in distinguishing between those in need of orthotics and not. Functional support testing with in-shoe orthoses or taping may be of more value.
- Compartment syndromes should be considered in patients with exercise-induced pain coupled with sensory or motor loss isolated to the calf to the foot without indications of low back involvement.

# Foot/Ankle/Lower Leg Diagnosis Table

Foot/Ankle/Lower Leg Diagnosis Table

Diagnosis	Comments	History Findings	Positive Examination Findings	Radiography/Special Studies	Treatment Options
Subluxation or Fixation of Talus Navicular Cuboid Cuneiforms Metatarsal-phalangeal Interphalangeal Joints	<ul style="list-style-type: none"> <li>Should be used when chiropractic manipulation is used as Tx for any foot/ankle/lower leg problem/Dx.</li> <li>Can be primary Dx if patient is asymptomatic or mildly symptomatic (e.g., mild stiffness or pain level &lt;2/10).</li> <li>Must indicate chiropractic exam findings to support Dx.</li> </ul>	<i>Nonspecific</i>	<p><i>Palpation</i>—Local tenderness or other signs of subluxation</p> <p><i>Ortho</i>—None</p> <p><i>Neuro</i>—None</p> <p><i>Active ROM</i>—Variable restriction</p> <p><i>Passive ROM</i>—End-range restriction</p> <p><i>Motion palpation</i>—Specific articular restriction or symptoms produced on end-range</p>	<ul style="list-style-type: none"> <li>Radiography not required for the diagnosis of subluxation.</li> <li>Radiographic biomechanical analysis may assist in treatment decisions.</li> </ul>	<ul style="list-style-type: none"> <li>Chiropractic adjustive technique.</li> <li>Decisions regarding specifically which technique(s) is/are applied and modifications to the given approach will be directed by the primary Dx and patient's ability to tolerate pre-adjustment stresses.</li> </ul>
Eversion Sprain of Ankle (specify degree) Plantarflexion/ Inversion Sprain (specify degree)	<ul style="list-style-type: none"> <li>The vast majority of ankle sprains are plantarflexion/inversion.</li> <li>Sprains may be associated with other soft tissue damage, fracture, and subluxation.</li> </ul>	<i>Mechanism</i> —Eversion strains the medial ankle with damage to the deltoid ligament and its components; plantarflexion/inversion strains the lateral ankle ligaments, in particular, anterior talofibular and the calcaneofibular ligaments	<p><i>Ortho</i>—Stability testing may indicate degree of damage:</p> <p><i>Anterior drawer</i>—Performed at 15°–20° plantarflexion (anterior talofibular)</p> <p>Talar tilt—Inversion test</p> <p>Kleiger test—Eversion test</p> <p>Swelling usually equal to degree of damage:</p> <ul style="list-style-type: none"> <li>Pain with mild swelling, no instability = grade 1</li> <li>Moderate swelling, some instability = grade 2</li> <li>Gross swelling and instability = grade 3</li> </ul>	<ul style="list-style-type: none"> <li>Radiography recommended to determine if fracture is present if patient is unable to bear weight or there is bony tenderness at either malleolus, cuboid, or navicular.</li> </ul>	<ul style="list-style-type: none"> <li>Refer for surgery if gross instability, dislocation, or fracture is found.</li> <li>For grades 1 and 2, P.T. to reduce swelling; consider mild manipulation.</li> <li>Orthotic support (taping or brace) based on degree of injury.</li> <li>Myofascial therapy.</li> <li>Biomechanical advice with regard to sports; possible recommendation of protective brace or taping in early rehab.</li> <li>Strengthening and preventive exercises.</li> </ul>

Hallux Valgus Bunion of First MTP Joint	<ul style="list-style-type: none"> <li>The vast majority of patients are female, and wearing high heels may be an accelerating factor.</li> </ul>	<p><i>Mechanism</i>—Abduction of the proximal phalanx of the first toe causes a sling effect from pull of local tendons; protrusion medially causes development of a painful bunion</p> <p><i>Symptoms/Signs</i>—Medial big toe pain often worse with tight-fitting shoes</p>	<p><i>Ortho</i>—None; based on observation</p>	<ul style="list-style-type: none"> <li>Radiography only necessary if there is an associated arthritide as the cause (e.g., RA) or to determine degree of deviation.</li> </ul>	<ul style="list-style-type: none"> <li>Use of orthotics may be helpful to compensate for associated factors such as forefoot varus.</li> <li>Avoidance of high heels and tight-fitting shoes.</li> <li>Use of taping or night-sling to hold first toe in alignment may be helpful temporarily.</li> <li>Surgery may eventually be needed.</li> </ul>
Metatarsalgia	<ul style="list-style-type: none"> <li>General term to indicate pain at metatarsals; usually due to some underlying biomechanical stress.</li> <li>Differentiate from stress fracture of metatarsals.</li> </ul>	<p><i>Mechanism</i>—Chronic stretching of transverse ligaments due to various causes, including excessive weight, repetitive trauma, hammer toes, or direct trauma</p> <p><i>Symptoms/Signs</i>—Pain at bottom of foot increased by tight shoes</p>	<p><i>Palpation</i>—Tenderness found at metatarsals, often at the sole</p> <p><i>Ortho</i>—Transverse compression of metatarsals increases pain; tuning-fork test negative</p>	<ul style="list-style-type: none"> <li>Radiography not usually necessary initially except to rule out fracture with acute trauma or stress fracture with repetitive trauma (e.g., runners).</li> <li>Bone scan may be needed if radiographs are not indicating stress fracture yet still suspected based on history.</li> </ul>	<ul style="list-style-type: none"> <li>Use of metatarsal pads (proximal to metatarsal heads) may provide some symptom relief.</li> <li>Correct or modify suspected biomechanical faults.</li> </ul>
Hallux Rigidus	<ul style="list-style-type: none"> <li>Must be differentiated from capsular sprains and gout.</li> </ul>	<p><i>Mechanism</i>—Due to either osteoarthritic changes of aging or repetitive capsular sprains in athletes; secondary to other arthritides</p>	<p><i>Ortho</i>—Restricted flexion and extension of first MTP joint; worse with passive dorsiflexion</p> <p><i>Observation</i>—Dorsal bunion may be present</p>	<ul style="list-style-type: none"> <li>Radiography may be necessary to rule out other arthritides or sesamoid involvement.</li> <li>A dorsal ring of osteophytes may be evident with hallux rigidus.</li> </ul>	<ul style="list-style-type: none"> <li>Use of a stiff-soled shoe or rocker-bottom shoe may help.</li> <li>Failure of conservative regimen should result in podiatric or orthopaedic referral.</li> </ul>
Diagnosis	Comments	History Findings	Positive Examination Findings	Radiography/Special Studies	Treatment Options
Turf Toe or Other Digit Sprains	<ul style="list-style-type: none"> <li>Common injury in sports where athletes play on artificial surfaces, wear worn-out shoes, or play barefoot.</li> </ul>	<p><i>Mechanism</i>—Hyperextension of the toe(s) may result in capsular sprain on plantar surface; hyperflexion may result in similar problem on dorsal surface, often found with beach volleyball</p>	<p><i>Ortho</i>—Pain increases with direction of injury force; passive dorsiflexion or plantarflexion; swelling is usually minimal</p>	<ul style="list-style-type: none"> <li>Radiography not usually necessary.</li> </ul>	<ul style="list-style-type: none"> <li>Taping to limit motion and correction of any underlying biomechanical causes, such as worn-out shoes, helps prevent further injury.</li> </ul>
Plantar Fasciitis	<ul style="list-style-type: none"> <li>Plantar fasciitis is not due to heel spur; rather, the constant strain on fascia is cause of heel spur.</li> <li>Patient may be treated successfully without elimination of heel spur.</li> </ul>	<p><i>Mechanism</i>—Strain or stretching of plantar fascia may be due to pes planus or pes cavus foot</p> <p><i>History</i>—Sharp pain across bottom of foot; often worse when first walking in the morning</p>	<p><i>Palpation</i>—Discrete tenderness at medial tubercle of the calcaneus</p> <p><i>Ortho</i>—Pain increased by passive dorsiflexion of first toe or coupled with passive dorsiflexion of ankle</p>	<ul style="list-style-type: none"> <li>Radiography may reveal an associated heel spur; however, resolution of heel spur should not be used as an outcome measure for treatment success.</li> </ul>	<ul style="list-style-type: none"> <li>Temporary symptomatic relief may be accomplished through taping.</li> <li>Ice and mild stretching.</li> <li>Orthotic prescription for compensation of pronation or supination problems.</li> <li>Correct any suspected biomechanical faults.</li> <li>Myofascial therapy.</li> </ul>
Achilles Tendinitis (Tendinosis) Tendinosis is a newer term used to indicate intra-tendinous degeneration due to atrophy (aging, microtrauma, vascular compromise, etc.). This is considered noninflammatory with hypocellularity, variable vascular ingrowth, local necrosis, and/or calcification, with accompanying fiber disorientation.	<ul style="list-style-type: none"> <li>Found mainly in athletes who run or jump as main component of sport.</li> </ul>	<p><i>Mechanism</i>—Primarily due to eccentric strain of Achilles tendon with repetitive activities; area affected is 2 cm proximal to insertion</p> <p><i>History</i>—With full tear, patient unable to plantarflex foot; with partial tears, complaints of burning along distal end of tendon</p>	<p><i>Palpation</i>—Knotty swelling found just proximal to insertion with chronic tendinosis; with acute, discrete tenderness, with or without swelling</p> <p><i>Ortho</i>—Thompson test indicates loss of passive plantarflexion effect of Achilles, indicating rupture; partial tears are not detectable</p> <p>ROM—Passive dorsiflexion coupled with resisted plantarflexion or toe raises may increase pain</p>	<ul style="list-style-type: none"> <li>Radiography not generally useful; however, with full ruptures disruption of Kager's triangle may be evident.</li> <li>Partial tears may be evident with diagnostic ultrasound.</li> <li>Definitive Dx may require MRI.</li> </ul>	<ul style="list-style-type: none"> <li>Full ruptures may be managed conservatively with plantarflexion immobilization or treated surgically (conservative treatment results in high re-tear rate).</li> <li>Tendinitis in general may be initially managed with ice, stretching, and temporary taping support.</li> <li>Long-term management includes orthotic prescription, if necessary, and stretching of Achilles.</li> </ul>

Tibialis Anterior or Tibialis Posterior Tendinitis/Tendinosis	<ul style="list-style-type: none"> <li>Should be differentiated from shin splints if possible.</li> <li>Tibialis tendinitis is differentiated by tenderness or pain along tendon rather than at the origin (shin splints represents a broader involvement and more periosteal involvement at origin).</li> </ul>	<p><i>Mechanism</i>—Chronic strain to anterior tibialis is often due to running or walking on hard surfaces or shoes tied too tightly, whereas posterior tendinitis is usually secondary to hyperpronation</p> <p><i>History</i>—Pain on anterior if across top of ankle; posterior pain on medial side of ankle and foot</p>	<p><i>Palpation</i>—Tenderness along tendon; often toward distal end</p> <p><i>Ortho</i>—Worse with stretch of tendon or contraction corresponding muscle</p>	<ul style="list-style-type: none"> <li>Radiography not necessary unless there is a suspicion of an underlying arthritis such as RA.</li> </ul>	<ul style="list-style-type: none"> <li>Ice and taping may bring symptomatic relief initially.</li> <li>Myofascial release may be effective for subacute or chronic problems.</li> <li>Correction or compensation of associated biomechanical faults through orthotic prescription may be necessary.</li> </ul>
Shin Splints	<ul style="list-style-type: none"> <li>Ill-defined disorder that may represent periosteal involvement of tibia.</li> <li>Two types: anterior and posterior.</li> </ul>	<p><i>Mechanism</i>—Anterior type found more in anterior/lateral muscle origin due to diminished shock-absorption capabilities of foot; posterior type</p> <p><i>History</i>—Patient with anterior type may have Hx of running or standing on hard surfaces; patients with posterior type may have Hx of hyperpronation problems</p>	<p><i>Palpation</i>—Tenderness is just lateral to middle tibia with anterior type and posteromedial at the middle or lower tibia with posterior type</p> <p><i>Ortho</i>—Pain may be increased by stretching involved tendons; tuning fork negative</p>	<ul style="list-style-type: none"> <li>Radiographs should be ordered when chronic or when stress fracture is suspected (runners and/or females with menstrual irregularities).</li> <li>Persistence of pain indicates need for bone scan to rule out stress fracture.</li> </ul>	<ul style="list-style-type: none"> <li>Taping is often effective for symptom relief.</li> <li>Buying new running shoes is often corrective for runners.</li> <li>Correction or compensation of biomechanical faults is often necessary for prevention.</li> </ul>
Morton's Neuroma	<ul style="list-style-type: none"> <li>Must differentiate from metatarsalgia; both may be reproduced by transverse compression.</li> <li>The natural history of neuromas is to resolve and return regardless of Tx approach.</li> </ul>	<p><i>Mechanism</i>—Entrapment of a digital nerve by intermetatarsal ligaments leads to amorphous deposits</p> <p><i>Signs/symptoms</i>—Pain on bottom of forefoot, less when barefoot; insidious onset</p>	<p><i>Palpation</i>—A nodule may be palpable on plantar surface in intermetatarsal space (more common in 2nd or 3rd)</p> <p><i>Ortho</i>—Passive dorsiflexion of MTP or interphalangeal joints may increase pain; decreases with passive plantar flexion</p>	<ul style="list-style-type: none"> <li>Radiography not usually indicated.</li> </ul>	<ul style="list-style-type: none"> <li>Forefoot mobilization and temporary metatarsal pad may be beneficial.</li> <li>Orthotics may be needed.</li> <li>Surgical excision may be needed eventually.</li> </ul>
Tarsal Tunnel Syndrome	<ul style="list-style-type: none"> <li>Must be distinguished from nerve root cause due to low back involvement.</li> </ul>	<p><i>Mechanism</i>—Posterior tibial nerve is stretched or compressed in tarsal tunnel; often due to hyperpronation; may be due to trauma or swelling</p> <p><i>History</i>—Numbness and tingling across bottom of foot</p>	<p><i>Neuro</i>—Nerve root testing is negative; reproduced by passive dorsiflexion and eversion of the foot/ankle; Tinel's sign at medial ankle may reproduce complaints; sensory deficit on bottom of foot present; motor signs are rare</p>	<ul style="list-style-type: none"> <li>Radiographs not usually indicated.</li> <li>Nerve conduction studies may be needed to confirm.</li> </ul>	<ul style="list-style-type: none"> <li>If swelling is cause, efforts directed at decreasing swelling.</li> <li>If biomechanical in origin, correct or compensate through orthotic prescription or mobilization/manipulation.</li> </ul>
Myofasciitis	<ul style="list-style-type: none"> <li>Used when specific trigger points are identified on physical examination.</li> <li>Also may be used if a strain is not evident from the history but there are indicators of muscle tenderness, stiffness, or pain.</li> </ul>	<p><i>Onset</i>—Nonspecific regarding onset</p> <p><i>Symptoms</i>—Patient usually complains of pain, aching, and/or tenderness in specific muscle or tendon areas that may radiate pain in nondermatomal pattern</p>	<p>Trigger points are evident as localized tenderness in a muscle that corresponds to traditional (Travell/Simons) trigger point charts; these points may be local or refer pain when compressed</p>	<ul style="list-style-type: none"> <li>Not required or recommended.</li> </ul>	<ul style="list-style-type: none"> <li>Myofascial approaches, such as myofascial stripping, trigger point massage, or spray and stretch, are the standard.</li> <li>Home stretching and modification of activity suggestions.</li> </ul>
Laxity Hypermobility	<ul style="list-style-type: none"> <li>This is an adjunctive code to identify causation or the result of a patient's primary diagnosis, such as a sprain or strain due to hypermobility.</li> <li>Use Laxity code if laxity is confined to the involved joint only; use Hypermobility if multiple joints are lax.</li> </ul>	<p>A history of a single event, traumatic injury to the joint is not found; however, either overuse (microtrauma) or generalized inherent looseness is evident</p>	<p>Capsular or ligament testing reveals "looseness" that falls within the physiologic range of normal</p>	<ul style="list-style-type: none"> <li>Not usually recommended unless when differentiating pathological laxity from congenital or overuse acquisition.</li> </ul>	<ul style="list-style-type: none"> <li>Strengthening program.</li> <li>Bracing or functional taping during rehabilitation or during strenuous activities.</li> </ul>

Part II

# Neurologic Complaints

# CHAPTER 15

## Weakness

### Context

As with many patient complaints, it is imperative to have the patient define his or her complaint: What does “weak” mean to the patient? Without a clear description, the doctor may be led to the assumption that a neurologic or muscular etiology is the cause when, in fact, weakness is actually fatigue associated with an infectious, metabolic, oncologic, pharmacologic, or psychologic (e.g., depression) disorder. Patients experiencing pain with movement will often express a sense of weakness. In addition, patients may interpret a sense of clumsiness, tightness, instability, or uncoordinated movement as “weakness.” Determine first, then, whether the patient has general weakness or is substituting or misinterpreting another physical sign/symptom as weakness (**Exhibit 15-1**). If the complaint is more generalized, see [Chapter 21](#), Fatigue, and [Chapter 23](#), Sleep and Related Complaints.

In the context of chiropractic practice, it is most common to find a regional complaint of weakness with associated signs of pain and/or numbness and tingling. It would be unusual to find a patient with signs of central nervous system origin (unless previously diagnosed); the chiropractor must be vigilant, however, in searching for these findings. When weakness is associated with a concomitant complaint of region-specific pain, there must

be a diligent search for an anatomic lesion. If there is an objectifiable strength deficit, a major concern is the permanency of this loss.

## General Strategy

### History

- Determine what the patient means by a complaint of “weakness.” Is it a general sense of fatigue or tiredness or a specific regional or joint weakness?
- Is there a history of trauma that would lead one to suspect rupture of a muscle, ligament, or tendon? (Eventually this would be a painless weakness.)
- Is the onset sudden, with diffuse areas of neurologic weakness and/or associated signs of difficulty with speech, cognition, consciousness, or affect? (These deficits are suggestive of a cerebrovascular event.)
- Is the onset insidious with either persistence or progression of symptoms, or an addition effect of more neurologic signs? (The latter is typical of expansile lesions such as tumors.)
- Is there an improvement of neurologic signs, but recurrence? (This is suggestive of a vascular process or multiple sclerosis.)
- Has there been a period of disuse (immobilization with either a sling or cast) or support worn an extended period of time?
- With a specific regional weakness, are there associated sensory complaints such as pain, numbness/tingling, or unusual sensations? (Localize and attempt to match the complaint with a specific nerve root or peripheral nerve pattern.)

# Examination

- First determine whether there are signs of an upper motor neuron lesion (UMNL) or a lower motor neuron lesion (LMNL).
- If there is a single regional weakness, attempt to localize it segmentally by associating any deficits in motor or sensory function.
- If a clear distinction is not found for differentiating the site of a lesion, further studies, including electrodiagnostic studies or magnetic resonance imaging (MRI), or both, must be considered.

## **Exhibit 15-1 Defining Patient's Complaints of Weakness**

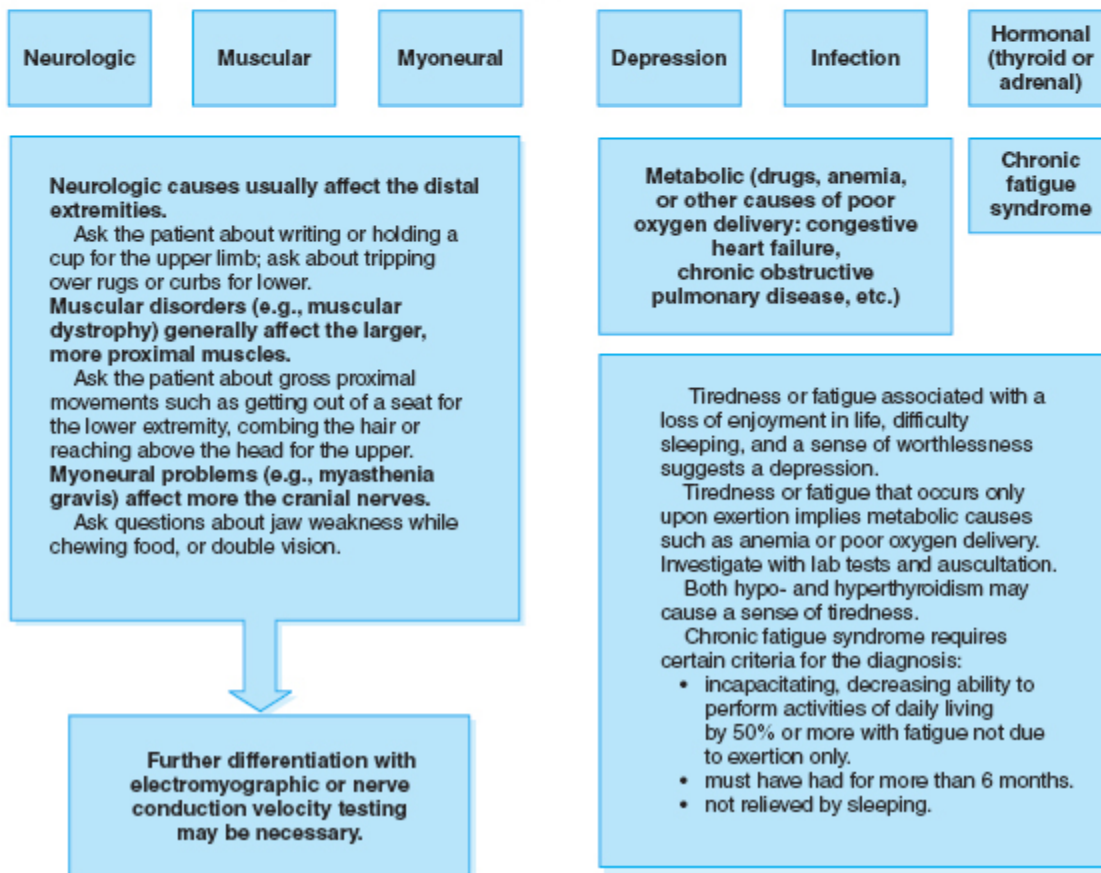

# Patient complains of weakness

Differentiate between specific regional weakness and general weakness

Differentiate objective from subjective if possible  
(e.g., restricted movement or joint laxity misinterpreted by patient as weakness due to perceived increased effort)

## Management

- Weakness due to a UMNL should always be referred to a neurologist immediately.
- Weakness associated with myasthenia gravis should be referred for medical management.
- Most cases of nerve root or peripheral nerve weakness can be managed conservatively for one month, monitoring for worsening or progression (which would warrant referral for a second opinion).

## **Relevant Anatomy and Physiology**

Although integration for smooth and coordinated muscle function is a complex process involving both ascending and descending pathways, for general strength the examiner's focus is on the corticospinal (and corticobulbar) tracts. Information that has been integrated at a higher level is sent to the anterior horn cells via the corticospinal tracts. From this point, information is sent out to the spinal nerves that divide into anterior and posterior primary rami. The posterior rami innervate the deep muscles of the back. The anterior rami form four plexuses that eventually, through a process of recombination (roots to trunks to division to cords), form peripheral nerves. All peripheral nerves interact with the target muscle(s) at the myoneural junction.

Corticospinal tract function includes inhibitory influences. Increased excitability due to cortical divorce from the alpha motoneuron results in increased muscle tone with passive movement. The hyperexcitable alpha motoneuron also causes an increase in deep tendon reflexes. A number of older reflexes that disappear with maturation of the nervous system are unmasked (e.g., Babinski's reflex). Although pathologic reflexes are hyperreflexic, the fact that the reflex

is intact indicates a functioning alpha motoneuron and peripheral motor nerve.

An important anatomic design is the laminated arrangement of spinal tracts within the spinal cord. Fibers innervating the lower parts of the body are more superficial and lateral. Compressive lesions would present with a temporal presentation of sequential, ascending weakness. This lamination is also true of ascending sensory tracts. Therefore, an accompanying ascending sensory loss may be found.

For neurologic weakness to occur there must be a lesion somewhere along the corticospinal or corticobulbar paths (cortex, brainstem, spinal cord) or at the anterior horn cell, myoneural junction, or muscle. There are some generalizations that will guide the examiner in discriminating among the various neurologic and muscular causes. The first discrimination is whether there are any signs of a UMNL or an LMNL.

- A UMNL indicates pathology in the cerebral hemispheres, brainstem, or spinal cord. Interruption of inhibitory influences eventually leads to increased reflexes and an increase in muscle tone and spastic paralysis; pathologic reflexes such as Babinski's appear also.
- An LMNL indicates pathology in the anterior horn cell or motoneuron. Interruption of the reflex loop leads to absent or decreased deep tendon reflexes. Disconnection from the motoneuron leads to atrophy and fasciculations. Muscle tone may be normal or decreased (flaccid paralysis).

## **Stroke**

Stroke is the third leading cause of death in the United States. Although it indicates a vascular cause of neurological deficit, the use of the term *stroke* is not always consistent with some vascular events such as subarachnoid hemorrhage, subdural hematomas, and epidural hematomas not included under the category of stroke due to more diffuse involvement of the central nervous system.

Stroke is an acute onset of neurological deficit that is vascular in origin and lasts at least 24 hours. It represents a focal area of damage in the brain that leads to diffuse clinical consequences based on the region affected. Therefore events that are shorter in duration or have more diffuse involvement have a different categorization. A transient ischemic accident (TIA) represents an event that resolves usually within 24 hours after onset, often in the first 30 minutes. Statistically, one-third of patients who suffer a TIA will have a full stroke within the next five years. Reversible, ischemic, neurological deficit (RIND), also called a minor stroke, is reserved for events that fully recover but take more than 24 hours; often several days. TIAs and RIND represent ischemic (i.e., blockage) events, not hemorrhage. Other cerebrovascular events that are more diffuse and do not classically fit under the definition of stroke are termed *global cerebral ischemia*. Global cerebral ischemia is more often the consequence of myocardial infarction or subarachnoid hemorrhage.

Chiropractors are not in a clinical position or level of expertise to diagnose where in the brain a stroke is occurring, but generally signs and symptoms will inevitably reveal the side of involvement and often the vascular area involved if clinically divided into an anterior versus a posterior circulation. Generally, weakness and sensory findings manifest on the opposite side of the lesion below the neck. Aphasia usually indicates the left cortex. The anterior circulation derived from the internal carotid artery supplies much of the cortex and subcortical white matter,

the basal ganglia, and the internal capsule. When it is involved there is a combination of motor or sensory findings, language/speech deficits, and memory loss. The posterior circulation derived from the vertebral arteries, the branching basilar arteries, and their branches supply mainly the cerebellum, thalamus, brainstem, and parts of the occipital and temporal areas. Signs and symptoms are generally related to brainstem dysfunction including coma, drop attacks, vertigo, nausea, and ataxia.

Following are some examples of how more localization of the lesion site can be determined based on testing for specific neurological deficits:

- Because medial brainstem lesions involve the pyramidal tracts, lesions will usually cause contralateral spastic hemiplegia with no sensory loss. Further localization can be made through examination for deficit in the oculomotor nerve (i.e., midbrain), the abducens nerve (i.e., pons), and the hypoglossal nerve (i.e., medulla).
- Because lateral brainstem lesions will more often involve the spinothalamic tracts, with sensory loss as the main feature primarily involving pain and temperature. At the caudal pons and medulla where the spinothalamic and spinal trigeminal tracts travel closely together, there will be ipsilateral loss of pain and temperature in the face with contralateral loss in the trunk and limbs. Further distinction can be made by testing cranial nerves VII, VIII, IX, and X. At higher levels, localization involves testing the motor and principal trigeminal nuclei for the midbrain, the superior cerebellar peduncle, and the rostral pons and caudal midbrain, and for the rostral midbrain, the medial lemniscus and trigeminothalamic tracts.
- One of the most commonly involved areas with stroke is the internal capsule. This area includes the

pyramidal tracts, the somatosensory tracts, and, closely located, the corticobulbar tracts. Involvement of the dorsal internal capsule would then result in contralateral findings of spastic hemiplegia, contralateral lower face weakness, and contralateral anesthesia. If more ventral, the lesion may affect the optic radiation with an additional finding of contralateral homonymous hemianopsia.

There are generally two types of stroke: (1) thromboembolic (ischemic) stroke, representing occlusion or blockage of blood supply to the target area, and (2) hemorrhagic stroke, representing usually rupture and bleeding, often under high pressure due to arterial involvement. These are further divided and classified by the location of the lesion. Hemorrhagic is intracerebral, whereas ischemic stroke is either from a local thrombus or from a distantly originating embolus. There is also a combination of effects when an ischemic infarct leads to hemorrhagic conversion because the blood vessels become fragile and rupture.

Embolic infarct forms distally and travels to the brain, whereas thrombotic infarct is a blood clot that forms locally, usually due to atherosclerosis. Generally, embolic occur suddenly with rapid onset of symptoms, whereas thrombotic may be slow to develop. Other helpful discriminators are that stroke events that have the same clinical signs each time are generally from the cerebral circulation while those that differ each time are often cardiac in origin and are embolic. Some generalizations include that large-vessel infarcts generally occur from emboli (although proximal thrombus may occur). Small-vessel infarcts occlude small penetrating vessels to deep structures such as basal ganglia, thalamus, and internal capsule or the brainstem. Some small-vessel infarcts are sometimes referred to as lacunar because they form small cavities (lakes). Specific

lacunar syndromes have been identified. So where do emboli develop prior to reaching the cerebral circulation? Following are some common examples:

- Cardioembolic—30% of those that have electrocardioversion for arrhythmias throw emboli
- Dissection—dependent on type of dissection, emboli can be thrown
- Patent foramen ovale—an atrioventricular defect, this is associated with emboli and may have a relationship to migraine headache
- Deep vein thrombosis—more commonly travel to the lungs
- Other than thromboembolism, air, fat, and septic emboli are also possible

The most common nontraumatic cause of hemorrhagic stroke is chronic hypertension. Hemorrhagic stroke usually causes symptoms by compressing adjacent tissue (which then may produce ischemia). Hemorrhagic stroke tends to cause more severe headache and neurological depression than ischemic stroke. Neurologic deficits do not generally correspond to any single blood vessel.

A distinction must be established between general cardiovascular risk with associated complications of myocardial infarction, stroke, and peripheral vascular disease and stroke that is not atherosclerotic but instead is related to dissection (i.e., intimal tearing) or reflexogenic vasospasm. This latter type is more often the cause of vertebrobasilar (VB) stroke.

It is clear that many of the risk factors for atherosclerosis and subsequent stroke can be modified, whereas those related to vascular weakness other than hypertension are difficult to modify other than management of the underlying condition.

## Evaluation

### History

After having the patient clarify whether he or she feels weak, tired, or fatigued, the most revealing line of questioning is in relation to daily activities (**Table 15-1**). Ask the patient to describe the activity that causes the feeling of weakness in an attempt to determine whether he or she means a specific regional weakness, an uncoordinated or clumsy sensation, or the exertion fatigue felt with some systemic and cardiopulmonary disorders. If it appears to be a regional complaint, further clarify by extracting a description that localizes upper or lower extremity and proximal or distal weakness. This line of questioning focuses on the generalization that neurologic diseases usually start distally, whereas myopathies usually become more evident proximally. For example, difficulty using the fingers or hands would be more suggestive of a neurologic cause, whereas difficulty with combing the hair or reaching behind the back would be more suggestive of a myopathy. In the lower extremities, tripping over rugs or curbs is more suggestive of a neural cause, whereas difficulty rising from a seated position is more often myopathic (especially if nonpainful).

**Table 15-1** History Questions for Weakness: Determining the General Cause

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Do you feel weakness of your arm or leg, hands or feet?	A yes would imply a neurologic or muscular disorder; a no requires further questioning.	Do you feel generally weak (tired or fatigued)?	Think more of metabolic and endocrine problems, infection, or depression.
		Are you taking any medications?	Antihypertensives, antihistamines, and barbiturates are common culprits.
		Is this feeling always there or only when you exert yourself?	If the feeling is only with exertion consider cardiopulmonary/vascular causes (including anemia).
Are specific daily activities difficult because of weakness?	Attempt to determine whether a specific body-area weakness is upper or lower, proximal or distal.	Lower extremity <ul style="list-style-type: none"> <li>proximal—getting up from chair, toilet, car</li> </ul>	Proximal usually indicates an endocrine or myopathic problem (painless weakness).
		<ul style="list-style-type: none"> <li>distal—tripping over rugs, curbs, cords</li> </ul> Upper extremity <ul style="list-style-type: none"> <li>proximal—combing hair, reaching overhead</li> <li>distal—writing, typing, opening jars</li> </ul>	Distal usually indicates a neurologic disorder.
		Head <ul style="list-style-type: none"> <li>whistling, blowing, chewing, speaking, swallowing, keeping soap out of eyes while showering</li> </ul>	Cranial nerve dysfunction often implies a medullary or pontine disorder, especially if accompanied with extremity findings. Fatigue after repeated action points to myasthenia gravis.
Is there associated numbness and/or tingling?	A neurologic cause is likely. Look for a patch of skin that correlates with a dermatome or peripheral nerve pattern.	Is the numbness constant or intermittent?	Constant would imply a neurologic cause (possibly metabolic/endocrine); intermittent would imply transient or early neurologic compression.
Is there pain associated with the weakness?	Weakness is often the result of neurologic inhibition due to pain (example: knee gives out).	If it is not painful now, was there ever trauma (injury) to the area?	Rupture of muscles, tendons, or ligaments may result in loss of function that is eventually painless.

Some characteristic patterns of “weakness” that suggest a global fatigue may help guide the examiner through questioning (see [Chapter 21](#), Fatigue).

- Patients with an infectious cause are often tired after exertion. This may also occur with anemia or cardiopulmonary disorders.
- The weakness associated with endocrine and electrolyte disorders is often felt more proximally.

Either hypo- or hyperthyroidism may cause weakness. It is more often (80% to 90%) found with hyperthyroidism. Also, hypo- or hyperadrenal disorders may present with a complaint of weakness. Electrolyte imbalances, high or low, may lead to weakness. Evaluation with a general screening lab workup may give direct or indirect indications of these causes.

- Fatigue or tiredness that seems worse after eating may indicate hypoglycemic reactions, reaction to alcohol consumption, or a delayed reaction from overingestion of caffeine.
- Medications often will have a sedative effect that may be augmented by the use of alcohol or other drugs such as antihypertensives, antihistamines, codeine, and barbiturates.
- Fatigue or tiredness throughout the day may be suggestive of a sleep disorder, including the possibility of depression. A characteristic insomnia pattern is often associated with reactive depression; with endogenous (neurochemical) depression, the patient often awakens early and finds it difficult to fall back to sleep (see [Chapter 20](#), Depression).

A sense of weakness may be a misinterpretation by the patient. For example, if a patient has hip stiffness, it may feel as if lifting the knee toward the chest is weak; muscle testing in the midrange, however, might indicate normal strength. Instability may present similarly. If a patient has laxity of the shoulder, overhead movements may feel “weak” because of the inability of the shoulder musculature to compensate for ligamentous/capsular laxity at higher levels of elevation.

Muscle cramps are most often related to sports or occupation. However, a multitude of diseases have possible associated cramping, including Parkinson’s disease, numerous central nervous system disorders/diseases,

diabetes, peripheral nervous and peripheral vascular disease, and hemodialysis. Muscle cramps occur in almost half of pregnant women. Oral supplementation of calcium appears effective in most cases. If cramping is associated with walking, consider vascular insufficiency and intermittent claudication and hyper- and hypothyroidism. Medications associated with cramping include, but are not limited to, cisplatin and vincristine. Cramping may be described for various drug-induced myalgias, from cimetidine and cholestyramine. Severe vomiting or hyperventilation may cause relative alkalosis with calcium, resulting in cramping and paresthesias. Rarer causes (often metabolic deficiency diseases) include the following:

- McArdle's disease—muscle phosphorylase deficiency
- Carnitine palmitoyltransferase II deficiency—genetic disorder of lipid metabolism
- Brody's disease—phosphoglycerate kinase deficiency (myoglobinuria)
- Tarui's disease—phosphofructokinase deficiency
- Isaac's syndrome—neuromyotonia
- Stiff man syndrome—back and abdominal cramping

For similar or overlapping complaints with weakness, such as tremors and ticks, and for the possibility of more serious inherited disorders, see **Tables 15-2** and **15-3**.

## Examination

Following are some pattern generalizations that may help guide the examination:

- Cerebrum—Generally a combination of UMNL and associated problems with cognitive functions or mood suggests a cortical pathologic process.

**Table 15-2** Muscular Disorders

<b>Procedure</b>	<b>Comments</b>
<b>Muscular Dystrophies</b> Duchenne's dystrophy	Both Duchenne's and Becker's are X-linked recessive disorders. Duchenne's involves a defect in dystrophin and has an onset within the first five years of life. Becker's usually has normal dystrophin. The pelvis area is affected first, then eventually limb involvement with both. With Becker's there is a slow progression with a normal longevity; however, with Duchenne's there is eventual respiratory muscles involvement, with death occurring within about 15 years of the onset. Duchenne's is detectable using DNA probes in late pregnancy. Diagnosis after birth is prompted by weakness which must be differentiated electromyographically and with serum creatine kinase levels.
Facioscapulohumeral	An autosomal dominant disorder that can occur at any age. It affects the face and shoulder girdle, although the pelvis and legs are eventually affected. There is minor disability with a normal longevity.
Limb-girdle (Erb's)	A variable genetic inheritance, usually autosomal recessive, with onset from ages 10 to 30 years. The pelvis and shoulder may be affected first. A wide variety of presentation and prognosis with the possibility of severe disability at middle age.
<b>Myopathies</b>	There are many, yet rare, disorders that may cause myopathy. These include glycogen storage diseases, such as Pompe disease, or errors in lipid metabolism, such as carnitine

## Congenital

deficiency. There usually is multisystem involvement; however muscle-only may occur, such as nemaline myopathy or central core myopathy. Clinically the disease would be seen in an infant or child who cannot move, with flaccid limbs. Must be differentiated from cerebral palsy.

Steroid (acquired)

Patients on high-dose steroid therapy such as Prednisone are prone to developing steroid myopathy. Clues are that the CK and nerve conduction tests are normal but EMG demonstrates short-duration, low-amplitude motor unit potentials (MUPs) with early and rapid recruitment. Muscle biopsy demonstrates type 2 fiber atrophy.

Mitochondrial

A diverse group of disorders that affects skeletal muscle. This may be seen microscopically as "ragged red fibers" (accumulation of abnormal mitochondria) using the modified Gomori stain. Patients may have either ophthalmoplegia or limb weakness (especially after exercise).

## Channelopathies

Myotonic dystrophy (Steinert's disease)

Most common adult-onset muscular dystrophies occurring in 5 per 100,000 individuals. This is an abnormal trinucleotide repeat problem along chromosome 19 and possibly chromosome 3. Characterized by abnormal muscle relaxation, many individuals notice this after shaking hands with inability to relax. Other features include proximal and distal weakness, diabetes mellitus, early cataracts, premature balding, hypersomnia, and abnormalities of the heart and GI system. Serum creatine kinase Z(CK) levels are generally 10 times normal. Associate electrodiagnostic testing is found.

	Selective genetic analysis of blood and muscle confirm the diagnosis.
Myotonic congenita	An inherited trait involving the long arm of chromosome 7. Individuals have myotonia without weakness initially. Complaints are stiffness and weakness, worse with inactivity or cold and improved with exercise. Muscle hypertrophy may be present. Treatment is with a variety of drugs used with other myotonic conditions, including quinine, procainamide, or phenytoin, among others.
<b>Inflammatory Dermatomyositis and polymyositis</b>	This inclusion body myositis begins insidiously in middle age. Progression is usually proximal, first evident in the lower extremities. Serum creatine kinase levels may be normal and sometimes increased. Responsiveness to corticosteroids is not encouraging. Recent suggestions of intravenous immunoglobulin are still being investigated.
<b>Familial Periodic Paralysis Hypokalemic</b>	The most common familial periodic paralysis. This autosomal dominant disorder involves gene mutations of the dihydropyridine receptor that is involved with chloride channels. Other conditions that affect potassium levels must be evaluated, such as renal, endocrine, and GI causes. This rare condition (1.25 per 100,000) is characterized by attacks, which occur during adolescence, of paralysis that is precipitated by carbohydrate ingestion, alcohol, cold exposure, stress, and resting after exercise. Hypokalemia is a consequence, not a cause, of the disease.
Hyperkalemic	A possible defect in the sodium channel gene on the long arm of chromosome 17, attacks usually occur after exercise lasting less than

an hour. They are relieved by several medications, including glucose, glucose and insulin, or calcium gluconate (intravenous). Prevention is sometimes attempted with daily acetazolamide or chlorothiazide.

**Table 15-3** Movement Disorders

<b>Type and Causes</b>	<b>Clinical Presentation/Management</b>
<b>Tremors</b> Essential	Also called benign essential (familial) tremor, this autosomal dominant tremor is a fine-to-coarse tremor that is usually not present at rest but apparent with skilled acts. Tremor mainly involves the hands and head, usually not the lower extremity. It is enhanced by emotional stress and sometimes dramatically relieved (temporarily) with a small amount of alcohol.
Resting	A resting tremor is seen primarily with Parkinson's disease, disappearing with movement.
Cerebellar	Cerebellar tremors are often associated with multiple sclerosis and are intention tremors. The limb oscillates as it approaches an intended object. Other tremors include sustained tremor seen primarily with the proximal muscles when maintaining a fixed or weight-bearing posture. Titubation is a more gross tremor of the head and body that remits with lying down. Asterixis, or "liver-flap," is seen with some hepatic or metabolic encephalopathies.
<b>Dyskinesias</b> Myoclonus	Myoclonus is the brief, jerking movement felt by many individuals while falling asleep. Abnormal myoclonus, felt as brief involuntary contractions of a muscle or group of muscles, may occur secondary to other disorders such as uremia, Alzheimer's, epilepsy, slow viruses (Creutzfeldt-

	Jakob's disease), hypoxia, or head trauma. If there is an underlying metabolic disorder, it must be addressed. Anti-epileptic medication or 5-HTP with carbidopa may be used.
Tics <ul style="list-style-type: none"> <li>• Simple tics</li> </ul>	Repetitive, brief, rapid involuntary movements that may develop as mannerisms and resolve with time.
<ul style="list-style-type: none"> <li>• Tourette syndrome</li> </ul>	An autosomal dominant disorder with variable penetrance. Simple tics may progress to complex tics involving respiratory or vocal manifestations, including compulsive vocalizations with swearing. Some of the tics are under the individual's control for a few seconds. Treatment usually involves medication such as benzodiazepines or antipsychotics such as haloperidol.
Choreas and athetoses	Choreas are brief, purposeless movement of the distal extremities and face that are involuntary. The most common causes are Huntington's chorea, Sydenham's chorea related to rheumatic fever, SLE, and drug induced. Athetoses are writhing movements, flowing in nature, and often involve the proximal limb musculature. Both are due to dopaminergic overactivity in the basal ganglia.
Hemiballismus	Hemiballismus is a violent movement disorder where the arm (occurs on one side usually) or leg is flung about continuously. Usually the result of infarct or tumor of the contralateral subthalamic nucleus. Usually self-limiting over two months. Treatment is usually with antipsychotics.
Huntington's	An autosomal dominant disorder that involves degeneration of parts of the CNS, including the caudate nucleus and small cell bodies. GABA and substance P levels decrease. The individual experiences deterioration that is progressive, leading to choreiform movements, and intellectual and motor decline. The onset is usually middle age with both sexes affected equally. No treatment is available. Medication is used to manage choreiform movements and agitated behavior.
Dystonia	Dystonia is a sustained abnormal posturing or a

	<p>disruption of a movement pattern due to altered muscle tone. There are several types, including generalized (a rare hereditary problem with fixed plantarversion and inversion of the foot), focal which is confined to a single region, and segmental which is a focal dystonia that spreads to an adjacent region. Several disorders are associated or named dystonias, including:</p> <ul style="list-style-type: none"> <li>• Meigs' syndrome (blepharo-omandibular syndrome)—involuntary blinking, grimacing, or jaw grinding that begins in middle-aged individuals (should be differentiated by tardive dyskinesia usually associated with medication side effects).</li> <li>• Torticollis—deviation of the head and neck to one side, which can be voluntarily corrected initially.</li> <li>• Spastic dystonia—spasms of laryngeal muscles resulting in a voice change, sounding hoarse, cracking, or strained.</li> <li>• Occupational dystonia—associated with a specific, usually repetitive, activity such as writer's cramp.</li> <li>• Symptomatic dystonia—associated with specific diseases such as Wilson's, lipidosis, and cerebral palsy, among others.</li> </ul> <p>For local dystonias, botulism A toxin is injected into the area, which often results in relief of muscle spasm.</p>
<b>Drug-induced</b>	<p>Several classes of medications may cause blocking of dopamine receptors in the CNS resulting in extrapyramidal signs, including Parkinson's, tardive dyskinesias, and acute dystonia. These medications include benzothiazine, antipsychotics, and antiemetics.</p>
<b>Parkinson's</b>	<p>Two types: Primary involves degeneration of the pigmented cells of the substantia nigra, locus coeruleus, and other areas involved in dopaminergic cells. Secondary Parkinson's is usually the result of medications that act as dopamine blockers (see above). Signs include a pill-rolling tremor (5–8 Hz), difficulty initiating and stopping movement, muscle rigidity, slowness of movement, and a mask-like facial appearance. Dementia affects approximately half of patients.</p>

<b>Progressive Supranuclear Palsy (Steele-Richardson-Olszewski syndrome)</b>	Degeneration of the basal ganglia and brainstem leading to loss of voluntary eye movement control, pseudobulbar palsy, axial dystonia, and eventually dementia. Onset is during middle age. The first sign may be inability to look up with eye movement only; must use neck extension to look up, as when climbing stairs.
<b>Cerebellar/Spinocerebellar</b>	<p>Abnormalities related to the cerebellum may result in dystonias. The range of disorders includes infarcts, hemorrhages, infections, and tumors. Tumors include neuroblastoma cystic astrocytoma. Neurologic disease or disorders include multiple sclerosis, Chiari malformation (cerebellar tissue extends into cervical spinal canal), or basilar invagination with platybasia (flattening of the base of the skull as is sometimes seen in Paget's disease of bone). Degenerative disease results in ataxia and includes:</p> <ul style="list-style-type: none"> <li>• Friedreich's ataxia—an autosomal recessive disorder, with onset during childhood or early adolescence, resulting in upper extremity ataxia and dysarthria. Large-fiber sensory loss leads to loss of vibration and position sense.</li> <li>• Abetalipoproteinemia (vitamin E deficiency) and Refsum's disease—similar characteristics to Friedreich's ataxia.</li> <li>• Cerebellar ataxias—inherited disorder that affects middle-aged individuals with most of the pathologic aspects occurring in the cerebellum.</li> <li>• Multiple systems atrophy (olivopontocerebellar atrophy)—a group of variable disorders including Déjérine-Thomas disorder, Shy-Drager syndrome (autonomic involvement), and Machado-Joseph disease.</li> </ul>

- Cerebellum—Combinations of ataxia, vertigo, and/or dysarthria suggest a cerebellar pathologic process. Cerebellar disorders usually result in problems with the rate, range, and force of movements. The cerebellum is often divided into three functional areas. The

vestibulocerebellum (archicerebellum) includes the flocculonodular lobe and is involved in maintaining equilibrium, coordinating eye and neck movements, and is integrated with the vestibular nuclei. The middle vermis of cerebellum (paleocerebellum) is important for stance and gait. Finally, the lateral hemispheres (neocerebellum) control primarily ballistic types of movements and fine, coordinated movements of the limbs, particularly the arms.

- Brainstem—Cranial nerve problems are often predominant with a crossed pattern of involvement (i.e., the face on the lesion side and the body on the opposite side). The corticospinal tract crosses at the lower medulla.
- Spinal cord—A spinal cord lesion usually has a sensory level; sensory disturbance is found below the level of the lesion. At the level of the lesion an LMNL is often present; below are UMNL signs. In addition, if the lesion is expansive, loss of pain and temperature is often associated with an upper limb weakness that gradually descends to the trunk and lower extremity. Compressive lesions will produce the opposite (if anterior), an ascending pattern of motor weakness. If localized posteriorly, a loss of proprioception is evident.
- Nerve root—Weakness is often associated with low back or neck pain. In addition, there are accompanying sensory complaints such as numbness and/or tingling. More specifically, the pain should follow a related dermatome with weakness in a specific myotome. If there is a corresponding deep tendon reflex (DTR), it will be decreased or absent.
- Peripheral nerve—Like nerve root problems, a distinctive sensory pattern often accompanies peripheral nerve irritation or compression. This pattern should be distinct from the nerve root pattern, as

should the distinctive muscle weakness grouping (assuming a motor component to the nerve). DTRs may be affected.

- Myoneural junction—Myoneural dysfunction is usually more evident with muscles supplied by cranial nerves. Characteristically, repeated contraction causes progressive weakness, with recovery with rest. This is typical of myasthenia gravis.
- Myopathy—Typically, myopathic weakness is evident first proximally. Examples include muscular dystrophy and inflammatory disorders of muscle. There are no sensory findings, and reflexes should be intact. Further investigation with laboratory or electromyographic (EMG) testing is necessary.

A high level of suspicion will have been gained by a thorough history. If there is a sense of a UMNL it is prudent to begin with a search for signs, including hyperreflexia, a pathologic reflex (Babinski's), and eventually changes in muscle tone (spastic weakness). If the lesion appears to be spinal, a search for a sensory level is extremely helpful. A sensory level is a combined finding where there is a sensory disturbance below the level of the lesion accompanied by signs of an LMNL at the level and signs of a UMNL below the level.

The standard grading scale for muscle strength is as follows:

- Grade 5—complete range of motion (ROM) against maximal resistance
- Grade 4—complete ROM against gravity and some resistance
- Grade 3—complete ROM against gravity
- Grade 2—complete ROM if gravity is eliminated
- Grade 1—palpable or visible evidence of muscle contraction, yet no movement

- Grade 0—no evidence of muscle contraction

This standard approach is based on ROM and resistance to gravity or examiner resistance. The distinction between grades 2 and 3, for example, is that with a grade 2 strength the patient is only able to slide his or her leg across the table (gravity is eliminated), while a patient with a grade 3 strength is able to lift the leg off the table (against gravity). The faults of this system lie in the evaluation being dependent on full ROM (isotonic contraction) and the limited choices for grading. Most patients should be examined using isometric muscle testing in an effort first to determine whether pain is causing inhibition or whether true weakness is present. Also, it is important to determine whether normal strength is present within the ROM available.

Although orthopaedic muscle testing has been used to correlate muscle weakness with other localizing neurologic findings (dermatome and deep tendon reflex), other information may be gained. When a muscle is found to be weak it is important to determine why. If the muscle tests weakly and painfully, this response serves little function as a nerve root localizer, yet it is extremely valuable as a soft tissue localizer. In other words, pain often inhibits contraction. Therefore, it is difficult to determine true neurologic function when contraction is painful. If a muscle tests weakly but is painless, there is a high level of suspicion of neurologic weakness or a tendon rupture. Often a palpable bulge or deformity, combined with other findings, clearly differentiates between the two events.

When a muscle is weak and the test is painless, the neurologic differentiation is still incomplete. What becomes apparent when trying to narrow down the possibilities is the overlap among different levels of branching of the peripheral nervous system with regard to motor innervation. For example, if a patient was found to have weakness of the triceps, the extensor carpi radialis, and the extensor carpi

ulnaris, the first suspicion may be radial nerve damage. If the brachioradialis is still strong, however, and the small muscles of the thumb (such as the abductor, opponens, and adductors) are also found to be weak, radial nerve damage is not likely. The two remaining peripheral nerves (median and ulnar) may account for the small muscle weakness, but they could not account for the triceps and extensor carpi weaknesses. This is also true of the divisions and trunks of the brachial plexus. However, the common root level of all weak muscles is C8 and T1. Neither has an associated deep tendon reflex. Neither alone could account for all the weak muscles; therefore, a search for where both could be affected reveals the suspected site at the lower trunk of the brachial plexus. This would be strongly reinforced with a finding of sensory abnormality over the dermatomes for C8 and T1; medial arm down to fifth and fourth fingers.

When performing manual muscle testing, it is important to realize some inherent weaknesses. As mentioned above, pain may cause a muscle to test weakly, and although not necessarily helpful in localizing a neurologic level, it does indicate a structure in need of attention. The other variables that influence a patient's ability to contract a muscle are numerous. These include time of day, gravity, velocity of the test maneuver, technique and instructions of the examiner, ambient noise, and inability to stabilize the muscle origin.<sup>1</sup> Some practical examples of this variation are as follows:

- If one tests the internal tibial rotators with the knee flexed to 90°, but the hip is placed in different positions, strength will vary with hip placement even though the tibia remains the same.
- If the patient feels unstable, she or he may not be able to contract the appropriate muscle(s) fully or may recruit other muscles to assist.
- If the examiner fails to instruct or prewarn the patient, a force may be applied too quickly for the patient to

react, resulting in movement at the joint that could be interpreted as weakness by the examiner.

When a pattern is not clear and a lesion site is not obvious, electrodiagnostic studies may clarify the source (**Table 15-4**). Electrodiagnostic studies, mainly EMG and nerve conduction velocity (NCV) studies, are limited according to the experience and expertise of the examiner. When performed appropriately, however, these studies may help differentiate and in some cases identify the degree of damage when a neuronal pathology exists. EMG uses needle insertion into muscle to test muscle and nerve.<sup>2</sup> The spontaneous activity generated or the response generated with contraction helps distinguish between axon injury and demyelination disorders. NCV uses surface electrodes to measure velocity and the amplitude of an evoked response to an electrical stimulus. Both motor and sensory nerves can be tested.

When an anterior horn cell (or its fibers) is damaged, a specific group of muscle fibers is affected. Surviving neurons are able to sprout collateral fibers to reinnervate the denervated muscle fibers. These changes are reflected on the EMG.

- Because denervated muscle fibers are highly irritable, prolonged activity occurs with needle insertion (this may also occur with myopathy).
- At rest with the needle inserted, spontaneous activity consisting of fibrillations, positive sharp waves, and fasciculations indicate a neurogenic abnormality.
- During contraction of the muscle a reduction in the density pattern, interference pattern, and mean amplitude of motor unit potentials (MUPs) occurs with neurogenic disorders. With myopathies, the duration and amplitude of MUPs are decreased, but the interference pattern is unaffected.

NCV studies involve electrical stimulation at one or more sites along a peripheral nerve measured at a correlated muscle. For a motor NCV, the time it takes from each point of stimulation to the appearance of the muscle potential is referred to as the latency. The conduction velocity is calculated by dividing the distance between two points of stimulation and the time it takes to travel between the two points. Latencies are prolonged and velocities are decreased when there is an internodal demyelination or localized axonal narrowing as seen with specific neuropathies (e.g., carpal tunnel syndrome). More important, however, are the compound muscle action potential (CMAP) and the sensory nerve action potential (SNAP) amplitudes, which are more sensitive to traumatic peripheral nerve injury.<sup>3</sup> Following are some generalizations that may be helpful:

**Table 15-4** Electrodiagnostic Studies

Condition/ Structure	NCV	SNAP/CMAP	EMG	SSEP
Nerve root/anterior horn (radiculopathy) (axonal degeneration)	Probably normal	Usually reduced in 2–3 weeks; SNAP normal if lesion is proximal to DRG	Fibrillation potentials, positive sharp waves, decreased recruitment; MUPs decreased	Interpeak latency between Erb's point and dorsal columns may localize to nerve root
Peripheral neuropathy	Slowed velocity, increased latency (within 1 week)	Unaffected unless conduction block	Not segmental or specific for nerve root	May help localize based on latency
Brachial plexus lesions	Not usually useful	SNAPs decreased or absent	No fibrillation in paraspinal muscles	Sometimes valuable in localizing

Key: NCV, nerve conduction velocity; SNAP, sensory nerve action potential; CMAP, compound muscle action potential; SSEP, somatosensory-evoked potentials; DRG, dorsal root ganglion; MUP, motor unit potential.

- Axonal degeneration will demonstrate normal velocities with NCV studies, but a reduced amplitude of evoked responses. EMG evidence takes about three weeks to surface, revealing spontaneous activity at rest, such as fibrillations and positive sharp waves; during contraction, there is a reduction in the density pattern, interference pattern, and mean amplitude of the MUPs.

- Demyelination disorders will demonstrate early changes in the nerve conduction velocity with relatively normal evoked amplitude responses.

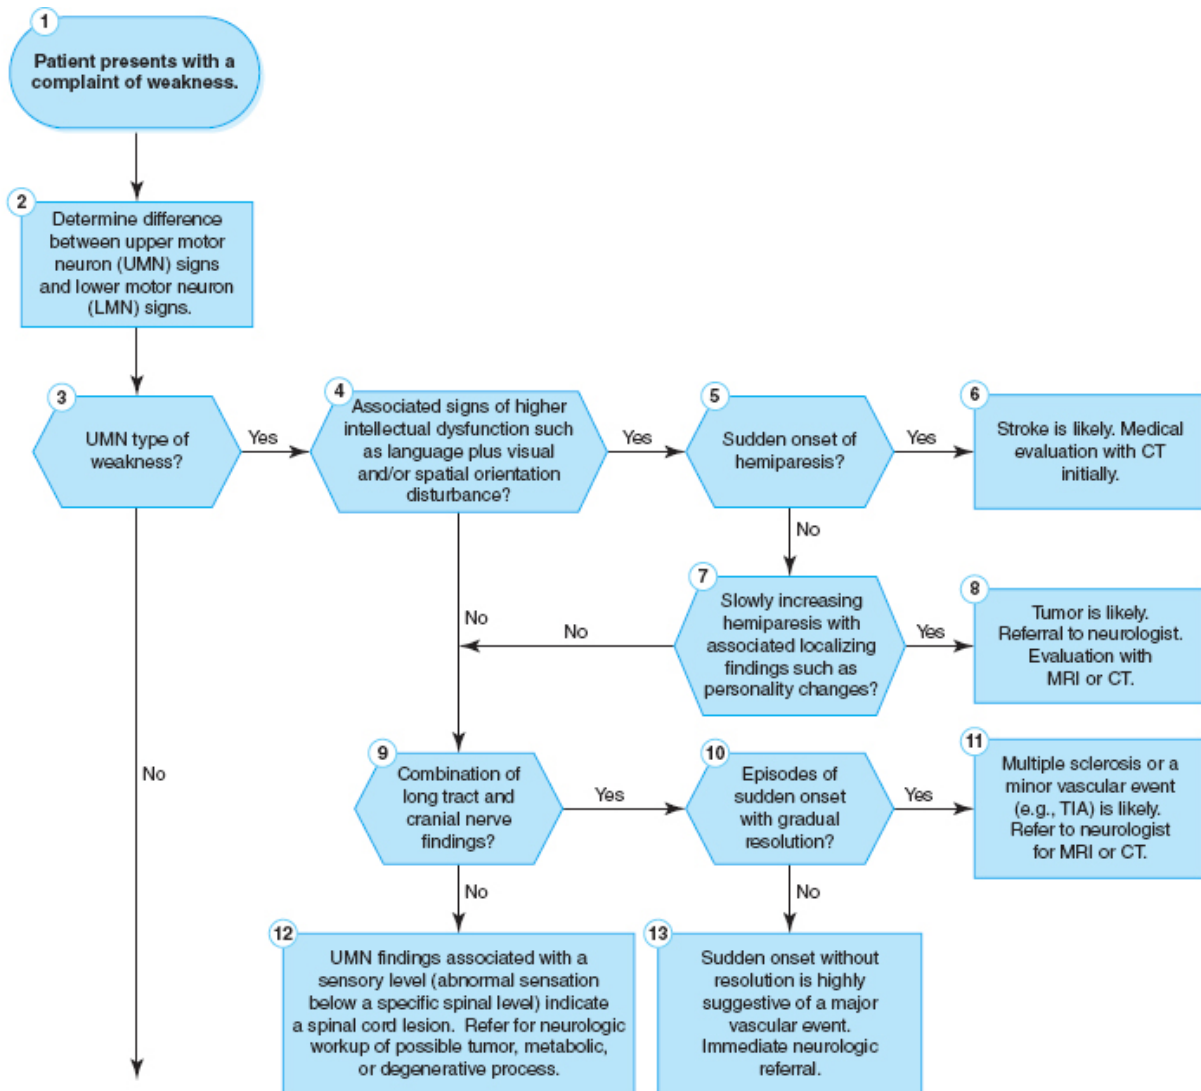

When a proximal weakness pattern is found, further testing for a myopathic cause should include laboratory testing (e.g., lactate dehydrogenase) and muscle biopsy.

## Management

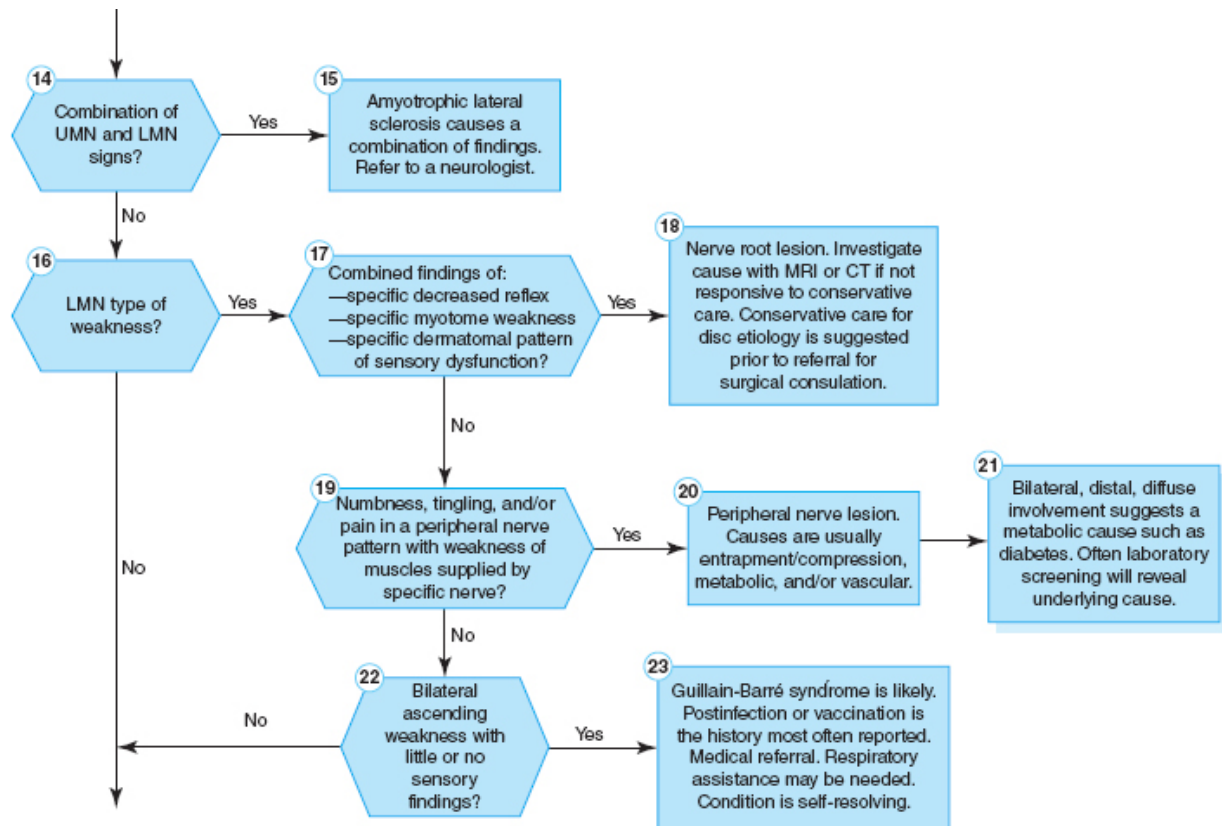

Medical management is necessary for patients with UMNL, myasthenia gravis, Guillain-Barré syndrome, and drug- or toxin-induced neuropathy, or in the event that no known cause can be found. Most other causes of regional or specific weakness can be managed conservatively through a combination of spinal adjusting and muscular re-education. The reader is directed to chapters on specific disorders for a more detailed description of conservative management recommendations.

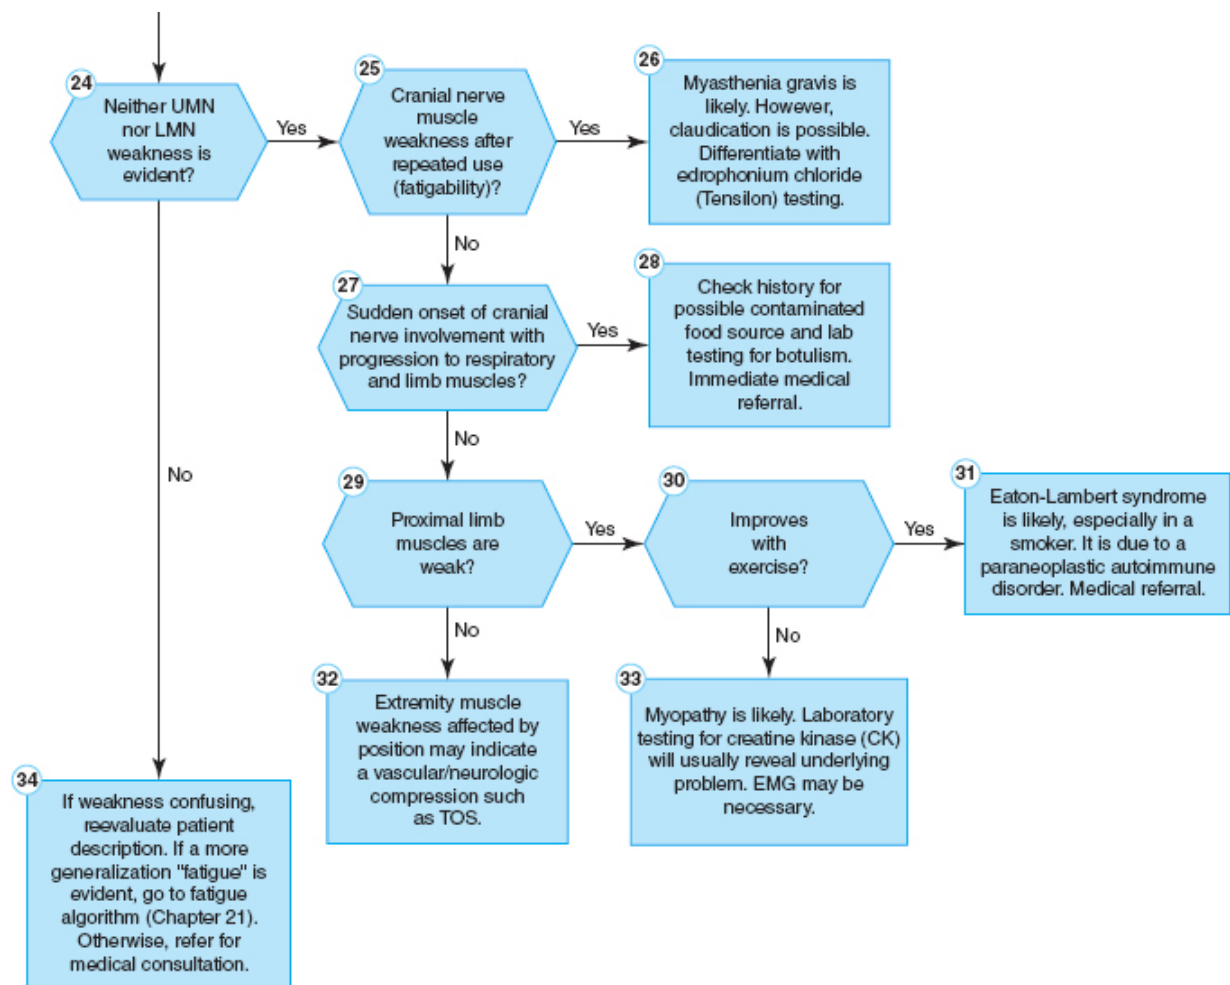

## Algorithm

An algorithm for evaluation and management of weakness is presented in **Figure 15-1**.

**Figure 15-1** Weakness—Algorithm

# Selected Neurologic and Muscular Diseases\*

## Bell's Palsy

### Classic Presentation

The patient complains of facial weakness and distortion and is unable to close one eye. There may be an associated ear pain. The patient does not recall any cause, just simply "woke up with it."

### Cause

The cause is unknown; however, it is believed that a viral infection may cause an inflammatory reaction in the facial nerve near the stylomastoid foramen or in the facial nerve path through the temporal bone. Other causes of facial nerve involvement include stroke, cerebral tumor (mainly involves lower face), Ramsay Hunt syndrome (herpes vesicles visible in the ear), mastoid infection, fracture, or cerebellopontine angle tumors (associated hearing loss).

### Evaluation

The patient's face appears expressionless on the involved side. If the case is severe, the palpebral fissure is widened and the patient cannot close the eye on the involved side. A deficit in taste and a hyperacusis may also be present.

### Management

There is still a debate as to whether Bell's palsy should be treated initially. The general belief is that because 60% of patients recover completely without treatment and that the patients who do not usually have a more severe form, corticosteroids should be given only if the palsy is complete. It has not been demonstrated conclusively that this helps, but it does appear to reduce pain. The best approach is to monitor the degree of involvement for two or three

days. If severe after this time, referral for a limited course of corticosteroids is warranted. Eye drops and a patch may be needed until eye closure is possible. Faradic stimulation or other physical therapy approaches may prevent contracture of facial muscles in long-term cases. Poorer prognosis is assumed with patients who are elderly, have hyperacusis, or have severe initial pain.

## **Parkinson's Disease (Paralysis Agitans)**

### **Classic Presentation**

The patient is older (aged 45 to 65 years) with a complaint of difficulty with movement and associated tremors. Often the patient has no specific complaint, yet on physical examination, the cardinal signs of parkinsonism are present. These include rigidity, bradykinesia, tremor, and walking difficulties.

### **Cause**

Parkinson's disease is due to dopamine depletion caused by degeneration of the nigrostriatal system. This leads to an imbalance between dopamine and acetylcholine. The extrapyramidal system that controls the smoothness of movement is profoundly affected.

### **Evaluation**

The cardinal clinical features of Parkinson's disease are resting tremor, bradykinesia, rigidity, and asymmetric onset.<sup>4</sup> Researchers performing a systematic review of the literature attempted to determine the value of common signs and symptoms associated with the diagnosis of Parkinson's.<sup>5</sup> Their recommendations are to pay particular attention to the following: patients who report difficulty turning in bed, opening jars, and rising from a chair. Important signs include rigidity, tremor, bradykinesia, micrographia, and a shuffling gait. The glabella tap and heel-to-toe tests may also be valuable. As the disease progresses, the patient appears to have a blank, emotionless facial expression. Seborrhea of the skin is also frequently seen. Although muscle strength is good, the patient is slow to react. There is often a visible tremor (four to six cycles per second) that is present at rest and is less severe with voluntary movement. Passive movement of the limbs reveals a characteristic rigidity (i.e., cogwheel or ratchet). Tapping over the bridge of the nose (two times per second) creates a sustained blink response (Myerson's sign). The patient's walk will often demonstrate a classic

festinating gait in which the patient takes many small, shuffling steps and has difficulty stopping. The arms do not swing automatically with walking. Some of the early signs are difficult to differentiate from signs of old age. Even in later stages it is difficult to distinguish between autopsy-diagnosed multiple-system atrophy, supranuclear palsy, and cortical-basal ganglionic degeneration. On heavily weighted T2 magnetic resonance imaging (MRI), there is narrowing of the substantia nigra para compacta in patients with Parkinson's disease. Other MRI findings may help differentiate Parkinson's disease from other similar disorders.

## Management

Treatment is aimed at either blocking the effects of acetylcholine with anticholinergic drugs or restoring dopamine levels with levodopa (precursor to dopamine). Early parkinsonism is not usually treated. Mild parkinsonism is treated with amantadine. With progression, levodopa is effective in treating many of the features of parkinsonism; however, it is associated with various dyskinesias and an "on-off" phenomenon characterized by abrupt fluctuations in symptoms. Sinemet is most often given.<sup>6</sup> It is a combination of levodopa and carbidopa. Carbidopa-levodopa (Sinemet) is sometimes given with other medications such as bromocriptine (ergot derivative). **Table 15-5** is a list of commonly used medications and their side effects. One study<sup>7</sup> indicated that estrogen replacement in early Parkinson's disease may lower symptom severity. Other approaches include posteroventral pallidotomy, bilateral fetal nigral transplantation, and electrical stimulation of the subthalamic nucleus.<sup>8</sup>

## Multiple Sclerosis

### Classic Presentation

The patient is younger (less than age 55 years) presenting with a history of dizziness, numbness, tingling, or weakness that resolved over a few days. Other similar neurologic events have occurred in the past.

### Cause

Multiple sclerosis (MS) is a disease characterized by patchy demyelination with reactive gliosis in the spinal cord, optic nerve, and white matter of the brain.<sup>9,10</sup> The cause is unknown, but MS is suspected to be an immune disorder. MS occurs mainly in individuals who live in temperate zones and especially in individuals of western European ancestry. The combination of a genetic predisposition coupled with decreased sunlight exposure may trigger the process for susceptible individuals. The relapsing/remitting type (RRMS) accounts for 85% of presentations. For most patients the onset is

predominantly between ages 20 to 40 years but for the progressive relapsing type of MS (least common) its onset more often is in patients older than age 40 years. There is an apparent genetic relationship due to the association of MS and HLA-DRB1. As part of a cascade of research on what appears to be an epidemic of vitamin D deficiency, a study<sup>11</sup> has found that high circulating levels of vitamin D are associated with a lower risk of multiple sclerosis. Another suspected associated risk is smoking.<sup>12</sup> The role of Epstein-Barr virus is still debated<sup>13</sup> but a 2007 study<sup>14</sup> does indicate that high titers of antibodies for Epstein-Barr virus B2LF1 are a strong predictor of MS.

**Table 15-5** Parkinson's Medications

Drug Class	Examples	General Mechanism	Interactions/Side Effects
Carbidopa	Sinemet Lodossyn	Prevents peripheral metabolism of levodopa in effect making more available to the brain. Also prevents the inhibitory effects of pyridoxine (B6) on levodopa. Used in the management of Parkinson's.	May cause visual disturbances, GI symptoms, confusion, involuntary movements, hallucinations, dyskinesia, hypotension, and depression with suicidal tendencies.
Levodopa (L-Dopa)	Dopar Larodopa	L-dopa is the metabolic precursor to dopamine. Its advantage is it crosses the blood-brain barrier. Helps restore levels of dopamine in extra-pyramidal areas of the brain. Used in the treatment of Parkinson's.	May cause choreiform and other involuntary movements, increase tremor and cause bradykinetic episodes (on-and-off phenomenon). Many other side effects occur including hallucinations, paranoid delusions, severe depression and suicidal tendencies. There are a host of other system effects that include possible dark sweat or urine and all the other common side effects of many medications.
Selegiline	Eldepryl	Increases dopaminergic activity partial action due to MAO inhibition and inhibition of dopamine reuptake. Used as adjunctive treatment for Parkinson's.	May cause visual disturbances, GI symptoms, confusion, hallucinations, dyskinesia, and hypotension.
Bromocriptine	Parlodel	Reduces prolactin levels and through a series of events activates dopaminergic receptors in the hypothalamus which then releases prolactin inhibiting factor. Used for amenorrhea/galactorrhea or female infertility, but also used as adjunctive therapy to levodopa for Parkinson's.	May cause headaches, agitation, nervousness, mania, orthostatic hypotension, Raynaud's, depression, acute MI, or shock.

## Evaluation

MS is characterized by episodic attacks that initially resolve but eventually leave residual neurologic deficits. The initial episode often will resolve in days, and the patient may remain symptom-free for months or years. Eventually, however, symptoms recur. Symptoms usually will involve a region and consist of numbness, tingling, weakness, diplopia, dizziness, or urinary sphincter dysfunction (urgency or hesitancy). Optic nerve involvement is common and often the first source of signs/symptoms. The frequency of initial attacks is prognostic for future disability severity. The clinical diagnosis is based on two or more distinct episodes at least three months apart with two distinct neurological deficits with partial resolution eventually. On physical examination, in addition to finding scotomas or nystagmus on the eye exam,

flexion of the neck may produce the Lhermitte sign of electric-shock sensations down one or both arms. MRI will demonstrate multifocal areas of patchy demyelination in the brain or cervical spinal cord. T2 images show these areas as hyperintense due to breach of the blood-brain barrier. T1 images demonstrate hypointense lesions (black or gray holes). On serial images lesions may disappear due to resolution of edema. Laboratory evaluation may reveal mild lymphocytosis or increased protein count in the cerebrospinal fluid (CSF; more often in acute attacks). Immunoglobulin G and oligoclonal bands are more often seen in the CSF. Other findings include an abnormal colloidal gold curve, mild mononuclear pleocytosis with lymphocytic predominance (< 40 cells/mL), and myelin debris.<sup>15</sup>

## Management

There is no cure for MS. During acute exacerbations, corticosteroids are sometimes used to speed recovery. In addition to prednisone and methylprednisolone, immunosuppressive therapy with interferon-beta 1b (e.g., Betaseron) is used. Other drugs include Copaxone, Tysabri, and Gilenya. Monitoring of liver function is important. Nutritional approaches are unproven, yet some research<sup>16</sup> suggests that an increase in polyunsaturated fatty acids and metabolic enzyme supplements assist in providing an adequate lipid pool for oligodendrocytes. Also, antioxidants such as vitamins A, beta-carotene, E, C with bioflavonoids, and selenium may help with myelin membrane peroxidation.<sup>17</sup> Relapses commonly occur in women two to three months after childbirth. **Table 15-6** lists some medications and side effects for the management of multiple sclerosis. Seventy percent of patients live active lives, although within 10 years 50% are using a cane or wheelchair. Life expectancy is approximately the same as those without the disease.

**Table 15-6** Multiple Sclerosis Medications

Interferon Beta 1a and 1b	Avonex Rebif Betaseron	A recombinant DNA medication that has effects that are antiviral, antitumor, antiproliferative, and immunomodulatory. Used in the management of relapsing multiple sclerosis.	Common to have side effects including headache, fever, chills, anxiety, nervousness, GI disturbances, alopecia, abnormal mood, emotional lability, and confusion. Possible lab effects on thrombocytes and granulocytes.
Isoniazid	INH Isotamine Laniazid Nydrazid Teebaconin	An anti-TB medication that interferes with the synthesis of bacterial proteins, lipids, and nucleic acids. Used also for high-risk individuals as a preventive. Additional use for tremors with multiple sclerosis.	May cause paresthesias, peripheral neuropathies, tinnitus, dizziness, hallucinations, increased liver enzymes, decrease in B vitamin absorption, RA and SLE-like syndromes, or possible agranulocytosis and aplastic anemia (rare).
Natalizumab	Antegren	A humanized monoclonal antibody used to treat multiple sclerosis and Crohn's disease. A receptor blocker that binds to alpha-4-beta-1 and alpha-4-beta-7 integrins, natalizumab prevents lymphocytes and eosinophils from moving from the bloodstream to outer tissue sites involved in inflammation. For multiple sclerosis it is used in combination with interferon beta 1-a).	Most common side effects are abdominal pain and headache.

## Guillain-Barré Syndrome

### Classic Presentation

The patient complains of bilateral leg weakness following either a viral infection or immunization. The patient may also complain of distal paresthesias.

### Cause

The cause is unknown; however, it is believed to be a demyelinating, autoimmune disorder. Association to a postviral illness may be found; however, association to vaccines has not been proven.

### Evaluation

The patient will have primarily motor signs, including loss of deep tendon reflexes. Because of autonomic involvement, there are fluctuations in blood pressure, abnormalities in sweating, and sphincter dysfunction. The weakness progresses variably, involving the arms and face in some patients. About 10% of patients have respiratory involvement. Examination of CSF demonstrates a high protein content; however, this may take two to three weeks to become evident.

# Management

The condition is self-resolving in 80% to 90% of patients within months. During this period of time, a minority of patients will require respiratory assistance. About 10% of patients will have residual disability, and about 3% will have relapses. Prednisone should not be given because of the possibility of prolonging recovery time. Plasmapheresis and intravenous immunoglobulin may be of benefit.

## Myasthenia Gravis

### Classic Presentation

The patient is often a young woman complaining of double vision, difficulty swallowing, or weakness of the arm with repeated use or weakness of the jaw muscles when chewing.

### Cause

Ocular myasthenia gravis (MG) occurs in 15% of cases but 50% of these progress to generalized MG (85% of MG patients). In 10% to 20% of infants born to MG mothers, transient MG symptoms occur, resolving in weeks to months. D-penicillamine may cause drug-induced MG. The peak age groups for myasthenia gravis (MG) are men older than 50 years, women aged 20 to 40 years, and then around age 70 years. Neuromuscular transmission is blocked by autoantibodies that bind to acetylcholine receptors, making them unavailable. The disease may be idiopathic or associated with a thymoma, thyrotoxicosis, rheumatoid arthritis, or lupus erythematosus. Thymomas are more common in older men. The initiation of MG may be related to prior viral infection including polio, measles EBV, or HIV.

### Evaluation

A recent review by Scherer et al.<sup>18</sup> evaluated the ability to determine if a patient has MG based upon the history and examination. Sixty-five percent of patients will have double vision and a drooping eyelid. However, less than one-fourth will have bulbar weakness, report slurred or nasal speech, alteration of the voice, or difficulty chewing or swallowing. Unintelligible speech during prolonged speaking and the presence of the peek sign increased the likelihood of an MG diagnosis, although absence did not rule it out. The peek sign is elicited by having the patient gently close the eyes.

Within 30 seconds (due to orbicularis oris weakness) the eyelid will start to elevate slightly revealing the sclera (peek sign). Using the eye with a higher degree of ptosis, three tests can be performed: the ice test, the rest test, and the sleep test. A latex glove finger filled with ice is placed over the ptotic eyelid for two minutes with the ice test. A latex glove finger filled with cotton is used as a placebo measure in the rest test, again held over the eyelid for two minutes. The sleep test involves having the patient close his or her eyes in a dark room for 30 minutes. A positive response is a complete response to one of the tests, or an improvement of 2 mm increase in the palpebral fissure. Other tests include the curtain test, which involves the examiner holding one lid open while the other gradually closes. If ptosis worsens when propping up the opposite eyelid or with sustained upward gaze a positive curtain sign is found. Strongly diagnostic is a response to an anticholinesterase medication, the Tensilon test (also called the edrophonium test). Lab testing includes an assay for anti-ACh receptor antibodies. Those without anti-AChR antibodies sometimes have antibodies to muscle-specific tyrosine-kinase (MuSK), which occurs more in females who have both bulbar and respiratory weakness. If thymoma is the cause, the lab test is for antistriated muscle (anti-SM) antibody (85% of patients over 40 years with thymoma).<sup>19</sup>

Repeated muscle contraction or eye movement leads to fatigue, although initial movement or contraction is strong. Reflexes and the sensory examination are normal. In older men, a chest radiograph and/or computed tomography may be considered in a search for a thymoma. Electrophysiologic testing will reveal a decreasing response to stimulation. Laboratory testing includes a new test to assay the circulating levels of acetylcholine receptor antibodies (sensitivity is 80% to 90%). Medical evaluation involves drug testing using a short-acting anticholinesterase, which causes a temporary increase in strength.

## Management

Standard anticholinesterase medications include pyridostigmine (Mestinon) neostigmine (Prostigmin), and ambenonium (Mytelase). For immunosuppression, oral corticosteroids may be used. **Table 15-7** lists these medications and their potential side effects. Those who have antibodies to MuSK may have a bad reaction to cholinesterase inhibitors but do better with plasmapheresis selected immunotherapy like Rituximab (monoclonal antibody against antigen on B cells). Thymectomy often is dramatically effective, and it is often recommended to patients under age 60 years. However, this choice should be reserved for those with progression or those unresponsive to medical management.

## Amyotrophic Lateral Sclerosis

# Classic Presentation

The patient is an adult who complains of muscle weakness and cramping in the hand. Progressively, signs and symptoms multiply, including difficulty in swallowing, chewing, coughing, or breathing.

## Cause

Amyotrophic lateral sclerosis (ALS) is part of a group of motor neuron diseases with degeneration of the anterior horn cells and motor nuclei of the lower cranial nerves, corticospinal and corticobulbar tracts. The disorder occurs between ages 30 and 60 years and is progressive. Although most cases are sporadic, there are some familial cases.

## Evaluation

This disorder is characterized by a combination of upper motor neuron and lower motor neuron lesion signs. Therefore, in addition to muscle atrophy and fasciculations, there are often brisk deep tendon reflexes. Sensory examination is normal, and the sphincters are not affected. EMG will reveal abnormal spontaneous activity in a resting muscle and a decrease in recruitment ability.

## Management

There is no treatment for ALS. The disease usually progresses to death over a period of about two to two-and-a-half years in most patients. The five-year survival rate is only 20%.

## Syringomyelia

# Classic Presentation

The patient is usually young. The parents are concerned about either the observation that the child injures his or her hands or arms and does not notice or the observation of a scoliosis.

## Cause

A syrinx occurs in the central spinal cord either as a developmental problem or due to destruction or degeneration of gray and white matter secondary to trauma or an intramedullary tumor. Many cases are associated with herniation of the cerebellar tonsils, medulla, and fourth ventricle into the spinal canal. This developmental disorder is referred to as an Arnold-Chiari malformation. In this condition, the syrinx is actually a dilation of the central canal.

## Evaluation

The patient will lose pain and temperature sense in a shawl-like distribution over the upper trunk and arms. Atrophy and areflexia also may be evident. Scoliosis is often present, and sometimes it represents a distinct opposite of the normal right-thoracic, left-lumbar curves, namely a left-thoracic, right-lumbar curve pattern. MRI evaluation will demonstrate both the Arnold-Chiari malformation with the cerebellar tonsils below the foramen magnum and also the level and extent of the syrinx.

## Management

Treatment is surgical with decompression, including laminectomy in the upper cervical region and shunting of fluid into the peritoneum in some cases.

## Neurofibromatosis

### Classic Presentation

The patient is often a child brought by parents concerned about multiple skin lesions on the trunk area. Otherwise the patient is often asymptomatic. In other cases, parents are concerned about a child's hearing or eyesight problem.

## Cause

Neurofibromatosis is a familial disorder that is either autosomal dominant or sporadic, occurring with no known cause. The characteristic lesions involve the Schwann cells and nerve fibroblasts. There are two distinct types, type 1 and type 2. The patient with type 1 will present with multiple hyperpigmented nodules. The patient with type 2 often presents with problems with hearing or eyesight.<sup>20</sup>

# Evaluation

Finding the characteristic café-au-lait lesions over the trunk, pelvis, or flexor creases of the arms is virtually diagnostic if six or more large lesions are found. The neurofibromas are slowly progressive and in type 1 may lead to the rare but deforming Recklinghausen's disease. With type 1, plexiform neuromas (overgrowth of subcutaneous tissue) and bone distortion occur. With type 2, intracranial tumors affect cranial nerves controlling eyesight, balance, and hearing.

# Management

There is no known treatment. Surgical removal of tumors of the skin and nerves is the only recourse for patients at this time.

## Muscular Dystrophy (Duchenne Type)

# Classic Presentation

Muscular dystrophy (MD) is a group of inherited myopathic disorders, each of which presents differently. The most common is the Duchenne type (pseudohypertrophic). The patient is between the ages of 1 and 5 years. The parents note that their child has difficulty in rising from a bent-over position, has a waddling gait, and falls often.

# Cause

Duchenne's is an X-linked recessive gene disorder. The defective gene leads to a marked reduction or absence of an important protein, dystrophin.<sup>21</sup>

# Evaluation

The characteristic difficulty in rising from a bent-over position may cause the patient to walk up the legs with his or her hands. Proximal muscle testing may indicate weakness. The disease affects the limbs first, then the shoulders. Pseudohypertrophy may occur as a result of fatty replacement of muscle. Mild mental retardation is also found. Laboratory studies will reveal markedly elevated creatine kinase (CK) levels. DNA analysis is the primary follow-up tool. If CK levels are elevated, deletion and duplication analysis is performed first; then, if negative, DMD testing for full sequencing for the DMMD gene for

point mutations is performed. Other tests include dystrophin protein assay and muscle biopsy.<sup>22</sup>

## Management

There is no treatment for the disease. However, for slowing the decline of muscle function prednisone may be helpful. Progression is rapid, leading to the need for a wheelchair. Patients progressively decline and finally die before age 20 years in most cases. Females on the maternal side of an affected child should be tested for elevations of CK or lactate dehydrogenase on several occasions. It is important to note that 50% of female carriers have twice the normal CK levels. These elevated markers may indicate the need for genetic counseling. Also, genetic studies in early pregnancy can determine whether the child will have Duchenne's. In late pregnancy DNA probes can be used on fetal tissue to diagnose Duchenne's in the fetus. There may be some potential hope for the use of gene therapy in the future.<sup>23</sup>

# CHAPTER 16

## Numbness, Tingling, and Pain

### Context

Patients complaining of pain do not necessarily have pathologic involvement of neural tissue but do have a response due to trauma or irritation of nociceptive nerve fibers. Patients complaining of numbness or tingling, however, are more likely to have disease, ischemia, or injury of neural tissue. The list of possible causes is enormous and can be narrowed down only by combining the findings of location, onset, and associated neural localizing findings (i.e., motor deficit or deep tendon reflex abnormality) (**Exhibit 16-1**). Although trauma or direct irritation often may be the source of these complaints, it is important to remember the sometimes transient response of neural tissue to ischemia (e.g., diabetes) or metabolic imbalance (e.g., uremia) that may occur with systemic processes.

Chiropractors are often faced with the presentation of a patient who claims numbness but when clinically evaluated has no objectifiable loss. Important discriminators are finding associated neurologic signs indicating nerve root or peripheral nerve pathology; however, these also are often absent. Possible explanations for this lack of evidence include the presence of a transient process,

misinterpretation of the sensation by the patient, a “referred” sensory abnormality, and malingering.

Sensory perversions are often divided into two categories: paresthesia and dysesthesias. Paresthesias are spontaneous, abnormal sensations, described by patients as “pins and needles” or tingling. Dysesthesias are irritating sensations evoked by normally nonnociceptive stimuli such as light touch. Sometimes used synonymously with dysesthesias is hyperpathia—normal stimuli are pain producing. Hypesthesia implies that there is an elevated threshold to stimulus. For example, pain is felt with a pinprick, but the applied pressure needed for pain perception is greater than would normally be required.

## **General Strategy**

### **History**

- Ask the patient to define what he or she means by a complaint of numbness, tingling, or other unusual sensations.
- Attempt to localize to a specific body region (distinguish between single and multiple areas, and whether the sensation is felt more distally in the hands or feet).
- Determine any associated symptoms such as pain or weakness.
- Determine whether the onset was abrupt or gradual and whether or not was related to trauma.
- Determine whether the patient has a known diagnosis of or indications of diabetes, alcoholism, liver or renal disease, or anxiety or depression; obtain a thorough drug history.

Attempt to differentiate chronic nociceptive pain from chronic central pain

## Evaluation

- Perform a neurologic examination focusing on sensory testing; begin distally in an attempt to determine selective loss or alteration of pain, temperature, light touch, vibration, and position sense.
- Examine the motor system in an attempt to correlate findings suggestive of nerve root or peripheral nerve involvement.
- When a clear picture is not evident, it may be necessary to proceed to electrodiagnostic or other specialized testing based on the suspected cause.

### **Exhibit 16-1 Narrowing the Possible Causes of Numbness**

## Patient complains of numbness

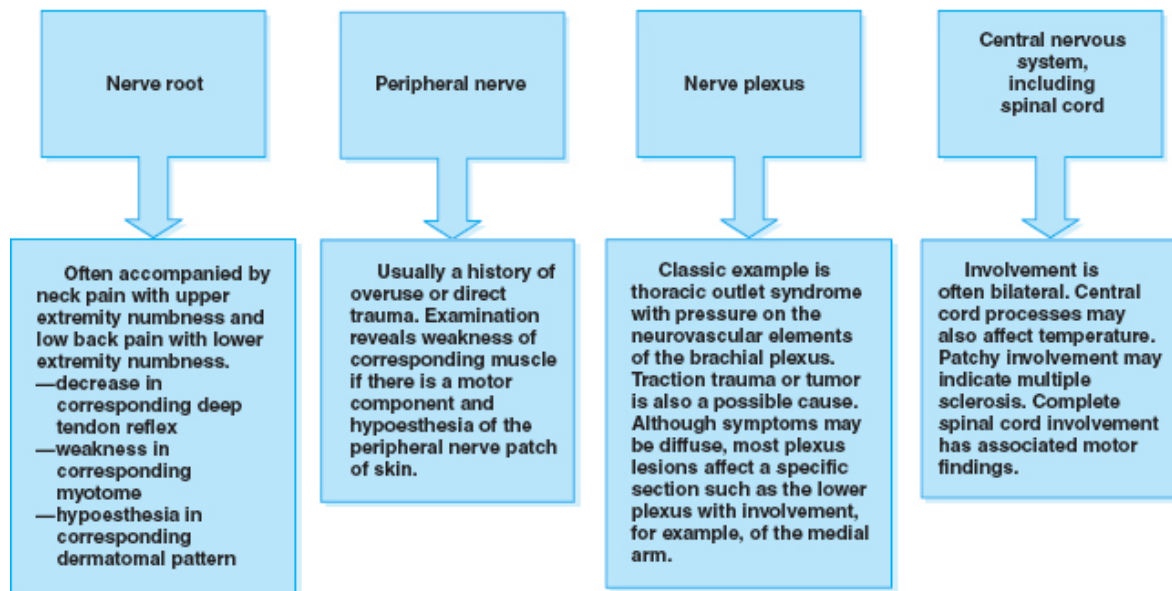

### Differentiate between objective and subjective numbness with a sensory examination

Subjective numbness is suggestive of referral or a transient process (no demonstrable sensory or motor findings; often diffuse, following no specific dermatomal pattern)

### Distinguish among various neurologic possibilities

## Management

- Most cases of isolated peripheral nerve or nerve root problems can be managed initially by the chiropractor; monitor for progression or unresponsiveness to determine need for neurologic consultation.

- Some metabolic disorders, such as uremia, often require referral for management; others, such as diabetes, can be comanaged.

## Relevant Anatomy

The following is a brief and generalized overview of the sensory nervous system. Participants in the sensory system include nerve cell bodies, nerve fibers, and sensory receptors. The types of sensations that are conveyed are generally divided into (1) pain and temperature, (2) touch, and (3) proprioception and vibration.

Free nerve endings are the primary receptors for pain and temperature. The signal is then carried to the first nerve cell body in the dorsal root ganglion (DRG). Fibers leaving the DRG enter the spinal cord by accessing Lissauer's tract (dorsolateral tract) and ascending or descending one or two segments before synapsing in the substantia gelatinosa. At this level interactions with interneurons influence transmission. From the second-order neuron. A delta (small myelinated) fibers cross the anterior commissure and ascend in the contralateral lateral spinothalamic tract, ascending to the thalamus to synapse primarily in the ventral posterolateral (VPL) nucleus of the thalamus. C fibers also cross in the spinal cord to ascend primarily in the anterior spinothalamic tract and terminate in the intralaminar and parafascicular nuclei of the thalamus. Both then continue to the somatic sensory area of the cortex. The lateral spinothalamic tract also carries touch and deep pressure sensations.<sup>1</sup>

For sensation of the head and related structures, the trigeminal nerve is the primary supply. Nerve cell bodies are found in the trigeminal ganglion. The spinal nucleus of the trigeminal nerve is devoted to pain and temperature. The main sensory nucleus serves the other sensory components

such as discriminative touch. These signals travel in the trigeminal lemniscus in the brainstem to the ventral posteromedial (VPM) nucleus of the thalamus.

Other than conscious pain conveyed through the anterolateral system, several pathways convey signals through medial pain pathways that affect emotion, motivation, withdrawal, arousal, and autonomic reactions to nociceptive stimulation. These tracts may also trigger responses that contribute to the central or supraspinal inhibition of pain. Following is a brief summary of these pathways and functions.

- **Spinoreticular tract**—Terminating in the reticular formation, this tract and the reticular formation provide information that influences autonomic nervous system (ANS) reflexes and the emotional experience and response to pain.
- **Spinomesencephalic tract**—Nociceptive signals terminate in the periaqueductal gray (PAG) of the midbrain and may also connect with the limbic system leading to a perception of diffuse, poorly localized pain, and also a fear response. Due to termination in the PAG, the spinomesencephalic tract may activate a descending inhibitory system that results in analgesia due to the release of serotonin.
- **Spinolimbic tract**—This pathway also provides for a non-localized perception of pain. Other manifestations are suggested through its synaptic connections to the midline thalamic nuclei, resulting in arousal and motivational effects via projections to both the frontal and cingulate cortex. It may also be involved in supraspinal inhibition of pain.

Nociceptive information projects through these tracts to at least four areas of the brain above the brainstem:

- To the parietal cortex for localization of pain only, but not the painful experience
- To the cingulate cortex of the limbic system for the emotional experience of pain
- To the temporal lobe for the imbedding of memory of the pain and what evokes pain
- To the hypothalamus for activation of the endocrine and autonomic nervous system

Descending systems, which are activated by the PAG of the midbrain and originate in the raphe nuclei and locus ceruleus, release serotonin (5-HT) and norepinephrine respectively. These neurotransmitters stimulate the endorphin-releasing interneurons and primary pain neurons, thereby “closing” the pain gate.

Larger, myelinated fibers participate in conveying information for proprioception and vibration. These include type Ia fibers for primary endings (annulospiral endings) in muscle spindles (intrafusal fibers) for stretch, and for Golgi tendon organs and ligament receptors for tension. Medium-size, myelinated nerves carry non-conscious proprioceptive information on type II fibers from muscle spindles (flower-spray endings) and joint mechanoreceptors (Pacinian corpuscles for movement and vibration and Ruffini for end-range stretch). Medium-size, myelinated type A-beta fibers carry fine touch and vibration through cutaneous and subcutaneous receptors. These include:

- Superficial (cutaneous): Meissner’s corpuscles—light touch and vibration; Merkel’s disks—pressure, and hair follicle receptors—displacement
- Subcutaneous: Pacinian corpuscles—touch and vibration; Ruffini’s corpuscles—stretching of skin

For conscious proprioception, fibers carry information to the first-order neurons in the dorsal root ganglion and then to

the posterior column of the spinal cord and ascend without crossing to synapse on second-order neurons in the nucleus gracilis and cuneatus in the medulla. They then cross to ascend in the medial lemniscus to the third-order neurons mainly in the VPL of the thalamus. After synapsing, the third-order neuron fibers ascend via the internal capsule to the corona radiata, accessing the neurons of the postcentral gyrus.

Other tracts convey non-conscious proprioceptive information to primarily the cerebellum. There are four tracts with the two devoted specifically to non-conscious proprioception. The other two are for the reporting of internuncial activity at the spinal cord level. These four tracts include the following:

- Posterior spinocerebellar—Conveys information primarily for the lower extremity and lower trunk. This information is muscle spindle information and some cutaneous information such as vibration. Fibers travel in the posterior columns (gracile fasciculus) to the posterior thoracic nucleus (dorsal nucleus; Clarke's nucleus or column) found only in T1-L1 (L2) segmentally. These remain ipsilateral (uncrossed) traveling to the cerebellum through the inferior cerebellar peduncle.
- Cuneocerebellar—Conveys information primarily from the upper extremity and upper trunk. Fibers travel in the cuneate fasciculus synapsing in the accessory cuneate nucleus in the medulla just superior and outside of the cuneate nucleus
- Anterior spinocerebellar—This tract relays information regarding the activity of spinal reflex arcs. They double-cross; initially cross and then cross back after entering the cerebellum through the superior cerebellar peduncle.

- **Rostral spinocerebellar**—This tract also relays information regarding the activity of spinal reflex arcs. It enters the inferior cerebellar peduncle without crossing.

Two other tracts that may be involved in behavioral reaction and learning related to pain include:

- **Spinotectal tract**—Follows spinothalamic tract but ends in the superior colliculus; turning the eyes toward the painful stimulus.
- **Spinoolivary tract**—Sends tactile info to the inferior olivary nucleus (just lateral to the pyramids); involved in motor learning and modifying learned reflex activities.

The general architecture of the spinal cord may give clues to certain patterns of sensory loss or weakness. Therefore, a compressive myelopathy, for example, may produce an ascending pattern of sensory loss if progressive. A spinal lesion more centrally located (e.g., syringomyelia) would interrupt fibers that cross, such as those conveying pain and temperature, while sparing the dorsal column pathways, leaving vibration and proprioception unaffected.

It is believed that paresthesias and dysesthesias are the result of either damage to large fiber axons or demyelination. This is most common with structural damage that occurs with peripheral nerve or nerve root compression or toxic/metabolic disorders that cause neuropathy. Numbness is more often the result of loss or damage to smaller sensory fibers affecting both pain and temperature perception.

Through stimulation of nociceptor afferents pain causes a complex multisystem response which potentially involves the following:

- Reflex muscle spasm via synaptic activation of  $\alpha$  motoneurons.
- Stimulation of the sympathetic nervous system resulting in vasoconstriction. Resulting ischemia may activate more nociceptors.
- Nociceptive stimulation of the hypothalamus causing the release of catecholamines, adrenocorticotrophic hormone (ACTH), cortisol, glucagon, anti-diuretic hormone (ADH), and other catabolic hormones, along with a concomitant decrease in the anabolic hormones insulin and testosterone

Chronic pain is a very common problem that is often divided into nociceptive chronic pain and neuropathic pain. With chronic pain of nociceptive origin, there is a pain generator present such as tissue damage from infection or pressure pain from a tumor. Neuropathic pain, though, is an example of pain becoming a disease rather than indicating tissue damage. In other words, the stimulus for pain no longer remains, but alterations in the peripheral or central nervous system continue to propagate pain. Peripherally there are several proposed mechanisms, including ectopic foci development, ephaptic transmission, and structural reorganization. When myelin damage is present, it is sometimes a reaction by the nervous system to produce excessive ion channels that are inserted into the demyelinated tissue which then becomes sensitive to stimulation. Another reaction that occurs with myelin damage is ephaptic transmission, also called cross-talk. This occurs when an action potential from a damaged neuron stimulates a neighboring neuron. Finally, structural reorganization can occur with changes in the dorsal horn where retraction of C fiber terminals is replaced with A-beta fiber axon terminals synapsing in areas that would normally receive only C fibers. This may result in normal sensation becoming painful.

Some specific proposed mechanisms for this induced chronic state and associated medical approaches are listed below.<sup>2</sup> Note that many of these medications are used for other disorders such as depression and seizures.

- In the DRG there is up-regulation of membrane channels in the nociceptive neurons:
  - sodium channel inhibitors—tricyclic antidepressants, carbamazepine, oxcarbazepine, phenytoin, lamotrigine, mexiletine, lidocaine
  - potassium channel inhibitors—gabapentin
  - calcium channel inhibitors—gabapentin and lamotrigine
- Sprouting sympathetic axons form “baskets” around nerve cell bodies. Inhibitors may include tricyclic antidepressants, bupropion, and venlafaxine.
- Sodium channels spread along axons at the site of peripheral nerve damage resulting in spontaneous discharges. Inhibitors are the same as listed above for sodium channels.
- Projections from the DRG to the interneurons in the spinal cord allow further transmission of pain signals through the release of substance P, calcitonin, gene-related peptide protein (CGRP), and glutamate.
- The second-order neurons in the spinal cord activated by glutamate through the  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors are prompted to fire spontaneously (central sensitization) through activation of the N-methyl- $\alpha$ -aspartate (NMDA) receptors through an increase in intracellular calcium and activation of protein kinases (PK). Potential inhibitors are gabapentin, dextromethorphan, opiates, selective serotonin reuptake inhibitors, topiramate, lamotrigine, and others.
- Ectopic activation of second-order neurons can also be caused by dynorphin, which is found in patients with

- chronic pain, through activation of NMDA receptors.
- Down-regulation of  $\gamma$ -aminobutyric acid receptors decreases inhibition of second-order neurons.
  - Sprouting of central terminals of non-nociceptive neurons in the DRG leads to hyperalgesia and tactile allodynia, which may be inhibited by levodopa.

Neuropathies, particularly peripheral neuropathies, are often divided into two general types based on the involved structure: axonal degeneration and paranodal or segmental demyelination. Although many disorders do not clearly fall into one category or the other, this distinction is important from the standpoint of physiologic testing. In evaluating nerve conduction, two responses are measured: the velocity (or latency) and the amplitude of the evoked response. Electrodiagnostic testing can evaluate either the sensory or motor component. In general, axonal degeneration results in relatively normal conduction; the evoked amplitude of the response, however, is decreased (with eventual electromyography [EMG] changes evident). Demyelination generally causes the reverse, with conduction velocity decreased yet normal evoked amplitudes (EMG is often normal).

Painful neuropathies may be divided into cause and type, primarily based upon specific underlying disease processes (see **Tables 16-1** and **16-2**). A broader classification includes two significant subtypes:

- 1.** Small-fiber painful sensory neuropathy—Only the A- $\delta$  (small myelinated) and nociceptive C (unmyelinated) nerve fibers are involved. This probably represents the most common cause for patients 50 years of age and older. An underlying cause is rarely determined.
- 2.** Small-fiber/large-fiber painful sensory neuropathy—This is partially a result of damage to small nerve fibers. Additionally, A- $\beta$  and A- $\alpha$  nerve fibers are

involved, changing the clinical picture due to the functional relationship to proprioception, vibration sensation, muscle strength, and muscle stretch reflexes such as deep tendon reflexes (DTRs).

**Table 16-1** Some Peripheral Neuropathies

<b>Type</b>	<b>History, Exam, and Special Testing Indicators</b>
Idiopathic, small-fiber neuropathy	Usually seen in patients over 50 years of age. Normal muscle strength, DTRs, and position and vibration sense. Reduction in pinprick in lower extremities. EMG and NCS are normal. Reduction in sudomotor function and, if performed, abnormal skin biopsy indicating small-fiber damage.
Diabetic peripheral neuropathy	Family and personal history. Adult onset with associated obesity, hypertension, hyperlipidemia. DTRs decreased with a reduction in distal sensation. Also may be associated with orthostatic hypotension. Abnormal EMG and NCS. Positives on laboratory for >126 mg/dl for blood glucose or HbA1c is 6.5% (47 mmol/mol) or higher.
Inherited neuropathy	Usually a family history. Examination reveals pes cavus/hammer toes presentation with decrease in DTRs and distal sensation loss. EMG and NCS are abnormal.
Connective tissue disease neuropathy	History of one of several diseases that may include rheumatoid arthritis, systemic lupus erythematosus, mixed connective tissue disease, SjÖgren's, or sicca syndrome. Reduction of DTRs and distal sensation. Abnormal EMG and NCS. Usually positive for antinuclear antibodies, extractable nuclear antigens, or rheumatoid factor.
Peripheral nerve-vasculitis neuropathy	Usually diagnosed with a systemic vasculitis. Examples include polyarteritis nodosa temporal arteritis, Takayasu's arteritis, and that associated with connective tissue disorders. Multiple and symmetric involvement of sensory and motor findings. Abnormal EMG and NCS. One of the following may be positive: rheumatoid factor, antinuclear antibodies, hepatitis C, cryoglobulins, antineutrophilic cytoplasmic antibodies.
Monoclonal	Found in older patients (age > 50 years). Variable findings

gammopathy of undetermined significance (MGUS) neuropathy	on neurological exam including decreased DTRs and distal sensation perception. Usually abnormal EMG and NCS. On lab, monoclonal gammopathy.
Paraneoplastic neuropathy	History of smoking, family history, exposure to asbestos or dyes, paints, printing rubber, textiles, or leather. Reduction in DTRs and reduction in distal sensation. Abnormal EMG and NCS. Anti-H $\mu$ antibodies.
Familial amyloid polyneuropathy	Family history. Sensory loss if primarily small-fiber with reduction in DTRs. Postural hypotension is commonly found. Abnormal EMG and NCS with possible NCS indicators of carpal tunnel syndrome.
Acquired amyloid polyneuropathy	History of plasma cell dyscrasia or monoclonal gammopathy. Sensory loss if primarily small-fiber with reduction in DTRs. Postural hypotension is commonly found. Abnormal EMG and NCS with possible NCS indicators of carpal tunnel syndrome. Monoclonal gammopathy if underlying cause.
Neuropathy of renal failure	Renal disease in history. Reduced DTRs with variable findings on sensory testing. Abnormal EMG and NCS. Laboratory indications of renal dysfunction.
Hereditary sensory autonomic neuropathy Sarcoid neuropathy	Family history is positive. History of foot ulcers or painless injuries. Pes cavus with hammer toes and decrease in DTRs with variable sensory findings. Abnormal EMG and NCS. Evidence of pulmonary sarcoidosis. Neurological exam indicates either multiple mononeuropathies or polyneuropathy. Abnormal EMG and NCS with elevated angiotensin-converting enzyme and abnormal chest findings, including perihilar lymphadenopathy and effusion.
Arsenic neuropathy	Exposure to pesticides, wood preservatives, or copper smelting. Reduction of DTRs, loss of all types of sensation with distal motor weakness, with Mees' lines. Abnormal EMG and NCS. Elevated arsenic levels in plasma, urine, nails, and hair.
Fabry's disease	Early age onset (< 20 years old) with associated renal failure or stroke. Normal motor, reflex, and sensory exam. Normal EMG and NCS. Reduced levels of $\alpha$ -galactosidase A in serum, leukocytes, or tears.
Celiac disease	GI symptoms. Sensation exam variable with distal sensation common and reduced DTRs. EMG and NCS may

	be normal or abnormal. Positive serologic testing for celiac disease IgA antigliadin and IgA endomysial antibodies.
HIV-related neuropathy	One or more of the following may be positive: homosexual, drug abuse, blood transfusion, or treatment with antinucleosides. Sensation exam variable with distal sensation loss common and reduced DTRs.
	EMG and NCS abnormal. HIV antibody positive.

The clinical presentation of each type is summarized below:

- Exclusive or dominant involvement of small fibers—  
There is a discrepancy between the severity of pain complaint and objective findings on examination. Patient is often over the age of 50 years. Although older patients may have some decrease in pinprick sensation, these patients have an abnormal degree, including involvement from the feet to the level of the knees (rarely above the knees). While touch sensation may be affected, other sensations are usually unaffected, such as proprioception and vibration. Muscle strength and DTRs are normal.
- Mixed neuropathies involving small and large fibers—  
These usually will decrease proprioception, vibration sense, and will include muscle weakness and decreased or absent DTRs. Although it is common for vibration sensation in the elderly to be decreased, the vibration loss often extends into the ankles with mixed neuropathies.

**Table 16-2** Some Named Sensory Mononeuropathies

Name	Nerve	Causes
Numb chin syndrome	Mental nerve	Often ominous, indicating possible metastatic

		process
Facial sensory neuropathy	Trigeminal nerve	Other than typical trigeminal neuralgia, consider sarcoidosis, Sjögren's syndrome, scleroderma, toxins, or neoplasm
Cheiralgia paresthetica	Superficial radial nerve	Direct trauma, handcuffs, intravenous lines, blood draws
Digitalgia paresthetica	Digital nerves of fingers or toes	Usually due to compression from direct trauma in hands (e.g., bowler's thumb) or pressure from transverse ligaments in toes
Notalgia paresthetica	Posterior rami of T2-T6	Subluxation of related vertebrae or due to pressure from multifidus muscle
Intercostal neuralgia	Intercostal nerves	Diabetes, herpes zoster (shingles), pregnancy, subluxations including rib subluxations
Maigne's syndrome Meralgia paresthetica	Posterior rami of T11-T12 Lateral femoral cutaneous nerve	Subluxation of related vertebrae Diabetes, obesity, prolonged sitting, pregnancy, holster, tool belt, surgical table
Gonyalgia paresthetica	Infrapatellar branch of saphenous nerve	Idiopathic, knee trauma, surgery, "influenza knee," viral, diabetes

- A recent animal study by Dilley and Bove<sup>3</sup> demonstrated that nerve inflammation disrupts axoplasmic transport and induces a mechanical sensitivity in C fiber nociceptor axons through the accumulation and insertion of mechanosensitive elements.

## **Complex Regional Pain Syndromes—Types I and II (formerly known as Reflex Sympathetic Dystrophy and Causalgia, respectively)**

Reflex sympathetic dystrophy (RSD), now called complex regional pain syndrome (CRPS1), is often the result of severe trauma such as fractures, crush injuries, myocardial infarction, strokes, peripheral nerve injury, or certain medication use. The clinical result is a combination of pain and swelling that includes mainly the distal extremities (usually one) and involves vasomotor instability (including Raynaud's), trophic skin changes, and bone demineralization (Sudeck's atrophy). The accepted belief regarding the cause of RSD is aberrant sympathetic reactivity following injury or other precipitating event. The first phase may be pain and swelling with an increase in sweating and hair growth in the involved area. Classically, the next phase (occurring three to six months later) is characterized by the skin gradually changing to a shiny appearance that is cool to the touch. Eventually (three to six months after the second phase) this may progress to atrophic skin and the development of flexion contractures. When this occurs in the shoulder it is referred to as shoulder-hand syndrome. Causalgia, or CRPS II, is similar, but it is believed to be due to damage to a peripheral nerve. It too is a regional pain syndrome. Evaluation will likely include radiographs to detect osteopenia (Sudeck's atrophy) secondary to RSD. Evaluation of sympathetic dysfunction may include the use of thermography and sudomotor testing. Management is disappointing, with a host of approaches having been taken, from early mobilization and physical therapy in the earlier stages to the use of medical intervention. Drugs that have been incorporated include adrenergic blockers, calcium channel blockers, phenytoin, NSAIDs, opioids, and calcitonin. Stellate ganglion blocks are often used for upper-extremity CRPSs. More recently

gabapentin (Neurontin) and pregabalin (Lyrica) are commonly prescribed.

## Evaluation

## History

The onset is often suggestive of an underlying cause.

- Sudden traumatic onset—When a related, localized area of the body is affected, a traumatic neuropathy is likely; when associated with neck or back trauma, an associated dermatome or myotome-related complaint of pain or weakness may help localize to a segmental level; bilateral complaints suggest spinal cord involvement.
- Sudden nontraumatic onset—This is more suggestive of a vascular cause. When relatively localized to a single area, vascular infarction as occurs occasionally with diabetes is likely; when more generalized or affecting a side of the body, a central vascular event is more likely (stroke or transient ischemic attack). Multiple sclerosis may also present with a rather sudden onset as either a localized or more diffuse pattern.
- Chronic onset—It is always important to ask about the patient's current medications (this may reveal a side effect of a medication or suggest a past diagnosis), and also any past diagnoses with a focus on diabetes, alcoholism, hepatic or renal disease, rheumatoid arthritis (RA), pregnancy, and depression or anxiety.

Complaints of numbness localized to the face or more generalized over the body with no apparent cause should

raise the suspicion of anxiety with consequent hyperventilation. Distal numbness in a “stocking-and-glove” distribution is characteristic of metabolic and particularly diabetic neuropathy. This distribution is often bilateral.

If a complaint of numbness is related to a specific occupational or sports activity, it is important to identify any element of either direct compression of a specific nerve or possibly muscle or fascial entrapment. This requires the patient to demonstrate a working posture and any repetitive maneuvers employed.

Complaints associated with diabetes may have a metabolic cause (myelin affected) or be due to neural ischemia. Numbness that seems associated with pregnancy may be due to either fluid compression or vitamin deficiency. If numbness or tingling is present in a patient with RA, fluid compression is likely the primary cause.

Patients with coexisting spinal complaints often will be able to contribute localizing information with regard to pain and weakness. Coupling an outlined pain pathway or movement weakness with the area of numbness or tingling will usually discriminate between a peripheral nerve problem and a nerve root problem. This is further distinguished on the physical examination (**Figures 16-1** and **16-2**).

## Examination

The examination must focus on finding which sensory component is affected.<sup>4</sup> Test the patient with his or her eyes closed and alternate the sensory stimulus, applying the stimulus in a random pattern. For example, using a pin and brush alternately touch the patient in a random fashion so that a pattern cannot be detected by the patient. Test the patient for the following:

- Alternate touching with the sharp and dull edge of a pin or broken tongue blade
- Light touch with a brush, wisp of cotton, or gentle touch from examiner's finger pads
- Temperature with small hot and cold test tubes
- Vibration with a struck tuning fork (128 vibrations per second)

Most neuropathies begin with distal sensory loss (the longer nerves affected most often). If no abnormalities are found distally, it is unusual to find proximal loss. If distal loss is found, progress upward to better define the involved area. With all sensory testing, it is important to compare sides. Specifically when testing with a pinwheel or touch, it is important to perform simultaneous testing because of the effect known as sensory extinction. Unilateral testing will be unrevealing, but when both bilateral areas are tested, a sensory deficit is exposed indicating a cortical sensory disorder. Other cortical sensory testing includes the following:

- Stereognosis—Have the patient identify an object placed in his or her hand while the patient's eyes are closed.
- Two-point discrimination—With either a two-point discriminator or a premeasured opened paper clip determine the patient's ability to feel both points of stimulation at the same time; in general, discrimination at the fingertip is 2 to 4 mm; dorsum of fingers, 4 to 6 mm; palms, 8 to 12 mm; and dorsum of hand, 20 to 30 mm.
- Graphesthesia—Write letters or numbers on the palm of the patient's hand with his or her eyes closed; ask the patient to identify what you are writing.

**Figure 16-1** Dermatomes of the upper extremity and the cutaneous innervation of the arm by the peripheral sensory nerves.

**Figure 16-2** Sensory innervation of the lower extremity. (A) Peripheral nerve innervation. (B) Dermatomal (root) innervation.

Proprioception is evaluated by testing joint position sense. The third and fourth digits of the upper and lower extremities have the most sparse innervation and therefore may reveal loss earlier than other digits.<sup>5</sup> The joint is grasped on the lateral surfaces and separated as much as possible from the other digits, being careful not to touch the other digits. The patient, with eyes closed, is asked whether the joint is being held up or down by the examiner. Another evaluation of position sense is the Romberg test. The ability of the patient to keep his or her standing balance with the eyes closed indicates an intact proprioceptive system. If the patient is able to balance (weight equally distributed between both legs) with the eyes open, yet loses balance with the eyes closed, he or she is relying on visual input for balance control. Abnormalities of vibration or position sense indicate problems with large fiber neurons and/or dorsal column disease.

In chiropractic practice, a common presentation is neck or low back pain with associated extremity complaints of pain, numbness, or tingling. Although it is hoped that a pattern match will be made with these complaints and an objective demonstration of sensory loss, motor loss, or an associated deep tendon decrease, this is often not the case. For example, patients with neck pain may complain of a diffuse sense of numbness or paresthesias in the hand. They are unable to localize to a dermatome, and objective testing fails to clarify the diagnosis. It may be helpful first to attempt provocation maneuvers. For the nerve root, this includes standard orthopaedic testing of the related spinal area, such as cervical compression/distraction for the upper extremity or the straight leg raise or Kemp's test for the lower extremity. Additional provocation testing for peripheral nerves is accomplished by either tapping (if the nerve is superficial) or compression through direct pressure or muscle contraction. Patients who associate the complaint with an activity can be asked to repeat or hold the position

(whichever is appropriate) in an attempt to reproduce the complaint.

When the area of involvement overlaps between a dermatome and a peripheral nerve skin patch, selected muscle testing, provocation tests, or an associated tendon reflex may help differentiate the source. For example, if the patient had a sensory area loss over the anterior thumb and two fingers, either median nerve involvement or a C6 nerve root lesion is possible. However, a median nerve disorder would not affect the brachioradialis reflex and a C6 nerve root disorder would not cause a positive Tinel's sign over the median nerve (unless there is a double-crush syndrome).

When the complaint is diffuse or nondermatomal, consideration of referral sources should be next. These may include facet irritation or trigger points. Reproduction may be possible with trigger point palpation, but facet involvement is difficult to demonstrate clinically except for the relief sometimes provided by an adjustment.

If the diagnosis is still in question, consideration of electrodiagnostic or special imaging studies is warranted. In most cases it would be appropriate to treat for a one-month period prior to utilizing these expensive procedures. The use of electrodiagnostic studies (EDS), such as electrical muscle stimulation (EMS) and nerve conduction studies (NCS), is focused on distinguishing among several possibilities:

- Mononeuropathy: an example is local/focal entrapment such as tarsal tunnel syndrome
- Differentiating multiple mononeuropathies: usually involves peripheral nerve vascular disease (vasculitis)
- Polyneuropathies: usually symmetric
- Axonal neuropathies: diabetes, for example
- Demyelinating neuropathies: multiple sclerosis, for example

A normal EDS evaluation indicates that the cause is nonneuropathic, possibly due to local inflammation, arthritis, referral pain, or central nervous system pain such as a myelopathy. A search for small-fiber involvement may include the following tests:

- Sudomotor reflex test: quantitates sweating and is approximately 80% sensitive for small-fiber damage<sup>6</sup>
- Skin biopsies: demonstrate loss of intraepidermal nerve fibers (not widely available)
- Quantitative sensory testing: assesses smallfiber damage through measurement of pain and temperature thresholds in the skin (not as sensitive or specific as sudomotor testing or skin biopsies)

EMG and nerve conduction velocity (NCV) studies are reserved for difficult cases. EMG uses needle insertion into muscle to test muscle and nerve.<sup>6</sup> The spontaneous activity generated upon insertion or the response generated with muscle contraction helps distinguish between axon injury and demyelination disorders. NCV studies use surface electrodes to measure velocity and the amplitude of an evoked response to an electrical stimulus. Both motor and sensory nerves can be tested. Important concepts are as follows:

- Axonal degeneration will demonstrate normal velocities with NCV studies, but a reduced amplitude of evoked responses. EMG evidence takes about three weeks to surface, revealing spontaneous activity at rest, such as fibrillations and positive sharp waves; during contraction, there is a reduction in the density pattern, interference pattern, and mean amplitude of the motor unit potentials (MUPs).
- Demyelination disorders will demonstrate early changes in the nerve conduction velocity with

relatively normal evoked amplitude responses.

## Management

Management is based on the suspected cause. Most peripheral nerve and nerve root disorders can be managed by a chiropractor for one month, being sure to monitor for any worsening or nonresponse to care that might require referral. Chronic pain requires different approaches. The potential central modulation that facilitates many cases of chronic pain requires a combination of behavioral and medical approaches if not responsive to conservative care. Predictors of chronicity should always be considered in baseline measures of incoming patients including regional functional outcome tools and global assessments of function such as the SF-36. Another strong predictor that can be measured and responded to in management is fear avoidance behaviors that tend to prolong recovery. Many musculoskeletal disorders such as low back pain, neck pain, and headache become chronic and may require a multimodal approach. Neuralgias secondary to diabetes and herpes are often in need of specific medications. Metabolic disorders often require medical evaluation and management; diabetes, however, often can be comanaged. See more thorough discussions of individual disorders in related chapters of this text.

Conservative management is based on the premise that “closing the pain gate” can be accomplished without the use of medication. Cutaneous stimulation through vibration, massage, myofascial stripping, taping, and bracing likely affect cutaneous and subcutaneous receptors that send their signals through large fiber afferents reaching the spinal cord prior to pain signals. Counterirritation using transcutaneous electrical stimulation (TENS), acupuncture, or capsaicin are also used.

Proposed mechanisms for the chiropractic adjustment are that:

- Stimulation via mechanoreceptor activity in the posterior columns provides large-fiber dampening of pain transmission at the spinal cord level.
- Stimulation of nuclei in the brainstem through the spinomesencephalic tract and at the PAG activate descending fibers back down the spinal cord to inhibit pain.
- Reflex inhibition of tight muscles via group Ib inhibitory interneurons: Group Ib afferents from Golgi tendon organs, as well as cutaneous and joint mechanoreceptor afferents, can stimulate Ib inhibitory interneurons that are located in lamina VII of the spinal gray. These Ib interneurons inhibit  $\alpha$  motoneurons, which leads to relaxation of spasmed muscle.
- A fast-stretch applied to a tight muscle stimulates Golgi tendon organs and activates Ib afferents, which then produce reflex inhibition (inverse stretch reflex) of the same tight muscle that was stretched. The net result is relaxation of the tight muscle.

Current medical management of painful neuropathies has been estimated as achieving only a 30% to 50% reduction in pain.<sup>7</sup> There is a range of medications prescribed, including antidepressants and antiseizure medications. Some of the representative medication classes and examples follow:

- Antidepressants: includes tricyclic antidepressants and selective serotonin reuptake inhibitors
- Anticonvulsants: includes carbamazepine, phenytoin, gabapentin, and lamotrigine
- Antiarrhythmics: includes mexiletine
- N-methyl-D-aspartate glutamate
- Narcotic and non-narcotic analgesics

- Levodopa
- Topical agents: capsaicin and topical lidocaine

For a more complete list of medications see [Tables 1-12 through 1-14 in Chapter 1: General Approaches](#).

## Algorithm

An algorithm for evaluation and management of numbness is presented in [Figure 16-3](#).

# CHAPTER 17

## Headache

### Context

Severe headache causes significant financial impact on the individual, the employer, and the healthcare system. Considering only the cost of lost work and productivity, migraine headaches have a price tag of approximately \$13 to \$17 billion annually.<sup>1, 2</sup> This equals 112 million “bedridden days” per year. Direct costs for migraines are approximately \$100 per patient annually for a total U.S. annual cost of \$1 billion. More important to the individual is the finding of a recent study<sup>3</sup> indicating that migraine headache’s negative impact on patients’ quality of life is greater than that of other chronic conditions such as osteoarthritis, hypertension, or diabetes. One recent study found that children evaluated at a headache center had a quality of life comparable to children with rheumatoid diseases or cancer.<sup>4</sup> It has been estimated that up to 10% of children ages 5 to 15 years and 28% of adolescents experience migraine headaches.<sup>5, 6</sup> Fifty-seven percent of men and 76% of women report at least one significant headache per month.<sup>4, 7</sup> Approximately 27 million Americans have suffered from migraine headaches.<sup>8</sup>

Although they are a common human ailment, headaches, more often than not, do not warrant a visit to the doctor’s office. Whether obviously associated with flu, excessive drinking, skipped breakfast, or other factors, the patient is

quite aware of a connection to the headache. Many patients resort to over-the-counter (OTC) medications. In fact, headaches may be the most common reason for the use of OTC analgesic medications.<sup>9</sup> When a patient does seek an opinion or treatment, the headache has become either unbearable (affecting lifestyle) or worrisome (the patient thinks there may be a tumor), or there has been head trauma. Of patients reporting headaches, 27% have sought alternative management. Chiropractic care was the most common alternative therapy sought by these patients.<sup>10</sup>

In the chiropractic office one of the most common headache presentations is associated with whiplash. In fact, headache is one of the two most reported complaints after whiplash. Many studies indicate that a high percentage of whiplash patients (70% to 90%) develop a headache.<sup>11-16</sup>

Chronic headache that is unresponsive to treatment is a difficult scenario. First on the list of mechanical possibilities should be temporomandibular (TMJ) disorders.<sup>17-19</sup> Some differentials include tenderness of the pterygoids, tenderness of the TMJ, clicking in the TMJ, and abnormal mandibular movement patterns on opening and closing.<sup>20</sup> Overlap with clinical indicators of tension-like headache is common.

## **Migraine<sup>21,22</sup>**

- Migraine is prevalent in 6.5% of males and 18.2% of females.
- Prevalence increases from age 12 years to 40 years and then declines.
- 51% of patients report at least a 50% reduction in work or school productivity.
- 27.9 million Americans suffer from migraine (increase over 10-year period likely related to growth in population).

- Less than half of patients who met the criteria for migraine were diagnosed correctly (possibly due to finding that only 49% of internal medicine residents and 62% of family practice residents felt prepared to treat headache patients).<sup>21</sup>
- In one study, in patients that met the IHS criteria for migraine, 42% were diagnosed with sinus headache and 32% were diagnosed with tension headache.<sup>21</sup>

### **Episodic Tension-Type**

- Prevalence of 38% of U.S. adults

## **Cluster**

- Prevalence of < 0.1% of U.S. adults

## **Cervicogenic**

- Prevalence of 18% of U.S. adults

Only about 2% of patients in-office and 4% of patients in an emergency department setting will be diagnosed with a headache indicating serious pathology (e.g., tumor, AVM, aneurysm).<sup>23</sup> The categorization of headaches by the International Headache Society (IHS) distinguishes among the primary headache patterns and includes a category for cervicogenic headache.<sup>24</sup> The categories use specific criteria upon which to base the headache diagnosis. Unfortunately, the cervicogenic headache criteria are quite restrictive and exclusive of the other primary headache categories. In other words, there is a perception by the IHS that there could be no overlap or cervicogenic component to the other headache types. Yet research indicates that there is likely a

pure category of cervicogenic headache, a category that has a significant contribution from a cervicogenic component, and yet another category that is unrelated. Using the criteria set forth by the IHS, one study<sup>25</sup> determined a cervicogenic headache prevalence of about 18% in a random population sample of adults.

Although the vast majority of headaches are benign (not life-threatening), the doctor initially must screen for secondary causes prior to assuming one of four common primary patterns: migraine, tension-type, cervicogenic, and cluster headaches. Screening the patient with headaches historically is the most fruitful, time-effective, and inexpensive approach (**Exhibit 17-1**). Expensive imaging approaches are rarely needed.

## General Strategy

# History and Examination

- Determine whether the patient has a secondary cause for the headache, such as trauma, metabolic disease, toxic (drug) effect, infection, or intracranial pathology (see **Table 17-1**).
- Determine whether the patient's headache fits one of three categories of primary headache: migraine, tension-type, and cluster, or whether cervicogenic is likely.
- Determine whether there are any obvious triggers or patterns to the headache.
- Evaluate the patient for musculoskeletal factors that may cause or influence headaches.

# Management

The chiropractor should determine which cases are appropriate for referral. Referral is, in fact, rarely needed given the low incidence of serious causes. The red flags that warrant further investigation and possible referral include but are not limited to the following:

- Including sudden, severe headache (worst headache of their lives)
- A new headache in an older patient (possible tumor or temporal arteritis)
- Headache due to head trauma (possible subdural or epidural hematoma)
- Associated residual neurologic signs or symptoms (possible tumor or vascular event)
- Cognitive changes (e.g., confusion, drowsiness, giddiness)
- Vomiting without nausea (indicating increased intracranial pressure)
- Persistent or progressive headache
- Nuchal rigidity with or without fever (possible meningitis or subarachnoid hemorrhage, respectively)
- Suspicion of drug or alcohol dependence
- Headache associated with a diastolic blood pressure greater than 115 mm Hg (possible hypertensive headache)
- Persistent or severe headache in a child

For patients without these red flags, consider the following options for conservative care:

- Modify patient behavior (sleep, diet, and exercise) when determined by history as a significant factor.
- Manage with chiropractic manipulative therapy for an initial high-frequency period of one to three weeks, followed by a gradual tapering.

- Consider use of supplemental support or herbal alternatives including feverfew.
- If chiropractic management is unsuccessful, refer for or use nonpharmacologic treatment such as acupuncture or biofeedback.
- If nonpharmacologic management is unsuccessful, refer for medical management.

### **Exhibit 17-1 Historical Screening of the Patient with Headaches**

## Patient presents with a history of headaches

### Differentiate Referral from Nonreferral Case

#### History Questions

*History of head trauma?* (Consider subdural or epidural hematoma.)

*Slow or insidious onset of new headache?* (Consider tumor or vascular event such as an aneurysm or arteriovenous malformation [AVM].)

*Associated neurologic deficits?* (Consider all the above.)

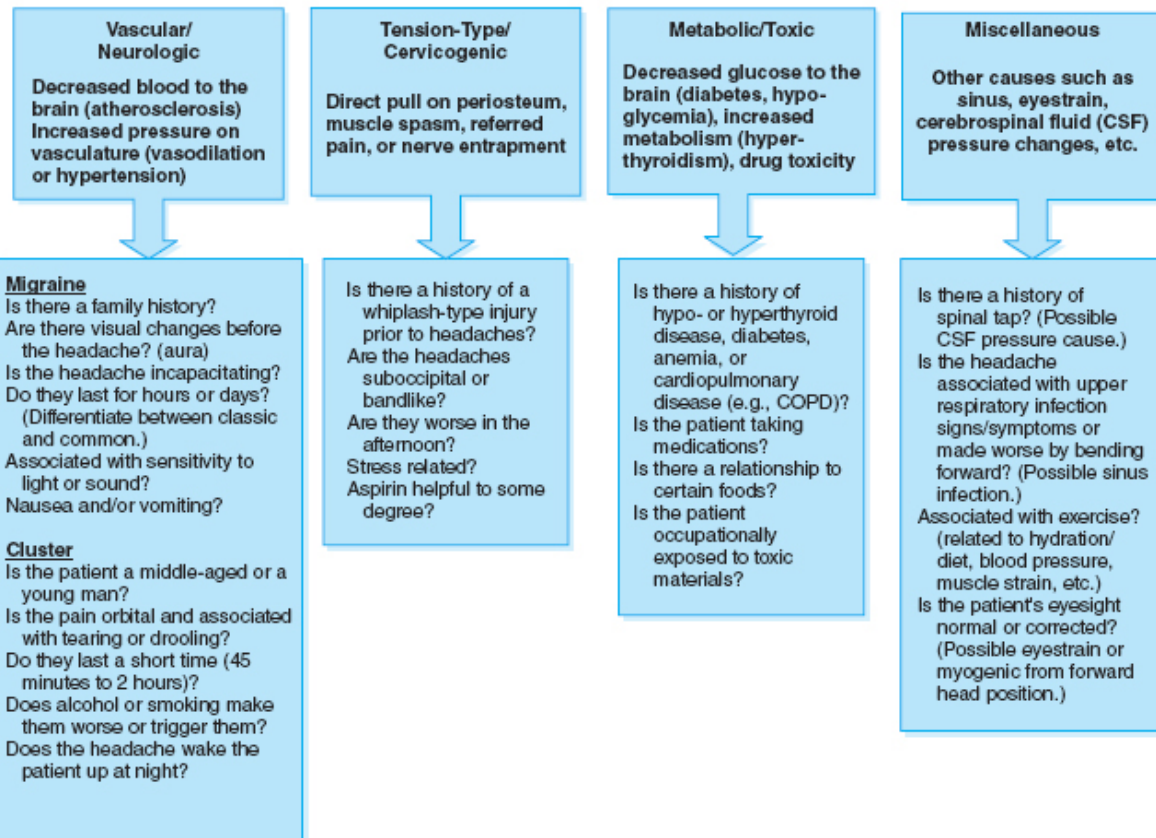

*New temporal headache in a older patient, especially when associated with vision deficit or aching trunk area?* (Consider temporal arteritis.)

*Occurs only with exertion and is progressively worse?* (Consider vascular cause such as aneurysm or AVM.)

*Associated with nuchal rigidity with or without fever?* (Consider subarachnoid hemorrhage without fever and meningitis with fever.)

### Differentiate by Type

**Table 17-1** Metabolic Causes of Headache

--	--

<b>Common</b>	<b>Less Common</b>
Hypo- and hyperthyroidism	Hypo-hyperadrenalism (Addison's/Cushing's)
Anemia and polycythemia	Pheochromocytoma
Hypoxemia	Carbon monoxide poisoning
Hypoglycemia	Vitamin A toxicity
Hypertension (especially malignant HTN)	Paget's disease (cranial bone involvement)
Uremia	Cranial tumors
Hypercarbia	Chronic leukemia
Hyponatremia	Hemoglobinopathies Parathyroid disease

## Theories of Causation of Primary Headaches

Although the treatment of headaches chiropractically has anecdotally been supported for years, only recently have models of causal relationships between headaches and cervical dysfunction and studies to confirm effectiveness been advanced. Recent research suggests that the older theories of vascular dilation with migraines<sup>26, 27</sup> and muscle contraction with tension-type headaches<sup>28</sup> do not adequately explain how these headaches occur. From genetic research, migraine appears to be an ionopathy, a disorder based on abnormal ion channels—primarily calcium channels that allow hyperexcitability.<sup>29</sup> Structurally, it appears that one of the primary sites is the dorsolateral pons.<sup>30</sup> It appears that a neurologic event occurs associated with an imbalance of serotonin.<sup>31-34</sup> This serotonin imbalance appears to be site-specific. In other words, too little or too much serotonin may contribute to headache development,

depending on where it occurs. In general, too little available serotonin centrally is the primary cause.

Dysfunction of brainstem modulation of sensory input is proposed as a major element of migraine and other headache pain. Large cranial blood vessels, proximal intracranial blood vessels, and the dura are innervated by the ophthalmic division of the trigeminal nerve. Posterior fossa structures are innervated by branches off the C2 nerve roots. Input from the trigeminal-innervated structures pass through the trigeminal ganglion synapsing in the trigeminocervical nucleus (complex). Information is then sent through the quintothalamic tract after decussating in the brainstem. Modulation of this nociceptive information is believed to come from the dorsal raphe nucleus, locus coeruleus, and nucleus raphe magnus.

Stimulation of cranial parasympathetic outflow occurs between neurons in the pons in the superior salivatory nucleus. This parasympathetic output is mediated through the pterygopalatine, otic, and carotid ganglia. This is referred to as the trigeminal-autonomic reflex and may be over-responsive in those with cluster and migraine headache.

For migraine headaches, increased local vascular concentrations of serotonin may act as part of an inflammatory cascade of chemical mediators including substance P.<sup>35, 36</sup> Neurogenic vascular inflammation results from antidromic stimulation of the trigeminal ganglion with release of tachykinins and calcitonin gene-related peptide causing plasma protein extravasation and vasodilation with degranulation of mast cells. In addition, it has been suggested that factors that may control this local neurogenic inflammation include a local C fiber nerve ending/mast cell feedback loop. The control of mast cells by histamine acting at H3 receptors may mitigate neurogenic inflammation.<sup>37</sup> Recent interest has focused on dopamine and its role in migraine with aura. Most migraine symptoms

can be induced with dopaminergic stimulation or ameliorated with dopamine receptor antagonists.<sup>38</sup> Also the role of inheritance of the dopamine D2 receptor (DRD2) NcoI allele is currently being studied.

Convergence of afferent information from cervical spinal nerves and the trigeminal nerve in the trigeminocervical nucleus may serve to explain a referred pain mechanism for both migraine and tension-type headaches, and perhaps for cluster headaches.<sup>39</sup> The trigeminocervical nucleus (**Figure 17-1**) is a continuous column of neurons formed by the caudal end of the spinal nucleus of the trigeminal nerve and the dorsal horn of the upper cervical spinal nerves (C1-C3). Descending fibers from the nucleus raphe magnus and other midbrain and pontine nuclei normally have an inhibitory effect on the spinothalamic neurons (directly and through interneurons), preventing transmission of pain signals. Deregulation may allow a lowering of the stimulus threshold necessary for pain perception, perhaps through a decrease in secreted serotonin. Therefore, afferent information that is not nociceptive in nature may become so due to lowering of the pain threshold and/or expansion of the receptor field. The result may be either referral to the head and face from irritation in the neck or referral of neck pain from irritation of intracranial pain-sensitive structures (e.g., intracerebral blood vessels causing posterior or suboccipital pain). Therefore structures innervated by C1-C3 including C2-C3 intervertebral disk annular fibers, deep muscles, joints, ligaments, and connections to the dura mater may be sources of referred pain to the head.

**Figure 17-1** The Trigemino-cervical Nucleus.

A more recent theory proposed by the inadvertent success of cosmetic surgery (i.e., brow lift surgery), is that there are peripheral triggers of trigeminal irritation or dysfunction. This theory is based on the possibility of local entrapment of superficial nerves in craniofacial muscles. This is further supported by the relief from migraine headaches through botulinum toxin injection of some of these muscles. A review of current evidence and approaches can be found in a review by Kung et al.<sup>40</sup>

A recent anatomic finding may further explain the relationship between response to chiropractic manipulation and headache. At the atlantooccipital junction, there appears to be a connective tissue attachment between the rectus capitis posterior minor muscle and the posterior spinal dura.<sup>41,42</sup> A proposed mechanism of increased dural tension through upper cervical dysfunction has been suggested as a cause of headache; in particular, cervicogenic headache.

Another structure implicated in the production or control of migraine and cluster headaches is the sphenopalatine ganglion (SPG), a branch of the facial nerve. The SPG

apparently contains a small percentage of trigeminal fibers and projects parasympathetic fibers to the cerebral vasculature.<sup>43</sup> Also, the SPG is a major source of nitric oxide synthase (NOS). It appears that the SPG may mediate vasodilation of cerebral blood flow when the trigeminal ganglion or the locus coeruleus is stimulated via NOS-containing nerve fibers that innervate the proximal anterior and middle cerebral arteries.

Hormonal influences on central serotonergic and opioid neurons may play a role in migraine headache in women. Plasma levels of serotonin have been found to increase significantly in women with migraine with aura and those with tension-type headaches. This fluctuation was not evident in migraine sufferers without aura. It is unclear whether this is a reflection of central serotonin effects.<sup>44</sup> Menstrual migraine appears to be due to estrogen withdrawal.<sup>45</sup> Sixty percent of migraine attacks in women are associated with menses, but only 14% are exclusively related.<sup>46</sup> Sustained increased estrogen levels with pregnancy and decreased levels with menopause appear to be related to changes in headache patterns. Migraine sufferers usually improve during pregnancy, especially after the first trimester. This improvement is suspected to be related to sustained high levels of estrogen. However, 25% of women notice no change in their headache pattern.<sup>47</sup> The effect of contraceptives on migraine headache is less clear. Several studies report no difference between those who took oral contraceptives and a placebo group.<sup>48</sup> Other studies suggest an increased severity and incidence.<sup>49</sup> Migraine prevalence definitely decreases with age; menopause, however, may trigger the onset or return of migraine.<sup>50</sup> Again, some studies indicate that estrogen replacement therapy increases or exacerbates migraine while others indicate estrogen alone or in combination with testosterone helps relieve migraine.

There is evidence that some patients with migraine share genetic markers with patients who have epilepsy.<sup>51</sup> This may explain why antiepileptic medication is more effective in this subgroup. There is no evidence, though, that those with migraine have a higher incidence of epilepsy except for the familial hemiplegia subgroup.

## History

Careful questioning of the patient during the history taking can point to the diagnosis (**Tables 17-2** and **17-3**).

- Determine any obvious triggers or causes of headaches from environmental, dietary, or medication sources.
- Determine any red flags suggestive of referral for medical management.
- Attempt to distinguish among three primary headaches, using the patient interview and headache diary.

Although the sequence of questioning is not as important as the comprehensiveness of the questioning, it is prudent next to rule out causes that might be obvious to the doctor but not necessarily to the patient. Questions to the patient should include the following:

- Do you have signs and symptoms of flu (especially fever or cough without nuchal rigidity)?

**Table 17-2** History Questions for Headache

Primary Question	What Are You Thinking?	Secondary Questions	What Are You Thinking?
Did you hit your head?	Fracture, subdural or epidural hematoma, post-concussion syndrome.	Did you lose consciousness and have difficulty with memory? Are you having difficulty with memory, walking, or talking?	Post-concussion syndrome. Subdural hematoma.
Are you taking any medications?	Side effect of drug, drug indicates past diagnosis, withdrawal from drug.	Did you recently stop taking medication? Was the medication given for your headaches? Were you recently prescribed a medication? Do you use recreational drugs? Drink (alcohol) heavily?	Withdrawal phenomenon. Rebound effect. Side effect of drug (vasodilators, etc.). Side effect or withdrawal phenomenon (with possible alcohol abuse use CAGE questions).
Is this a “new” headache?	Especially in older persons: tumor, temporal arteritis, or CNS vascular event.	(To an older patient) Is the headache throbbing at your temple? Is there associated vision loss with this temple headache? Do you have an associated complaint of a deep, throbbing ache in the upper trunk (neck and shoulder) area? Have you had the headache for several weeks without improvement? Is it worse when bending forward?	Temporal arteritis. Temporal arteritis. Temporal arteritis. Possible tumor. Possible tumor (especially with no signs of sinus involvement).
Do you have any disorders or diseases that you know about?	Headache is often associated with disorders such as diabetes, thyroid, COPD, hypertension, AIDS, cancer, etc. Perhaps the underlying disorder is the main cause.	Is the disorder being managed by a physician? Do you follow the management recommendations (diet, medication, lifestyle changes)?	Disorder not well-controlled. Disorder not well-controlled.

**Key:** CAGE, questions asked of an alcoholic: Do you need to Cut down? Does your drinking Annoy people? Do you feel Guilty about drinking? Do you use alcohol in the morning as an Eye opener?; NSAIDs, nonsteroid anti-inflammatory drugs; CNS, central nervous system; COPD, chronic obstructive pulmonary disease; AIDS, acquired immunodeficiency syndrome.

**Table 17-3** History Questions for Suspicion of Migraine Headaches

Primary Question	Possible Causes for Positive Response	Differentiating Questions	Suspicion
Do you have any unusual vision changes prior to the headache?	Migraine, TIA, cluster headache, glaucoma, eyestrain.	Do you see flashing lights, zig-zag lines, and/or blind spots? Do these go away in a short time (minutes to 1.5 hours)? Is the pain mainly around your eye with increase in tearing? Do you see halos around lights or lose your vision on the periphery (outsides)?	Migraine with aura. Migraine with aura (longer would suggest TIA). Cluster headache (possible migraine). Acute glaucoma.
Are they incapacitating?	Unless new in an older patient, it is likely to be migraine or cluster headache.	Do they last for hours or days? Do they last less than 2 hours and cluster (several a day) over weeks?	Migraine is likely. Cluster headache.
Do certain foods, alcohol, or smoking bring on the headache or make it worse?	Migraine and cluster headaches.	Do you notice that wine, cheese, or cured meats cause headaches? Does alcohol or smoking either trigger or make your headache worse?	Migraine likely. Cluster headache likely.
Is the headache related to sleep?	Migraine and cluster headaches.	Does either under- or oversleeping trigger a headache? Does it often wake you at night?	Migraine likely. Cluster headache likely.
Is there a family history of similar headaches?	Migraine, tension, depression.	Has a parent, grandparent, or sibling been diagnosed with migraine headaches?	Migraine.
Have you been diagnosed with migraine and been given medication?	Migraine, rebound migraine.	Have you taken sumatriptan or other serotonin receptor agonist or NSAIDs more often than twice a week or suddenly stopped taking them?	Rebound migraine.

Key: TIA, transient ischemic attack; NSAIDs, nonsteroid anti-inflammatory drugs.

- Have you recently been given a new prescription?
- Have you recently discontinued use of a prescription drug?
- Have you recently stopped smoking, drinking coffee, drinking alcohol, or using recreational drugs?
- Do you use recreational drugs?
- Do you get headaches after reading or have you had a recent change in eyeglass prescription?
- Are you occupationally exposed to toxic chemicals?

A recent study has pointed out the need to consider caffeine as a source of headaches in children.<sup>52</sup> Children who suffered from chronic daily headache who had a relatively high intake of sodas (1.5 liters of cola per day) were

gradually withdrawn from cola consumption over one to two weeks to avoid caffeine-withdrawal headaches. Findings showed that 33 out of 36 children were headache-free, which was sustained at a 24-week follow-up.

Migraine prevalence has been found to increase before menopause and decrease after natural menopause.<sup>53</sup> This is particularly true of women most susceptible to hormonal shifts, such as those suffering from premenstrual syndrome. Low estrogen and high follicle-stimulating hormone seem to correlate with lower migraine prevalence. Additionally, one study indicated that migraine without aura was associated with an occurrence of headache during the two days preceding menses and on the first two days of menses.<sup>54</sup>

---

## **Exertion/Activity-Related Headaches**

One of the major concerns with headache associated with exertion is the possibility of an underlying tumor or vascular weakness that may lead to sudden death. It appears as though this concern is worth addressing; however, although 50% to 60% of patients with brain tumors have headaches, only 25% experience exertion-related headaches.<sup>55</sup> When aneurysms rupture, the usual progression is a quick onset of headache followed by loss of consciousness and death. In patients with a slow leak, however, a severe headache may appear over several days or weeks. This “sentinel” headache appears in 30% to 60% of patients with eventual rupture.<sup>56</sup> Associated symptoms may include nausea, vomiting, visual disturbances and photophobia, aphasia, nuchal rigidity (without fever), and weakness. Immediate referral is necessary. Evaluation will include computed tomography (CT) scan for structural brain lesions and a lumbar puncture to detect a subarachnoid bleed.

It is important to screen athletes regarding some common culprits of benign exertional headaches, including dehydration, hyperventilation, hypoglycemia and/or poor

diet, alcohol use, caffeine withdrawal, and heat intolerance. They are more likely to be triggering mechanisms in the poorly conditioned athlete. When headache is associated with a specific activity, clues may be found with regard to the mechanism in some cases. For example, one common presentation is weightlifter's headache.<sup>57</sup> There are probably two possible explanations for this occurrence: (1) increased intracranial pressure is caused by the Valsalva-like maneuver with lifting, or (2) stretching or strain occurs in the cervical musculature/tendons.

Valsalva maneuvers increase intracranial venous sinus pressure. This in turn leads to a general increase in intracranial pressure, reducing cerebral blood flow. This effect is generally short-lived and benign. If the headache is persistent or severe, further evaluation with CT scan or magnetic resonance imaging (MRI) may be necessary. Overstrain due to maximum lift effort or abnormal posturing of the neck during activity may lead to a primarily subluxation/soft tissue-caused headache. Historical review of the mechanism of onset with regard to neck position and the onset of symptoms is valuable. Confirmation by physical examination, spinal palpation, and resolution with chiropractic care are likely with this etiology.

Migraine headaches occur in some athletes involved in short, strenuous activities, including weight lifting and short-distance running or swimming.<sup>58</sup> Although the mechanism is not clear, it has been proposed that hyperventilation leads to a decrease in partial pressure of carbon dioxide ( $PCO_2$ ) with resulting vasoconstriction. This leads to a migraine aura followed by vasodilation leading to the headache.

Acute altitude change from 3,500 m to 5,000 m may lead to acute mountain sickness, which presents as a throbbing headache that may be associated with malaise, nausea, and vomiting in some cases.<sup>59</sup> The onset is generally within the

first three days after ascent. After several days of acclimation, the headache resolves.

A distinct subcategory of sport-related headaches is found in divers.<sup>60</sup> There are a variety of mechanisms to consider.

- Skip breathing may lead to increased PCO<sub>2</sub>, vasodilation, and subsequent headache.
- Cervical and facial muscles may be overstrained through stabilizing the mouthpiece.
- A tight mask may compress the supraorbital and supratrochlear nerves.
- Dental cavities may be sensitive to the barometric pressure changes with deep diving.

## **Posttraumatic Headaches**

In automobile accidents and collision or contact sports, head and neck trauma are common. With direct trauma to the head, varying degrees of injury may occur, including cerebral contusion, sub- or epidural hemorrhage/hematoma, and intracranial artery dissection. Although it may seem logical that when damage is severe, headache would be immediate, this is not always the case. Slow leaks, as mentioned above, may take several hours, days, and rarely weeks to cause significant symptomatology. It would be prudent, though, to check all patients with head trauma for focal neurologic signs (in particular cranial nerves) and mental status.

## **Concussion**

Concussion is considered a subset of mild traumatic brain injury (MTBI), which carries with it the possibility of complex

pathophysiological processes that may not be immediately evident post-trauma. The definition of concussion does not include loss of consciousness. The biggest concern after concussion is post-concussion or post-concussive syndrome (PCS) where symptoms and neurological dysfunction may persist for weeks or months. Some of the most common signs/symptoms include headache, dizziness, difficulty concentrating, irritability, and other emotional and behavioral manifestations (e.g., mood changes, depression, restlessness, aggression, emotional lability, and apathy).

There are at least 3.8 million concussions in the United States annually, given that as many as 50% of concussions may go unreported.<sup>61</sup> Clearly the high-risk sports are those that are without protection and/or those that involve violent contact with the opposite team player; the highest incidence of concussion is in football, hockey, rugby, soccer, and basketball. It should be remembered that concussions occur in all sports, and in non-sports head trauma such as falls.

Headaches are the most common symptom; however, most athletes report the headache as similar to previous headaches but more frequent and longer lasting.

Although guidelines differ,<sup>62,63</sup> there is general agreement that:

- Concussion evaluation should be performed by healthcare professionals with specific training and experience in the assessment and management of concussion.
- Education of athletes as to the danger of concussion and what to look for in themselves and their teammates is of utmost importance. Educating parents, coaches, referees, and school administrators is important for recognition and proper management.
- Although various evaluation tools are available, a standardized assessment of function should be

administered to athletes prior to sport participation to establish a baseline, with the caveat that issues such as balance need to be evaluated with sports equipment on.

- Using a baseline comparison, the same evaluation tool should be utilized immediately after any suspected concussion.

A commonly utilized tool is the Sport Concussion Assessment Tool 3 (SCAT3).<sup>64</sup> This comprehensive approach uses an initial assessment similar to the Glasgow Coma Scale, immediately followed by observation and documentation of any concussion signs. Next, symptoms and symptom severity, neurocognitive function, and balance function are assessed. It is important to note that there is no evidence to support the use of a composite/total score. In other words, each section should be assessed separately. In a study<sup>65</sup> evaluating high school athletes using a baseline SCAT2 (the older version) it was found that concentration testing in high school athletes is unreliable because of high baseline error. In other words, baseline concentration scores should not be used as a comparator after concussion.

A return-to-play (RTP) clearance involves a gradual, step-by-step increase in physical demands and sports-specific activities, as well as a consideration of the risk for contact. If symptoms occur with activity, no further progression should occur and the athlete should be restarted at the preceding symptom-free step. The primary concern with a premature RTP is decreased reaction time leading to an increased risk of a second concussion with a known risk for prolongation of symptoms. A very serious concern, especially in the pediatric and young adult population, is second-impact syndrome (SIS).<sup>66</sup> In SIS, a rapid hydrocephalus occurs, greatly increasing intracranial pressure, which may result in death.

Other testing for neuropsychological function may be performed to evaluate cognitive function. Tests include:
